

z/OS Communications Server
3.2

IP Configuration Guide

Note:

Before using this information and the product it supports, be sure to read the general information under [“Notices” on page 1461](#).

This edition applies to 3.2 of z/OS® (5655-ZOS), and to subsequent releases and modifications until otherwise indicated in new editions.

About this document.....	xxxvii
Who should read this document.....	xxxvii
How this document is organized.....	xxxvii
How to use this document.....	xxxvii
How to provide feedback to IBM.....	xxxvii
Conventions and terminology that are used in this information.....	xxxviii
How to read a syntax diagram.....	xxxix
Prerequisite and related information.....	xl
Summary of changes for IP Configuration Guide.....	xlvi
Summary of changes for z/OS 3.2.....	xlvi
Changes made in z/OS Communications Server 3.1.....	xlvi
Part 1. Base TCP/IP system.....	1
Chapter 1. Overview of z/OS Communications Server.....	3
TCP/IP protocol stack.....	5
Multipath channel I/O process.....	5
Communications Storage Manager.....	5
Connectivity and gateway functions.....	5
Network protocol layer.....	7
Transport layer.....	7
File systems.....	7
Application Programming Interfaces.....	8
TCP/IP socket APIs provided by z/OS Communications Server	8
z/OS UNIX APIs.....	9
Chapter 2. IP configuration overview.....	11
IPv6 support.....	11
z/OS UNIX System Services concepts.....	11
Overview of data sets and UNIX files.....	12
Hierarchical file system concepts.....	12
References to installation data sets.....	13
Understanding search orders of configuration information.....	13
Configuration data set naming conventions.....	13
Configuration files for the TCP/IP stack.....	23
PROFILE.TCPIP search order.....	23
TCPIP.DATA search order.....	24
Configuration files for TCP/IP applications.....	25
Environment variables.....	25
MVS-related considerations.....	28
MVS system symbols.....	28
Automatic restart manager.....	29
Logging of system messages.....	30
Accounting - SMF records.....	32

Security considerations.....	34
Nonreusable ASIDs.....	35
TSO command authorization.....	36
UNIX System Services security considerations.....	36
Requirement for an OMVS segment.....	36
Authorization of TCP/IP started task user ID.....	37
Other user IDs requiring z/OS UNIX superuser authority.....	37
BPX.DAEMON FACILITY class profile.....	37
Program control.....	39
Defining TCP/IP as a UNIX System Services physical file system.....	40
Performance considerations.....	41
Fast path support.....	42
TCP receive window.....	44
TCP send window.....	44
Outbound serialization.....	45
Considerations for multiple instances of TCP/IP.....	45
Common INET PFS.....	45
Port management overview.....	46
Selecting a stack when running multiple instances of TCP/IP.....	52
Specifying BPXPRMxx values for a CINET configuration.....	55
Considerations for Enterprise Extender.....	55
Considerations for VIPA.....	56
Considerations for Fast Response Cache Accelerator.....	57
Considerations for extended address volumes.....	57
Considerations for networking hardware attachment.....	58
OSA Terminology.....	58
Virtual LAN.....	59
OSA VLAN.....	59
OSA Inbound Routing.....	60
Relationship of VLAN and OSA-Express primary router.....	63
Network configuration strategy with VLAN.....	64
OSA internal routing for a shared OSA physical port.....	72
OSA connection isolation.....	72
ARP offload and VIPA ARP processing.....	73
Checksum offload.....	73
TCP segmentation offload.....	73
Dynamic LAN idle timer.....	74
OSA-Express optimized latency mode.....	74
Inbound workload queuing.....	75
Fixed storage considerations for Network Express interfaces	78
Fixed storage requirements for OSA-Express QDIO and HiperSockets interfaces.....	79
Fixed storage considerations for OSA-Express 25 GBe interfaces	80
Mixing OSA types - configuration recommendation.....	81
Displaying OSA interface information.....	82
Configuring the OSA interface statement	82
HiperSockets concepts and connectivity.....	95
QDIO Accelerator.....	122
OSA-Express network traffic analyzer trace.....	125
Synchronization of OSA-Express diagnostic data.....	126
Prioritizing outbound OSA data.....	127
Using TEMPIP interfaces.....	128
Network Express RoCE Support.....	129
Determining the maximum transmission unit.....	130
Considerations for multiple servers sharing a TCP port.....	131
IBM z/OS Container Extensions network overview.....	132
Required steps before starting TCP/IP.....	135
Planning your installation and migration.....	135
Step 1: Install z/OS Communications Server.....	136

Verifying the initial installation.....	136
Step 2: Customize z/OS Communications Server.....	136
Step 3: Configure VMCF and TNF.....	139
Step 4: Update the VTAM application definitions.....	142
Step 5: Verify that the required address spaces are active.....	142
Step 6: Start the TCP/IP address space.....	143
Step 7: Set up cataloged procedures and configuration data sets.....	143
Chapter 3. Security.....	145
Application security.....	145
TCP/IP resource protection.....	146
Local user access control to TCP/IP resources using SAF.....	147
Stack access control.....	159
Port access control.....	159
Network access control.....	162
OSM access control.....	165
Socket option access control.....	165
Netstat access control.....	167
Fast Response Cache Accelerator access control.....	168
TCP/IP stack initialization access control.....	168
TCP/IP packet trace service access control.....	168
TCP connection information service access control.....	169
zERT information service access control.....	169
Real-time SMF information service access control.....	169
TCP/IP OSAENTA trace service access control.....	169
IPSec network management interface access control.....	170
Real-time application-controlled TCP/IP trace NMI access control.....	170
Syslogd isolation.....	171
IP filtering.....	171
Security considerations for the VARY command.....	172
Multilevel security.....	172
Configuration data set security.....	172
Network security principles.....	173
Cryptography: The foundation of good security.....	173
End to end security.....	174
Workload-based security deployment.....	174
Network security protocols.....	175
IPSec and VPNs	175
TLS and SSL.....	178
Application Transparent Transport Layer Security.....	182
Kerberos.....	182
Secure Shell (SSH).....	183
OSPF authentication.....	183
SNMPv3.....	183
Monitoring cryptographic network protection: z/OS encryption readiness technology (zERT).....	184
z/OS Encryption Readiness Technology (zERT) Concepts.....	184
Using z/OS Encryption Readiness Technology.....	194
Security event reporting: Integrated intrusion detection services.....	205
Defensive filtering.....	206
Network security services for the IPSec discipline.....	207
Network security services for the XMLAppliance discipline.....	211
Chapter 4. Preparing for IP networking in a multilevel secure environment.....	213
Understanding multilevel security concepts.....	213
Multilevel secure networking.....	213
Nonsecure systems.....	213
Managed systems.....	214
Multilevel secure systems.....	214

z/OS Communications Server TCP/IP stacks on z/OS multilevel secure systems.....	214
Network security zones.....	216
IBM zEnterprise System ensemble.....	216
Where your z/OS systems fit in your network.....	216
Planning stacks on your z/OS systems.....	217
Required configuration in a multilevel secure environment.....	217
Deciding whether to use restricted or unrestricted stacks.....	218
Steps for configuring global definitions for all stacks.....	219
Exempting certain users of certain programs from full Network Access Control.....	220
Configuring stack sysplex features in a multilevel secure environment.....	220
Defining security labels on other profiles in the SERVAUTH class.....	221
Planning your multilevel secure network.....	221
Planning for interactive UNIX System Services users in a multilevel secure environment.....	222
Steps for creating a separate home directory for each security label.....	222
Steps for setting stack affinity by security label.....	223
Host and domain name by security label.....	223
Planning for applications in a multilevel secure environment.....	224
Configuring z/OS CS applications in a multilevel secure environment.....	225
Changing your multilevel secure networking environment.....	233
Chapter 5. TCP/IP Customization.....	235
Configuring the syslog daemon.....	235
Starting and stopping syslogd.....	243
Configuring syslogd to receive remote messages.....	250
Configuring the z/OS syslogd to send messages to a remote syslogd.....	255
Interactions between syslogd and other components during IPL.....	256
Offloading log files.....	257
Setting permissions for log files and directories.....	258
Configuring syslogd for automatic archiving.....	258
Using syslogd for z/OS UNIX application programs.....	260
Usage notes.....	261
Diagnosing syslogd configuration problems.....	261
Syslog daemon name/token pair and ECSA storage mapping.....	262
Configuring TCPIP.DATA.....	262
Use of TCPIP.DATA and /etc/resolv.conf.....	263
Creating TCPIP.DATA.....	263
TCPIP.DATA statements.....	263
Using MVS system symbols in TCPIP.DATA.....	265
Configuring PROFILE.TCPIP.....	265
Changing configuration information.....	266
Setting up TCP/IP operating characteristics in PROFILE.TCPIP.....	266
Setting up physical characteristics in PROFILE.TCPIP.....	278
Setting up reserved port number definitions in PROFILE.TCPIP.....	286
Setting up the System Authorization Facility server access authorization class (optional).....	291
Configuring the local host table (optional).....	291
Creating HOSTS.LOCAL site host table.....	292
Creating /etc/hosts.....	294
Creating ETC.IPNODES and /etc/ipnodes.....	294
Verifying your configuration.....	296
Verifying TCPIP.DATA statement values in the native MVS environment.....	296
Verifying TCPIP.DATA statement values in the z/OS UNIX environment.....	296
Verifying PROFILE.TCPIP.....	297
Verifying interfaces with Ping and Traceroute.....	297
Verifying local name resolution with TESTSITE.....	297
Verifying PROFILE.TCPIP and TCPIP.DATA using HOMETEST.....	297
Verifying your X Window System installation (Optional).....	298
Customizing TCP/IP messages.....	299
Customizing message catalogs.....	299

Customizing message data sets.....	303
Chapter 6. Routing.....	307
Routing terminology.....	307
General terms.....	307
Interior Gateway Protocols.....	308
Route selection algorithm.....	309
The sample network.....	310
IPv4 static routing.....	311
Replaceable static routes.....	313
IPv6 static routing.....	313
Replaceable static routes.....	314
Static routing configuration examples.....	314
z/OS TCPCS4.....	314
z/OS TCPCS7.....	315
IPv4 dynamic routing using OMPROUTE.....	316
Open Shortest Path First.....	317
Routing Information Protocol.....	318
IPv6 dynamic routing using router discovery.....	319
Multiple routes from router advertisements.....	319
IPv6 dynamic routing using OMPROUTE.....	319
IPv6 OSPF protocol.....	320
IPv6 RIP protocol.....	320
OMPROUTE configuration.....	321
Run-time environment.....	321
Language Environment run-time considerations.....	322
OMPROUTE tuning considerations.....	322
Multiple TCP/IP stacks.....	322
TCP/IP stack routing table management.....	322
Using RIP, IPv6 RIP, OSPF, and IPv6 OSPF with OMPROUTE.....	322
Virtual IP addresses.....	323
Service policy.....	323
Multiple equal-cost routes.....	323
Sysplex autonomies.....	324
Steps for configuring OMPROUTE.....	324
Starting and controlling OMPROUTE.....	330
OMPROUTE parameters.....	330
Controlling OMPROUTE.....	331
Steps for configuring OSPF and RIP (IPv4 and IPv6).....	333
Minimizing the routing responsibility of z/OS Communications Server.....	352
Preventing futile neighbor state loops during adjacency formation.....	353
Verification of OMPROUTE IPv4 configuration and state.....	354
Displaying all OSPF configuration information.....	354
Displaying information about configured OSPF areas.....	355
Displaying configuration information about configured OSPF interfaces.....	355
Displaying information about configured Non-broadcast Multiple Access OSPF interfaces.....	355
Displaying information about configured OSPF virtual links.....	355
Displaying information about configured OSPF neighbors.....	356
Displaying the contents of a single OSPF link state advertisement.....	356
Displaying statistics and parameters for OSPF areas.....	357
Displaying the list of AS external advertisements.....	357
Displaying a list of non-AS external advertisements.....	357
Displaying current, run-time statistics and parameters for OSPF interfaces.....	357
Displaying current, run-time statistics and parameters for a specific OSPF interface.....	358
Displaying current, run-time statistics and parameters for OSPF neighbors.....	358
Displaying current run-time statistics and parameters for a specific OSPF neighbor.....	358
Displaying routes to other routers that have been calculated by OSPF.....	359
Displaying the number of LSAs currently in the link state database.....	359

Displaying statistics generated by the OSPF routing protocol.....	359
Displaying all of the RIP configuration information.....	359
Displaying information about configured RIP interfaces.....	360
Displaying the routes to be unconditionally accepted.....	360
Displaying current run-time information about RIP interfaces.....	360
Displaying current run-time information about a specific RIP interface.....	360
Displaying the global RIP filters.....	361
Displaying the routes in the OMPROUTE main routing table.....	361
Displaying the routes to a specific destination in the main routing table.....	362
Displaying the routes in all OMPROUTE IPv4 policy-based routing tables.....	362
Displaying the routes in an OMPROUTE IPv4 policy-based routing table.....	363
Displaying the routes to a specific destination in an IPv4 policy-based routing table	364
Displaying all of the generic configuration information.....	364
Displaying information about configured generic interfaces.....	364
Displaying current run-time information about generic interfaces.....	364
Verification of OMPROUTE IPv6 configuration and state.....	365
Displaying all IPv6 OSPF information.....	365
Displaying IPv6 OSPF area statistics and parameters.....	365
Displaying IPv6 OSPF interface statistics and parameters.....	366
Displaying statistics and parameters for a specific IPv6 OSPF interface.....	366
Displaying IPv6 OSPF virtual link statistics and parameters.....	366
Displaying statistics and parameters for a specific IPv6 OSPF virtual link.....	366
Displaying IPv6 OSPF neighbor statistics and parameters.....	367
Displaying statistics and parameters for a specific IPv6 OSPF neighbor.....	367
Displaying IPv6 OSPF link state database statistics.....	367
Displaying IPv6 OSPF link state advertisement.....	368
Displaying IPv6 OSPF external advertisements.....	368
Displaying IPv6 OSPF area link state database.....	368
Displaying IPv6 OSPF router routes.....	369
Displaying IPv6 OSPF routing protocol statistics.....	369
Displaying all of the IPv6 RIP information.....	370
Displaying information about IPv6 RIP interfaces.....	370
Displaying information about a specific IPv6 RIP interface.....	370
Displaying the routes to be unconditionally accepted by IPv6 RIP.....	370
Displaying the global IPv6 RIP filters.....	371
Displaying the routes in the OMPROUTE IPv6 main routing table.....	371
Displaying the routes to a specific destination in the IPv6 main routing table.....	372
Displaying the routes in all OMPROUTE IPv6 policy-based routing tables.....	372
Displaying the routes in an OMPROUTE IPv6 policy-based routing table.....	373
Displaying the routes to a specific destination in an IPv6 policy-based routing table.....	374
Displaying all of the IPv6 generic information.....	374
Displaying information about IPv6 generic interfaces.....	374
Displaying information about a specific IPv6 generic interface.....	375
Sample OMPROUTE configuration files.....	375
Policy-based routing.....	377
Options for configuring policy-based routing.....	378
Routing policy configuration.....	379
Getting started with policy-based routing.....	382
Configuring policy-based routing.....	382
Considerations for using policy-based routing with IP security.....	384
Considerations for mixed routing environments.....	385
Use of static routing with OMPROUTE.....	385
Use of IPv6 static routing with router advertisements.....	385
Use of policy-based routing with static or dynamic routing.....	386
Verifying static, dynamic, and policy-based routing.....	386
Verifying connections with Netstat, Ping, and Traceroute.....	386
Chapter 7. Virtual IP Addressing.....	389

Terminology.....	389
Introduction to VIPA.....	389
Moving a VIPA (for TCP/IP outage).....	391
Static VIPAs, dynamic VIPAs, distributed DVIPAs.....	391
Using static VIPAs.....	392
Steps for configuring static VIPAs for a z/OS TCP/IP stack.....	393
Steps for converting from IPv4 VIRTUAL DEVICE, LINK, and HOME definitions to the IPv4 VIRTUAL INTERFACE statement.....	395
Configuring static VIPAs for Enterprise Extender.....	396
Considerations when using static VIPAs with IPv6.....	396
Planning for static VIPA takeover and takeback.....	396
Using dynamic VIPAs.....	397
Configuring DVIPA support.....	397
Planning for dynamic VIPA takeover.....	397
Different application uses of IP addresses and DVIPAs.....	400
Configuring dynamic VIPAs.....	400
Configuring the multiple application-instance scenario.....	400
Configuring the unique application-instance scenario.....	401
Configuring application-instance DVIPAs for IBM z/OS Container Extensions (zCX).....	408
Choosing which form of dynamic VIPA support to use.....	409
Configuring distributed DVIPAs - sysplex distributor.....	410
Manually quiescing DVIPA sysplex distributor server applications.....	413
Route selection for distributing packets.....	414
Generic routing encapsulation.....	415
Dynamic port assignment.....	416
Sysplex-wide source VIPA.....	416
GLOBALCONFIG EXPLICITBINDPORTRANGE.....	419
Timed affinities.....	421
Sysplex-Wide Security Associations.....	424
Resolution of dynamic VIPA conflicts.....	428
Restart of the original VIPADEFINE TCP/IP after an outage.....	428
Movement of unique application-instance (BIND).....	429
Movement of a unique APF-authorized application instance (ioctl).....	433
Same dynamic VIPA for VIPADEFINE and BIND(), SIOCSVIPAs or SIOCSVIPAs6 ioctl, or MODDVIPA utility.....	433
Dynamic VIPA creation results.....	434
TIER1, TIER2, and CPCSCOPE keyword DVIPA contention resolution.....	438
IPv6 considerations.....	443
VIPARANGE.....	443
VIPADEFINE and VIPABACKUP.....	443
Unique application-instance scenario and IPv6-enabled applications.....	443
VIPAs, OSA, and Spanning Tree Protocol.....	444
Mixture of types of dynamic VIPAs within subnets.....	444
MVS failure and sysplex failure management.....	445
Applications and dynamic VIPAs.....	445
Configuring VIPAs for activation with VIPABACKUP.....	446
Example of configuring dynamic and distributed VIPAs.....	447
Verifying the DVIPAs in a sysplex.....	449
Using Netstat support to verify dynamic VIPA configuration.....	452
Verifying sysplex distributor workload.....	456
Dynamic VIPAs and routing protocols.....	460
IPv4 considerations for OMPROUTE.....	460
IPv4 considerations for Routing Information Protocol.....	461
IPv6 considerations.....	461
Chapter 8. TCP/IP in a sysplex.....	463
Connectivity in a sysplex.....	464
Sysplex subplexing.....	464

Dynamic XCF.....	468
Network interfaces monitoring.....	479
Sysplex problem detection and recovery.....	480
Target server connection setup responsiveness monitoring.....	496
Workload balancing.....	496
Single systemwide image	497
Horizontal growth	497
Ease of management	497
Internal load balancing solutions.....	498
Sysplex-aware external load balancing solutions.....	498
External IP workload balancing solutions.....	498
Choosing a load balancing solution.....	499
Sysplex distributor.....	503
BASEWLM - Distribution using WLM system weights.....	503
SERVERWLM - Distribution using WLM server-specific weights.....	504
Choosing between the BASEWLM and SERVERWLM distribution methods.....	507
BASEWLM and SERVERWLM display example.....	507
WEIGHTEDACTIVE - Distribution based on active connection load.....	508
Choosing between RoundRobin and WeightedActive distribution.....	509
Hot standby distribution.....	509
Timed affinity.....	512
SHAREPORT.....	512
QDIO Accelerator.....	513
Inbound workload queueing.....	513
Optimizing local connections.....	513
Policy interactions.....	513
Sysplex distribution optimizations for multi-tier z/OS workloads.....	515
Sysplex distributor optimization with the OPTLOCAL keyword.....	515
Sysplex distributor enhanced workload distribution for z/OS multi-tier, OPTLOCAL configurations.....	517
Sysplex distributor enhanced workload distribution for z/OS multi-tier, OPTLOCAL configurations with CPC affinity.....	519
Chapter 9. TCP/IP in an ensemble.....	521
Steps for configuring an interface for the intraensemble data network (CHPID type OSX).....	522
HiperSockets connectivity to the intraensemble data network.....	522
Operating and managing IEDN-enabled HiperSockets interfaces.....	524
Performance considerations for the IEDN-enabled HiperSockets function.....	525
Steps for enabling HiperSockets access to the intraensemble data network.....	526
Steps for enabling IPv6 on a stack for access to the intranode management network.....	527
Steps for using the intranode management network (CHPID type OSM).....	527
Routing considerations for the intraensemble data network.....	528
OMPROUTE considerations for the intraensemble data network.....	529
Sysplex distributor considerations for the intraensemble data network.....	529
Multilevel security and network access control considerations.....	529
Chapter 10. Shared Memory Communications.....	531
Shared Memory Communications over Remote Direct Memory Access.....	531
Remote Direct Memory Access over Converged Ethernet.....	532
Sharing RoCE Features.....	532
RoCE Express features virtualization environment.....	533
Network Express feature virtualization environment.....	534
Sharing Network Express features.....	534
Shared Memory Communications - Direct Memory Access.....	535
Shared Memory Communications concepts.....	535
Rendezvous processing.....	535
Shared Memory Communications links and link groups.....	538
SMC memory buffers.....	542

SMC-R staging buffers.....	543
SMC filters.....	543
Shared Memory Communications terms.....	543
Using Shared Memory Communications.....	546
Configuration considerations for Shared Memory Communications.....	546
Setting up the environment for Shared Memory Communications over RDMA.....	559
Configuring Shared Memory Communications over RDMA.....	560
Setting up the environment for Shared Memory Communications - Direct Memory Access.....	562
Configuring Shared Memory Communications - Direct Memory Access.....	562
Shared Memory Communications multiple IP subnet support (SMCv2: SMC-Rv2 and SMC-Dv2).....	564
SMC Enterprise ID	564
EID Format.....	566
User Defined EID (UEID).....	566
Multiple EIDs.....	566
System EID (SEID).....	567
Using UEID or SEID.....	567
SMC filters.....	567
Using SMC filters.....	568
Dynamic selection of SMC version and SMC type.....	568
SMC-Dv2.....	569
ISMv2.....	569
Enabling SMC-Dv2.....	569
SMC-Dv2 and ISM VCHID Association using PNetIDs.....	570
SMC-Rv2.....	572
RoCEv2.....	573
Enabling SMC-Rv2.....	573
Network Express and RoCEv2 device association and physical connectivity.....	574
OSA and RoCEv2 device association and physical connectivity.....	575
RoCEv2 Common Network Connectivity Considerations.....	576
SMC-Rv1 migration considerations.....	577
Sharing or reusing resources: SMC RIPADDR and PFID.....	578
SMC-Rv2 resilience, high availability with RoCEv2 and IP routing.....	578
SMC-Rv2 link groups.....	578
SMC interactions with other z/OS Communications Server functions.....	580
Sysplex distributor.....	580
Security functions.....	581
Intrusion detection services (IDS).....	581
TCP keepalive.....	582
TCP application data transfer options.....	582
Packet trace.....	583
SMC-R RoCE maximum transmission unit.....	583
Managing SMC communications.....	583
Managing your GLOBALCONFIG RoCE interfaces.....	583
Managing your ISM interfaces.....	585
Displaying SMC information.....	585
Monitoring SMC information.....	587
VTAM displays and tuning statistics.....	588
Stopping SMC-R.....	589
Stopping SMC-D.....	589

Part 2. Server applications.....591

Chapter 11. Accessing remote hosts using Telnet.....	593
The TN3270E Telnet server.....	593
Steps for starting the TN3270E Telnet server.....	593
Managing Telnet.....	601
Telnet diagnostic tools.....	604

Telnet configuration data set customization details.....	609
Configuring the z/OS UNIX Telnet server.....	678
Installation information.....	678
Environment variables.....	679
Starting, stopping, and administration of z/OS UNIX Telnet.....	679
otelnetd.....	682
SMF record handling.....	685
BPX.DAEMON considerations.....	685
Kerberos.....	685
Chapter 12. Transferring files using FTP.....	687
Configuring PROFILE.TCPIP for FTP.....	688
Configuring ETC.SERVICES.....	689
Configuring /etc/syslog.conf	689
Configuring the FTPD cataloged procedure.....	689
Security for the FTP server.....	690
Defining environment variables for the FTP server (optional).....	699
Configuring FTP with multiple TCP/IP stacks.....	700
Configuring TCPIP.DATA for FTP	700
Configuring FTP.DATA.....	701
Optionally configuring user-level server options using FTPS.RC.....	701
Data set attributes.....	701
Specifying attributes for new MVS data sets.....	703
Translation of data.....	705
z/OS UNIX named pipes.....	705
FTP code page conversion.....	706
Master catalog access.....	708
Customizing FTP message catalogs.....	708
Steps for creating a message catalog from the shipped catalog and preserving its timestamp.....	709
Accounting.....	710
Configure the FTP server for SMF (optional).....	710
Customizing Transport Layer Security and Kerberos security.....	711
Steps for customizing the FTP server for TLS.....	711
Steps for customizing the FTP server for Kerberos.....	716
Steps for customizing the FTP client for TLS.....	720
Steps for customizing the FTP client for Kerberos.....	726
Port 990.....	728
Steps for migrating the FTP client to use AT-TLS.....	728
Traversing firewalls with SSL/TLS secure FTP.....	730
Db2 and JES.....	733
Configuring the optional FTP user exits.....	734
The FTPSMFEX user exit (for the FTP server).....	734
The FTCHKIP user exit (for the FTP server).....	734
The FTCHKPWD user exit (for the FTP server).....	734
The FTCHKCMD user exit (for the FTP server).....	735
The FTCHKJES user exit (for the FTP server).....	735
The FTPOSTPR user exit (for the FTP server).....	736
The EZAFCMD user exit (for the FTP client).....	737
The EZAFCREP user exit (for the FTP client).....	737
Customizing the FTP-to-JES interface for JESINTERFACELevel 2 (optional).....	738
Configuring the FTP server for anonymous FTP (optional).....	739
Creating an anonymous directory structure in the z/OS UNIX file system.....	741
Configure the welcome banner page, login, and directory message (optional).....	743
Using magic cookies to represent information.....	744
Configuring the FTP server to log session (user ID) activity.....	744
Configuring to send detailed login failure replies to an FTP client (optional).....	745
Install the SQL query function (optional) and access the Db2 modules.....	745

Accessing Db2 modules.....	747
FTP.DATA updates for SQL query function.....	747
Verifying the FTP server.....	747
Verifying the FTP client.....	748
Verifying FTP.DATA statements.....	749
Verifying anonymous, banner, and other optional configuration information.....	751
Verifying the FTP-JES interface (optional).....	751
Chapter 13. The resolver.....	753
DNS overview.....	753
Domain names.....	754
Domain name servers.....	754
Resolvers.....	757
Querying name servers	759
Recommended reading.....	760
Resolver API calls.....	761
Starting the resolver.....	761
The default resolver settings.....	762
Customizing the resolver.....	762
The resolver setup file.....	763
The resolver address space.....	769
Managing the resolver address space.....	772
Steps for manually restarting the resolver.....	772
Steps for applying an interim fix to the resolver.....	773
IPv6 name servers and the resolver.....	773
Resolver functions.....	774
Resolver caching.....	774
Monitoring the responsiveness of Domain Name System name servers.....	786
Extension Mechanisms for DNS standards and the resolver.....	795
Resolver configuration files.....	796
z/OS XL C/C++ environment variables for configuration files.....	801
Search orders used in the z/OS UNIX environment.....	803
Search orders used in the native MVS environment.....	808
Chapter 14. Policy-based networking.....	813
Policy types and infrastructure overview.....	813
Configuration files and policy definition files.....	815
Managing changes to configuration files and policy definition files.....	815
Storing configuration files and policy definition files.....	816
Steps for managing policy changes.....	817
Policy infrastructure components.....	819
TCP/IP stack.....	819
Policy Agent.....	819
Traffic regulation management daemon.....	823
IKE daemon.....	823
Network security services daemon.....	823
Defense Manager daemon.....	823
SNMP Network SLAPM2 subagent.....	824
Sample policy infrastructure.....	824
Policy sample files.....	826
Policy types.....	827
QoS policy.....	828
IDS policy.....	828
IPSec policy.....	828
AT-TLS policy.....	829
Policy-based routing policy.....	830
zERT policy-based enforcement (ZERT) policy.....	831
Policy configuration files.....	832

Steps for configuring the Policy Agent.....	834
Step 1: Configure general information.....	834
Step 2: Configure Policy Agent as a policy server.....	837
Step 3: Configure Policy Agent as a policy client.....	842
Step 4: Configure policies in Policy Agent configuration files.....	842
Step 5: Configure Policy Agent to use the LDAP server using the ReadFromDirectory statement.....	843
Step 6: Configure Policy Agent for import services.....	844
Step 7: Configuring Policy Agent to automatically monitor applications.....	846
Add TLS/SSL to Policy Agent connections.....	847
Starting and stopping the Policy Agent.....	849
AUTOLOG considerations.....	849
Specifying environment variables.....	850
Main configuration file search order.....	851
Other considerations when starting the Policy Agent.....	851
Stopping the Policy Agent.....	852
Refreshing policies.....	852
FLUSH and PURGE considerations.....	853
Switching between local and remote policies.....	854
Verifying that policies are correctly defined and functioning properly.....	855
 Chapter 15. Quality of service.....	857
Differentiated Services policies.....	857
Integrated Services policies.....	859
Sysplex distributor policies.....	859
QoS-specific Policy Agent functions.....	859
Sysplex distributor policy performance monitoring configuration.....	860
Policy performance collection configuration.....	861
IPv4 type of service or IPv6 traffic class mapping configuration.....	862
Options for configuring QoS.....	863
Option 1: Use the IBM Configuration Assistant for z/OS Communications Server.....	863
Option 2: Manual configuration.....	864
Specifying the QoS configuration file based on Policy Agent role.....	864
Defining policies in a Policy Agent configuration file.....	864
Differentiated Services policy examples.....	864
RSVP policy example.....	865
Sysplex distributor policy example.....	866
Defining policies using LDAP.....	867
RSVP.....	867
Configuring the RSVP agent.....	868
Starting and stopping RSVP.....	868
SNMP Network SLAPM2 (nslapm2) performance monitor.....	869
Configuring the Network SLAPM2 subagent.....	869
Starting and stopping the Network SLAPM2 subagent.....	870
Verification.....	871
Verifying that the policies are installed in the TCP/IP stacks.....	871
Verifying that the expected traffic is mapping to the correct QoS policies.....	871
Verifying that the sysplex distributor policy functions are working correctly.....	872
Monitoring performance and tuning policies.....	872
Using pasearch.....	872
Using the Network SLAPM2 MIB to monitor policies.....	872
 Chapter 16. Intrusion detection services.....	877
Scan policies.....	877
ICMP scans.....	879
ICMPv6 scans.....	879
UDP port scans.....	880
TCP port scans.....	880

Attack policies.....	881
Traffic regulation policies.....	887
Traffic regulation policies for TCP ports.....	888
Traffic regulation policies for UDP ports.....	888
Options for configuring IDS.....	889
Option 1: Use the IBM Configuration Assistant for z/OS Communications Server.....	889
Option 2: Manual configuration.....	890
Specifying the IDS configuration file based on Policy Agent role.....	890
Defining IDS policies.....	890
IDS policy definition considerations	891
IDS scan policy example.....	893
IDS attack policy examples.....	895
Traffic Regulation policy examples.....	903
Verification.....	905
Are the correct policies active?.....	906
Is the expected traffic mapping to the correct policies?	906
Are the IDS policy functions working correctly?.....	906
TRMD.....	906
Running TRMD as a started task.....	907
Running TRMD from the z/OS UNIX shell.....	908
Stopping TRMD.....	908
trmdstat.....	908
Defensive filtering.....	908
 Chapter 17. IP security.....	 911
Terms and concepts for IP security.....	911
Terminology conventions for IP security.....	915
Commands used to administer IP security.....	915
Overview of using IP security.....	916
FIPS 140 mode and IP security.....	917
Configuring IP security.....	920
IP filtering.....	921
Filter rules and actions.....	921
Filtering criteria in an IP packet.....	922
Additional filtering criteria based on protocol.....	922
Additional filtering criteria based on network attributes.....	923
IP traffic patterns.....	925
Routed traffic and fragmented packets.....	925
Conditionally controlling IP filters.....	926
Special considerations when using IP security for IPv6.....	926
Neighbor discovery and multicast listener discovery.....	926
Stateless address autoconfiguration.....	927
IPv6-specific protocols.....	927
IPv6 address types.....	927
IPv6 extension headers.....	927
Considerations for IPv6 OSPF security.....	927
Default IP filter policy and IP security policy.....	929
Modifying the default IP filter policy.....	930
IP filter logging.....	947
IP filter discard action.....	947
Data encryption and authentication - IPSec.....	947
AH and ESP protocols.....	948
IPSec and symmetric key management.....	953
Manual key management.....	953
Dynamic key management - IKE and IPSec negotiations.....	954
IPSec and network address translation devices.....	960
Dynamic structures used to map Security Associations.....	961
Steps for preparing the z/OS system for IP security.....	963

IP security policy configuration.....	967
Overview of configuring IP security policy.....	967
Steps for configuring local IP security policy using only a common IP security configuration file.....	970
Steps for configuring remote IP security policy using only a common IP security configuration file.....	970
Steps for configuring local IP security policy using only a stack-specific IP security configuration file.....	971
Steps for configuring remote IP security policy using only a stack-specific IP security configuration file.....	972
Steps for configuring local IP security policy using both a stack-specific file and a common file.....	973
Steps for configuring remote IP security policy using both a stack-specific file and a common file.....	973
Component policies of IP security policy configuration files.....	974
Quick start using IP filtering and IPSec host-to-host.....	985
Steps for configuring IP security policy.....	1000
Configuring specific security models.....	1002
Configuring the IKE daemon.....	1069
Multiple TCP/IP stacks.....	1069
Run-time environment.....	1069
Language Environment run-time considerations.....	1070
IKE daemon configuration source information.....	1070
Policy Agent considerations.....	1070
Using network security services.....	1070
Certificate revocation checking.....	1072
Steps for configuring the IKE daemon.....	1073
Starting the IKE daemon.....	1076
Stopping the IKE daemon.....	1077
Controlling the IKE daemon.....	1078
Verifying policy installation.....	1078
Console messages.....	1078
Displaying TCP/IP configuration.....	1078
Displaying active filters with the ipsec command.....	1079
Displaying Security Associations with the ipsec command.....	1095
Displaying filter rules with the pasearch command.....	1097
Verifying filter action.....	1097
Security Associations.....	1101
Activating a Security Association.....	1101
Verifying the activation of a Security Association.....	1102
Verifying the use of an active Security Association.....	1102
Refreshing Security Associations.....	1103
Deactivating Security Associations.....	1104
Modifying active IP security policy.....	1105
IP security policy files.....	1105
Policy Agent image configuration files.....	1105
Policy Agent main configuration file.....	1105
Active Security Associations and the ipsec -f default command.....	1105
Displaying NSS client information.....	1106
Sysplex-Wide Security Associations and IP security.....	1107
NAT traversal and Sysplex-Wide Security Associations.....	1108
FIPS 140 mode and Sysplex-Wide Security Associations.....	1109
Shadow Security Associations.....	1109
Sample IP security policy files.....	1110
Chapter 18. Network security services.....	1111
Terms and concepts for network security services.....	1111
Network security services overview.....	1112

NSS IPSec discipline overview.....	1112
NSS XMLAppliance discipline.....	1113
Preparing to provide network security services.....	1113
Steps for authorizing resources for NSS.....	1114
NSS server certificate label naming considerations.....	1120
NSS client authorization example.....	1121
NSS server configuration considerations.....	1122
Using hash and URL certificate encoding types.....	1127
Creating certificate bundles.....	1128
Controlling the NSS server.....	1130
NSS server failover considerations.....	1131
NSS server capacity considerations.....	1132
NSS server certificate revocation support.....	1132
Managing network security services.....	1132
Chapter 19. Defensive filtering.....	1135
Global and stack-specific defensive filters.....	1136
Defensive filter names.....	1137
Defensive filter modes.....	1137
Allowing administrative access.....	1138
Filter-match logging.....	1138
TRMD.....	1139
Disabling defensive filters for a single stack.....	1139
Relationship between intrusion detection services and defensive filters.....	1139
Comparison of IP security filters and defensive filters.....	1140
The DMD run-time environment.....	1142
The DMD and Language Environment run-time options.....	1143
Enabling defensive filtering.....	1143
Enabling the IP security function.....	1143
Steps for configuring the DMD.....	1144
Steps for authorizing resources for the DMD and the ipsec command.....	1146
Steps for granting authority to start DMD.....	1146
Starting the DMD.....	1147
Stopping the DMD.....	1147
Using the DMD MODIFY command.....	1148
Chapter 20. Application Transparent Transport Layer Security data protection.....	1149
AT-TLS configuration in PROFILE.TCPIP.....	1149
TCP/IP stack initialization access control.....	1150
Options for configuring AT-TLS security.....	1150
Option 1: Use the IBM Configuration Assistant for z/OS Communications Server.....	1150
Option 2: Manual configuration.....	1151
Specifying the AT-TLS configuration file based on Policy Agent role.....	1151
AT-TLS policy configuration.....	1151
AT-TLS rules.....	1152
AT-TLS actions.....	1152
Getting started with AT-TLS.....	1154
Configuring the server system.....	1154
Configuring the client systems.....	1156
Steps for starting AT-TLS and verifying its operation.....	1158
Application compatibility with AT-TLS.....	1159
Policy considerations.....	1159
Reusable objects.....	1159
Common AT-TLS configuration file.....	1159
Exempting specific connections from AT-TLS.....	1159
Action refresh.....	1160
Achieving the basic level of security.....	1160
Picking the handshake roles.....	1160

Specifying the key ring.....	1161
Configuring more sophisticated security.....	1162
Cipher suite specification.....	1162
Limiting Key Exchange Elliptic Curves for TLSv1.0, TLSv1.1, and TLSv1.2.....	1162
Protocol versions.....	1163
Using TLSv1.3 protocol support.....	1163
Certificate validation.....	1164
Validating a host name against a certificate.....	1164
FIPS 140-2 support.....	1165
Certificate revocation support.....	1166
Encryption key refresh.....	1166
Additional security customization considerations.....	1166
Handshake timer.....	1166
Diagnostic traces.....	1167
Diagnosis considerations.....	1167
TLS function negotiation.....	1168
Session caching.....	1169
AT-TLS access control considerations.....	1169
Application model considerations.....	1170
Client application model.....	1170
Server application model.....	1171
Forked server application model.....	1172
CICS transaction model.....	1173
Advanced application considerations.....	1173
AT-TLS aware application considerations.....	1173
AT-TLS controlling application considerations.....	1173
Secondary connection application model.....	1174
Chapter 21. z/OS Load Balancing Advisor.....	1177
Steps for preparing to use the z/OS Load Balancing Advisor.....	1178
Step 1: Consider whether to use TLS/SSL (using AT-TLS on z/OS).....	1179
Step 2: Evaluate TCP/IP workloads to be load balanced and select a load balancing solution (optional).....	1180
Step 3: Decide who will have authority to start the Advisor (optional).....	1180
Step 4: Decide who will have authority to start the Agents (optional).....	1181
Step 5: Authorize the Agents to use WLM services.....	1181
Step 6: Determine how the Advisor and agent are to interact in a subplexing environment (optional).....	1182
Steps for configuring the z/OS Load Balancing Advisor.....	1182
Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional).....	1183
Step 2: Configure and start syslogd.....	1185
Step 3: Configure one Advisor per sysplex.....	1186
Step 4: Configure one Agent per z/OS system in the sysplex.....	1191
Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run (optional).....	1193
Step 6: Customize WLM policies for the Advisor and Agents (optional).....	1198
Step 7: Configure the external load balancers.....	1198
Steps for starting the z/OS Load Balancing Advisor.....	1201
Step 1: Start the TCP/IP stacks that the Advisor and the Agents will use.....	1201
Step 2: Start the target applications that will be the targets of load balancing.....	1201
Step 3: Start one Agent on each sysplex system you want to participate in this method of workload balancing.....	1201
Step 4: Start the one instance of the Advisor in the sysplex.....	1202
Step 5: Start the load balancers.....	1202
Verifying that the Advisor system is functioning correctly (optional).....	1202
Operating the z/OS Load Balancing Advisor.....	1203
Changing the logging level of the Advisor and Agents.....	1203

Interpreting Agent and Advisor display information.....	1203
Stopping or resuming workload distribution to particular members (QUIESCE and ENABLE).....	1216
z/OS Load Balancing Advisor configuration example.....	1218
Load balancer configuration details.....	1219
Advisor configuration details.....	1219
Agent configuration file on SYSB.....	1221
Agent configuration file on SYSA.....	1221
Customization of PROFILE.TCPIP.....	1221
Example displays.....	1223
Chapter 22. Automated domain name registration.....	1225
System overview.....	1225
Interaction with name servers.....	1226
Interaction with the z/OS Load Balancing Advisor.....	1226
Enabling TLS/SSL for ADNR.....	1227
Steps for configuring automated domain name registration.....	1227
Step 1: Decide which sysplex resources should be managed by ADNR.....	1228
Step 2: Decide on one or more domain names to be managed by ADNR.....	1228
Step 3: Decide which name server or name servers are to be managed by ADNR.....	1229
Step 4: Configure the selected name servers to be the primary master name servers for the domain names that ADNR is to manage.....	1229
Step 5: Delegate the domain names to be managed by ADNR to the selected name servers from the parent domain's name server.....	1229
Step 6: Configure the z/OS Load Balancing Advisor function.....	1230
Step 7: Define security server profiles for ADNR.....	1230
Step 8: Configure ADNR to automatically restart in case of application or system failure (optional).....	1231
Step 9: Configure and start syslogd (optional, but required to have ADNR write log messages and trace data to syslogd).....	1232
Step 10: Configure one ADNR application per sysplex.....	1232
Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional).....	1236
Step 12: Start the TCP/IP stacks on which ADNR and the LBA applications are to run.....	1236
Step 13: Start the z/OS Load Balancing Advisor and Agent.....	1237
Step 14: Start the target applications that are to be managed by ADNR.....	1237
Step 15: Start the ADNR application.....	1237
Step 16: Verify that the ADNR system is functioning correctly (optional).....	1237
z/OS Load Balancing Advisor configuration considerations.....	1238
Connectivity considerations.....	1238
Near real-time availability information of sysplex resources.....	1239
z/OS Load Balancing Advisor and Agent operational considerations.....	1239
Advisor operational considerations.....	1239
Agent operational considerations.....	1239
Name server configuration considerations.....	1240
Initial zone configuration.....	1240
Authorizing dynamic updates.....	1240
Updates to an ADNR-managed zone.....	1240
Authorizing zone transfers.....	1241
Limiting the duration of an outbound zone transfer.....	1242
Limiting the total number of simultaneous outbound zone transfers.....	1242
The .digrc file.....	1242
Split DNS (views).....	1242
Zone transfer formats.....	1243
ADNR configuration considerations.....	1244
Changing the ADNR configuration file.....	1244
Maintaining zone data integrity.....	1244
Steps for using the ADNR application in a sysplex subplexing environment.....	1245

Step 1: Plan how the new subdomains representing each subplex will fit into your DNS hierarchy.....	1246
Step 2: Configure the name servers that will be updated for the new subplex domains.....	1247
Step 3: Define and configure one Advisor per subplex.....	1247
Step 4: Update the Agent configuration files to communicate with the Advisor running in its subplex.....	1248
Step 5: Define one ADNR application per subplex.....	1248
Step 6: Assign the host_group and server_group statements from the sysplex ADNR configuration to the correct subplex domains.....	1248
Step 7: Configure the new ADNR instances to update the name server and zone for its subplex.....	1249
Step 8: Configure the new ADNR instances to communicate with the subplex Advisor.....	1249
Step 9: Update resolver configuration files (optional).....	1249
Step 10: Start the TCP/IP stacks, Advisor, Agent, ADNR, and target applications that are to be managed by ADNR.....	1249
Step 11: Verify that each subplex ADNR is functioning correctly.....	1249
Operating ADNR.....	1249
Changing the logging level of ADNR.....	1250
Changing the ADNR configuration dynamically.....	1250
Interpreting ADNR display information.....	1250
Diagnosing problems.....	1250
ADNR configuration example.....	1251
ADNR display examples.....	1258
Chapter 23. Simple Network Management Protocol.....	1267
SNMP overview.....	1267
Network management application.....	1268
SNMP protocols.....	1268
SNMP agent.....	1269
SNMP subagents.....	1270
Key generation commands	1272
Distributed Protocol Interface.....	1272
Trap forwarder daemon.....	1272
Processing an SNMP request.....	1272
Deciding on SNMP security needs.....	1273
Community-based security.....	1273
User-based security.....	1273
Decide on your security needs - community-based or user-based.....	1274
Step 1: Configure the SNMP agent.....	1275
Provide TCP/IP profile statements.....	1275
Provide community-based security and notification destination information.....	1276
Provide community-based and user-based security and notification destination information.....	1279
Migrating community-based configuration to SNMPD.CONF format.....	1281
Provide secure access to agent from subagents	1282
Allowing subagents with duplicate identifiers to connect.....	1283
Provide MIB object configuration information.....	1283
Common_INET considerations.....	1284
Start the SNMP agent.....	1285
Sample JCL procedure for starting OSNMPD from MVS.....	1285
Starting OSNMPD from z/OS UNIX.....	1285
Step 2: Configure the SNMP commands.....	1285
Configure the z/OS UNIX snmp command.....	1286
Configure the NetView SNMP command.....	1288
Step 3: Configure the SNMP subagents.....	1291
TCP/IP subagent configuration.....	1291
Step 4: Configure the Open Systems Adapter support.....	1291
OSA/SF prerequisites.....	1292
Required TCP/IP profile statements.....	1293

Subagent connection to OSA/SF when there are multiple TCP/IP instances.....	1294
Step 5: Configure the trap forwarder daemon.....	1294
Provide PROFILE.TCPIP statements.....	1295
Provide trap forwarder configuration information.....	1295
Starting and stopping the trap forwarder daemon.....	1295
Chapter 24. Remote print server.....	1297
Configuring the Remote Print Server.....	1297
Step 1: Configuring PROFILE.TCPIP for LPD.....	1297
Step 2: Updating the LPD server cataloged procedure.....	1298
Step 3: Updating the LPD server configuration data set.....	1299
Step 4: Creating a banner page (optional).....	1299
Chapter 25. Remote procedure calls.....	1301
Steps for configuring the PORTMAP address space.....	1301
Step 1: Configuring PROFILE.TCPIP for PORTMAP.....	1301
Step 2: Configuring security server (or RACF equivalent) items.....	1302
Step 3: Updating the PORTMAP cataloged procedure.....	1302
Step 4: Defining the data set for well-known procedure names.....	1302
Starting the PORTMAP address space.....	1303
Steps for configuring the z/OS UNIX PORTMAP address space.....	1303
Step 1: Configuring PROFILE.TCPIP for UNIX PORTMAP.....	1303
Step 2: Updating the PORTMAP cataloged procedure.....	1304
Starting the PORTMAP address space.....	1304
Steps for configuring the rpcbind address space.....	1304
Step 1: Configuring the PROFILE.TCPIP data set for rpcbind.....	1305
Step 2: Configuring security server (or RACF equivalent) items.....	1305
Step 3: Updating the RPCBIND cataloged procedure.....	1306
Step 4: Updating the /etc/services file.....	1306
Step 5: Configure SYS1.PARMLIB for rpcbind.....	1306
Starting the rpcbind address space.....	1307
Steps for configuring the NCS interface.....	1308
Step 1: Configuring PROFILE.TCPIP for NCS.....	1309
Step 2: Updating the NRGLBD cataloged procedure.....	1309
Step 3: Updating the LLBD cataloged procedure.....	1309
Chapter 26. Mail on z/OS.....	1311
Configuring the CSSMTP application.....	1311
Terms and concepts.....	1312
Setting up CSSMTP.....	1314
Customizing the CSSMTP configuration file to try mail again.....	1317
Customizing the CSSMTP configuration file to handle undeliverable mail.....	1318
Steps for granting authority to start CSSMTP.....	1319
Security for CSSMTP.....	1320
Steps for using Transport Layer Security for CSSMTP.....	1321
Steps for CSSMTP AUTH configuration.....	1323
Steps for configuring SMF records for CSSMTP (optional).....	1325
Monitoring CSSMTP.....	1327
sendmail to CSSMTP bridge.....	1327
Setting up the sendmail bridge.....	1328
Steps for creating and customizing the configuration file.....	1328
Security considerations for the sendmail bridge.....	1329
Configuring popper.....	1329
Update the /etc/services file.....	1330
Update the /etc/inetd.conf file.....	1330
Create the directory for the temporary maildrop file.....	1330
Start inetd.....	1330
Correct connection.....	1330

Popper command - administering received mail.....	1331
Chapter 27. TIMED daemon.....	1333
Starting TIMED from the z/OS shell.....	1333
Starting TIMED as a procedure.....	1333
Chapter 28. SNTP daemon.....	1335
Steps for starting SNTPD from the z/OS UNIX shell.....	1335
Steps for starting SNTPD as a procedure.....	1336
Stack affinity.....	1337
Chapter 29. Remote Execution	1339
UNIX REXEC.....	1339
TSO REXEC.....	1339
Configuring the TSO Remote Execution server.....	1339
Step 1: Configuring PROFILE.TCPIP for TSO Remote Execution server.....	1340
Step 2: Determine whether Remote Execution client will send REXEC or RSH commands....	1340
Step 3: Permit remote users to access MVS resources (optional).....	1340
Step 4: Prevent potential wait state for special conditions.....	1341
Step 5: Update the TSO Remote Execution cataloged procedure.....	1342
Step 6: Create a user exit routine (optional).....	1342
Step 7: Permit access to JESSPOOL files.....	1343
Configuring the z/OS UNIX Remote Execution servers.....	1344
Files for z/OS UNIX REXECD.....	1344
Files for z/OS UNIX RSHD.....	1344
Considerations for Kerberos authentication.....	1345
Setting up the z/OS UNIX RSHD installation exit.....	1345
Configuring TSO and z/OS UNIX Remote Execution servers to use the same port.....	1345
Chapter 30. Express logon services with the Digital Certificate Access Server.....	1347
Express Logon Feature.....	1347
Web Express Logon.....	1347
Using the DCAS server interface for your logon solutions.....	1347
What DCAS provides.....	1347
Customizing DCAS for TLS/SSL.....	1348
Transport Layer Security (TLS) terms.....	1350
Chapter 31. Miscellaneous server.....	1353
Discard protocol.....	1353
Echo protocol.....	1353
Character generator protocol.....	1353
Configuring the MISC server.....	1354
Step 1: Configuring PROFILE.TCPIP for the MISC server.....	1354
Step 2: Updating the MISC server cataloged procedure.....	1354
Appendix A. Setting up the InetD configuration file.....	1357
Appendix B. TLS/SSL security.....	1359
Secure Socket Layer overview.....	1359
Server authentication	1359
Client authentication.....	1360
Encryption algorithms.....	1362
Enable CSFSERV resources.....	1362
Appendix C. Express Logon Feature.....	1365
Configuring RACF services for Express Logon.....	1366
An example of configuring the Express Logon components.....	1367

Configuring the Host On Demand Telnet client.....	1367
Configuring the z/OS TN3270E Telnet server (two-tier solution).....	1367
Configuring the middle-tier Telnet server (IBM Communications Server for Windows example).....	1368
Appendix D. Using HCD.....	1369
Appendix E. Steps for preparing to run IP security.....	1391
Step 1: Setting appropriate UNIX System Services parameters.....	1391
Step 2: Ensure the IKE daemon's user ID has enough system resources.....	1391
Virtual storage capacity.....	1391
System message queue capacity.....	1392
UDP queue capacity.....	1392
Step 3: Authorizing the IKE daemon to the external security manager.....	1392
Steps for authorizing the IKE daemon to RACF.....	1392
Step 4: Authorizing the ipsec command to the external security manager.....	1393
Steps for authorizing the ipsec command to RACF.....	1393
Step 5: Authorizing IP security to ICSF (optional).....	1394

About this document

This document contains guidance material to enable you to configure IP address spaces, servers, and applications for z/OS Communications Server. This volume is part of a two-volume set:

- [z/OS Communications Server: IP Configuration Guide](#), which contains concepts and guidance, explaining an overall approach to IP configuration.
- [z/OS Communications Server: IP Configuration Reference](#), which describes parameters, options, and syntax of statements.

The information in this document includes descriptions of support for both IPv4 and IPv6 networking protocols. Unless explicitly noted, descriptions of IP protocol support concern IPv4. IPv6 support is qualified within the text.

For detailed information about configuration-related data sets and statements, see [z/OS Communications Server: IP Configuration Reference](#).

For detailed information about commands used during configuration, see [z/OS Communications Server: IP System Administrator's Commands](#).

This document refers to Communications Server data sets by their default SMP/E distribution library name. Your installation might, however, have different names for these data sets where allowed by SMP/E, your installation personnel, or administration staff. For instance, this document refers to the *hlq*.SEZAINST samples data set simply as SEZAINST. Your installation might choose a data set name of SYS1.SEZAINST, CS390.SEZAINST, or other high level qualifiers for the data set name.

Who should read this document

This document is intended for programmers and system administrators who are familiar with TCP/IP, MVS, z/OS UNIX, and the Time Sharing Option Extensions (TSO/E).

How this document is organized

This document is divided into the following parts:

Part 1, “Base TCP/IP system,” on page 1 contains information on configuring the base TCP/IP stack.

Part 2, “Server applications,” on page 591 contains information that explains the server applications for z/OS Communications Server.

Appendix A, “Setting up the InetD configuration file,” on page 1357 and other appendixes in part 3 provide extra information for this document.

“Notices” on page 1461 contains notices and trademarks that are used in this document.

“Bibliography” on page 1465 contains descriptions of the documents in the z/OS Communications Server library.

How to use this document

Use this document to perform the following tasks:

- Configure z/OS Communications Server
- Customize and administer z/OS Communications Server

How to provide feedback to IBM

We welcome any feedback that you have, including comments on the clarity, accuracy, or completeness of the information. See, [How to send feedback to IBM®](#) for additional information.

Conventions and terminology that are used in this information

Commands in this information that can be used in both TSO and z/OS UNIX environments use the following conventions:

- When describing how to use the command in a TSO environment, the command is presented in uppercase (for example, NETSTAT).
- When describing how to use the command in a z/OS UNIX environment, the command is presented in bold lowercase (for example, **netstat**).
- When referring to the command in a general way in text, the command is presented with an initial capital letter (for example, Netstat).

All the exit routines described in this information are *installation-wide exit routines*. The installation-wide exit routines also called installation-wide exits, exit routines, and exits throughout this information.

The TPF logon manager, although included with VTAM®, is an application program; therefore, the logon manager is documented separately from VTAM.

Samples used in this information might not be updated for each release. Evaluate a sample carefully before applying it to your system.

z/OS no longer supports mounting HFS data sets (The POSIX style file system). Instead, a z/OS File System (zFS) can be implemented. The term hierarchical file system, abbreviated as HFS, is defined as a data structure that has a hierarchical nature with directories and files. References to hierarchical file systems or HFS might still be in use in z/OS Communications Server publications.

Network Express and Open Systems Adapter-Express (OSA-Express) terminology:

- The Network Express feature is introduced with the IBM z17 processor family. The Network Express feature is the next generation of Open Systems Adapter (OSA) technology. The term OSA (Open Systems Adapter) is carried forward with Network Express. The IBM z17 processor supports both the Network Express and the OSA-Express7S features. In this information, when a general reference is made to OSA that applies to all these features, then the term OSA is used, and the acronym will appear in italics. This formatting style and guideline for usage for the term OSA is used throughout this document. When a distinction is necessary, then the specific feature name is used such as the Network Express feature
- The Network Express feature is defined as channel (CHPID) type OSH (Open System Adapter for Hybrid networks) that might operate in either 10 GbE or 25 GbE link speed. When this term is used in this information, the processing being described applies to either link speed. If processing is applicable to only one link speed, the full terminology, for instance, IBM 25 GbE Network Express will be used.
- Network Express is defined with new system architecture called Enhanced Queued Direct I/O (EQDIO). In this information there are many references to QDIO or OSA/QDIO. When the reference applies to both QDIO and EQDIO the reference just indicates OSA. When the reference is specific to the QDIO or EQDIO architecture, then the specific architecture is referenced, for example, OSA/QDIO or OSA/EQDIO. Some OSA references also use or include the channel type for OSA such as OSD (QDIO). When the reference applies to both features, then the term OSA is used. When a distinction is necessary then the specific channel or architecture type is used, OSD/QDIO or OSH/EQDIO.

Shared Memory Communications over Remote Direct Memory Access (SMC-R) terminology

- *RoCE*, which is a generic term representing IBM® 10 GbE RoCE Express, IBM 10 GbE RoCE Express2, IBM 25 GbE RoCE Express2, IBM 10 GbE RoCE Express3, IBM 25 GbE RoCE Express3, IBM 10 GbE Network Express and IBM 25 GbE Network Express feature capabilities. When this term is used in this information, the processing being described applies to all of these features. If processing is applicable to only one feature, the full terminology, for instance, Network Express will be used.
- RoCE Express2, which is a generic term representing an IBM RoCE Express2 feature that might operate in either 10 GbE or 25 GbE link speed. When this term is used in this information, the processing being described applies to either link speed. If processing applies to only one link speed, the full terminology, for instance, IBM 25 GbE RoCE Express2 will be used.
- RoCE Express3, which is a generic term representing an IBM RoCE Express3 feature that might operate in either 10 GbE or 25 GbE link speed. When this term is used in this information, the processing being

described applies to either link speed. If processing applies to only one link speed, the full terminology, for instance, IBM 25 GbE RoCE Express3 will be used.

- Network Express, which is a generic term representing an Network Express feature that might operate in either 10 GbE or 25 GbE link speed. When this term is used in this information, the processing being described applies to either link speed. If processing is applicable to only one link speed, the full terminology, for instance, IBM 25 GbE Network Express will be used. When configured with a CHPID type of NETH, the Network Express feature may operate as an RDMA network interface card.
- RDMA network interface card (RNIC), which is used to refer to the IBM 10 GbE RoCE Express, IBM 10 GbE RoCE Express2, IBM 25 GbE RoCE Express2, IBM 10 GbE RoCE Express3, or IBM 25 GbE RoCE Express3, IBM 10 GbE Network Express or IBM 25 GbE Network Express feature.
- Shared RoCE environment, which means that the *ROCE* feature can be used concurrently, or shared, by multiple operating system instances. The feature is considered to operate in a shared RoCE environment even if you use it with a single operating system instance.

Clarification of notes

Information traditionally qualified as Notes is further qualified as follows:

Attention

Indicate the possibility of damage

Guideline

Customary way to perform a procedure

Note

Supplemental detail

Rule

Something you must do; limitations on your actions

Restriction

Indicates certain conditions are not supported; limitations on a product or facility

Requirement

Dependencies, prerequisites

Result

Indicates the outcome

Tip

Offers shortcuts or alternative ways of performing an action; a hint

How to read a syntax diagram

This syntax information applies to all commands and statements that do not have their own syntax described elsewhere.

The syntax diagram shows you how to specify a command so that the operating system can correctly interpret what you type. Read the syntax diagram from left to right and from top to bottom, following the horizontal line (the main path).

Symbols and punctuation

The following symbols are used in syntax diagrams:

Symbol

Description

Marks the beginning of the command syntax.

Indicates that the command syntax is continued.

|

Marks the beginning and end of a fragment or part of the command syntax.

➤

Marks the end of the command syntax.

You must include all punctuation such as colons, semicolons, commas, quotation marks, and minus signs that are shown in the syntax diagram.

Commands

Commands that can be used in both TSO and z/OS UNIX environments use the following conventions in syntax diagrams:

- When describing how to use the command in a TSO environment, the command is presented in uppercase (for example, NETSTAT).
- When describing how to use the command in a z/OS UNIX environment, the command is presented in bold lowercase (for example, netstat).

Parameters

The following types of parameters are used in syntax diagrams.

Required

Required parameters are displayed on the main path.

Optional

Optional parameters are displayed below the main path.

Default

Default parameters are displayed above the main path.

Parameters are classified as keywords or variables. For the TSO and MVS console commands, the keywords are not case sensitive. You can code them in uppercase or lowercase. If the keyword appears in the syntax diagram in both uppercase and lowercase, the uppercase portion is the abbreviation for the keyword (for example, OPERand).

For the z/OS UNIX commands, the keywords must be entered in the case indicated in the syntax diagram.

Variables are italicized, appear in lowercase letters, and represent names or values you supply. For example, a data set is a variable.

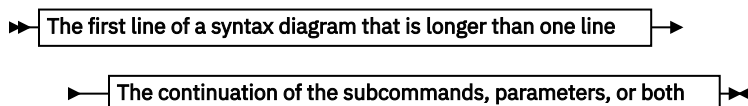

Syntax examples

In the following example, the P`U`t subcommand is a keyword. The required variable parameter is *local_file*, and the optional variable parameter is *foreign_file*. Replace the variable parameters with your own values.

Longer than one line

If a diagram is longer than one line, the first line ends with a single arrowhead and the second line begins with a single arrowhead.

Required operands

Required operands and values appear on the main path line. You must code required operands and values.

➤ REQUIRED_OPERAND ➤

Optional values

Optional operands and values appear below the main path line. You do not have to code optional operands and values.

Selecting more than one operand

An arrow returning to the left above a group of operands or values means more than one can be selected, or a single one can be repeated.

Nonalphanumeric characters

If a diagram shows a character that is not alphanumeric (such as parentheses, periods, commas, and equal signs), you must code the character as part of the syntax. In this example, you must code OPERAND=(001,0.001).

➤ OPERAND — = — (— 001 — , — 0.001 —) ➤

Blank spaces in syntax diagrams

If a diagram shows a blank space, you must code the blank space as part of the syntax. In this example, you must code OPERAND=(001 FIXED).

➤ OPERAND — = — (— 001 — — FIXED —) ➤

Default operands

Default operands and values appear above the main path line. TCP/IP uses the default if you omit the operand entirely.

Variables

A word in all lowercase italics is a *variable*. Where you see a variable in the syntax, you must replace it with one of its allowable names or values, as defined in the text.

➤ *variable* ➤

Syntax fragments

Some diagrams contain syntax fragments, which serve to break up diagrams that are too long, too complex, or too repetitious. Syntax fragment names are in mixed case and are shown in the diagram and in the heading of the fragment. The fragment is placed below the main diagram.

➤ Syntax fragment ➤

Syntax fragment

➤ 1ST_OPERAND — , — 2ND_OPERAND — , — 3RD_OPERAND ➤

Prerequisite and related information

z/OS Communications Server function is described in the z/OS Communications Server library. Descriptions of those documents are listed in “Bibliography” on page 1465, in the back of this document.

Required information

Before using this product, you should be familiar with TCP/IP, VTAM, MVS, and UNIX System Services.

Softcopy information

Softcopy publications are available in the following collection.

Titles	Description
<i>IBM Z Redbooks</i>	The IBM Z® subject areas range from e-business application development and enablement to hardware, networking, Linux®, solutions, security, parallel sysplex, and many others. For more information about the Redbooks® publications, see http://www.redbooks.ibm.com/ and http://www.ibm.com/systems/z/os/zos/zfavorites/ .

Other documents

This information explains how z/OS references information in other documents.

When possible, this information uses cross-document links that go directly to the topic in reference using shortened versions of the document title. For complete titles and order numbers of the documents for all products that are part of z/OS, see [z/OS Information Roadmap \(SA23-2299\)](#). The Roadmap describes what level of documents are supplied with each release of z/OS Communications Server, and also describes each z/OS publication.

To find the complete z/OS library, visit the [z/OS library](#) in [IBM Documentation](#) (<https://www.ibm.com/docs/en/zos>).

Relevant RFCs are listed in an appendix of the IP documents. Architectural specifications for the SNA protocol are listed in an appendix of the SNA documents.

The following table lists documents that might be helpful to readers.

Title	Number
<i>DNS and BIND</i> , Fifth Edition, O'Reilly Media, 2006	ISBN 13: 978-0596100575
<i>Routing in the Internet</i> , Second Edition, Christian Huitema (Prentice Hall 1999)	ISBN 13: 978-0130226471
<i>sendmail</i> , Fourth Edition, Bryan Costales, Claus Assmann, George Jansen, and Gregory Shapiro, O'Reilly Media, 2007	ISBN 13: 978-0596510299
<i>SNA Formats</i>	GA27-3136
<i>TCP/IP Illustrated, Volume 1: The Protocols</i> , W. Richard Stevens, Addison-Wesley Professional, 1994	ISBN 13: 978-0201633467
<i>TCP/IP Illustrated, Volume 2: The Implementation</i> , Gary R. Wright and W. Richard Stevens, Addison-Wesley Professional, 1995	ISBN 13: 978-0201633542
<i>TCP/IP Illustrated, Volume 3: TCP for Transactions, HTTP, NNTP, and the UNIX Domain Protocols</i> , W. Richard Stevens, Addison-Wesley Professional, 1996	ISBN 13: 978-0201634952

The z/OS Basic Skills Information Center

The z/OS Basic Skills Information Center is a web-based information resource intended to help users learn the basic concepts of z/OS, the operating system that runs most of the IBM mainframe computers in use today. The Information Center is designed to introduce a new generation of Information Technology professionals to basic concepts and help them prepare for a career as a z/OS professional, such as a z/OS systems programmer.

Specifically, the z/OS Basic Skills Information Center is intended to achieve the following objectives:

- Provide basic education and information about z/OS without charge
- Shorten the time it takes for people to become productive on the mainframe
- Make it easier for new people to learn z/OS

To access the z/OS Basic Skills Information Center, open your web browser to the following website, which is available to all users (no login required): <https://www.ibm.com/support/knowledgecenter/zosbasics/com.ibm.zos.zbasics/homepage.html?cp=zosbasics>

Summary of changes for IP Configuration Guide

This document contains terminology, maintenance, and editorial changes, including changes to improve consistency and retrievability. Technical changes or additions to the text and illustrations for the current edition are indicated by a vertical line to the left of the change.

Summary of changes for z/OS 3.2

The following content is new, changed, or no longer included in z/OS 3.2.

New

The following content is new.

September 2025 release

None

Changed

The following content is changed.

September 2025 release

Updated TLS changes in:

- [“TLS-enabled FTP” on page 181](#)
- [“Steps for customizing the FTP client for TLS” on page 720](#)
- [“Steps for migrating the FTP client to use AT-TLS” on page 728](#)
- [“Add TLS/SSL to Policy Agent connections” on page 847](#)
- [“Protocol versions” on page 1163](#)

Updates for Network Express

- [“Connectivity and gateway functions” on page 5](#)
- [“Setting up TCP/IP operating characteristics in PROFILE.TCPIP” on page 266](#)
- [“Setting up physical characteristics in PROFILE.TCPIP” on page 278](#)
- [“QDIO Accelerator” on page 513](#)
- [“Inbound workload queueing” on page 513](#)
- [“Rendezvous processing” on page 535](#)

Deleted

The following content is deleted.

September 2025 release

- Considerations for Common Information Model providers
- CIM provider access control

Changes made in z/OS Communications Server 3.1

The following content is new, changed, or no longer included in z/OS 3.1.

New information

June 2025 refresh

- z/OS Communications Server support for the IBM Network Express feature. See the following topics for more information:
 - [“Considerations for networking hardware attachment” on page 58](#)
 - [“Network Express feature in EQDIO mode” on page 82](#)
 - [“Network Express Auto-Migrate function” on page 91](#)
 - [“Steps for capturing the results of an EQENET INTERFACE statement created with Auto-Migrate” on page 92](#)
 - [“OSA VLAN” on page 59](#)
 - [“OSA Terminology” on page 58](#)
 - [“OSA Inbound Routing” on page 60](#)
 - [“Network Express virtual MAC routing” on page 61](#)
 - [“VLAN configuration considerations” on page 65](#)
 - [“OSA internal routing for a shared OSA physical port” on page 72](#)
 - [“ARP offload and VIPA ARP processing” on page 73](#)
 - [“Checksum offload” on page 73](#)
 - [“TCP segmentation offload” on page 73](#)
 - [“Inbound workload queuing” on page 75](#)
 - [“Dynamic LAN idle timer” on page 74](#)
 - [“OSA-Express optimized latency mode” on page 74](#)
 - [“Steps for enabling OSA-Express QDIO inbound workload queuing” on page 78](#)
 - [“Fixed storage considerations for Network Express interfaces ” on page 78](#)
 - [“Fixed storage considerations for OSA-Express 25 GBe interfaces ” on page 80](#)
 - [“Mixing OSA types - configuration recommendation” on page 81](#)
 - [“Displaying OSA interface information” on page 82](#)
 - [“Network Express RoCE Support” on page 129](#)
 - [“Sharing Network Express features” on page 534](#)
 - [“System requirements for SMC-R using Network Express on IBM z17 or later environment ” on page 558](#)
 - [“Network Express and RoCEv2 device association and physical connectivity” on page 574](#)

March 2025 refresh

- Added SMTP AUTH. For more information, see [“Terms and concepts” on page 1312](#).
- Added Steps for CSSMTP AUTH configuration. For more information, see [“Steps for CSSMTP AUTH configuration” on page 1323](#). This function is available with APAR PH61015 on z/OS 3.1 and V2R5.

February 2025 refresh

- Added steps for granting authority to start DMD. For more information, see [“Steps for granting authority to start DMD” on page 1146](#). This also applies to z/OS 2.4 and 2.5.

March 2024 refresh

- Network support for IBM z/OS Container Platform, see the following topic:
 - [“IPv4 and IPv6 search order for IBM z/OS Container Platform environments” on page 807](#)

September 2023 release

- AT-TLS currency with System SSL, see the following topic:

- [“Validating a host name against a certificate” on page 1164](#)
- AT-TLS support for x25519 and x448 key exchange for TLSv1.2, see the following topic:
 - [“Limiting Key Exchange Elliptic Curves for TLSv1.0, TLSv1.1, and TLSv1.2” on page 1162](#)
- FTP server JES access control , see [“\(Optional\) Steps for controlling user access to FTP JES mode” on page 695.](#)
- z/OS UNIX syslogd support for secure logging over TCP, see the following topics:
 - [“Considerations when receiving messages using TCP” on page 253](#)
 - [“Configuring the z/OS syslogd to send messages to a remote syslogd” on page 255](#)
 - [“Interactions between syslogd and other components during IPL” on page 256](#)

Changed information

June 2025 refresh

- zERT monitoring enhancements, see the following topics:
 - Updated [“How does zERT discovery provide the information?” on page 186](#)
 - Updated [“How does zERT aggregation provide the information?” on page 191](#)
 - Updated [“How does zERT enforcement work?” on page 194](#)
- z/OS Communications Server support for the IBM Network Express feature. See the following topics:
 - Updated EZAZCX and EZ6ZCX section. For more information, see [“Connectivity and gateway functions” on page 5](#)
 - Updated Shared Memory Communication Terms. For more information, see [“Shared Memory Communications terms” on page 543](#)
 - Updated SMC-D details. For more information, see [“Rendezvous processing” on page 535](#)
 - Updated Procedure to configure SMC-D . For more information, see [“Configuring Shared Memory Communications - Direct Memory Access” on page 562](#)
 - Updated Netstat DEvlinks/-d report details. For more information, see [“Displaying SMC information” on page 585](#)
 - Updated figure. For more information, see [Appendix C, “Express Logon Feature,” on page 1365](#)

March 2025 refresh

- Updated Step 3 in Before you begin section. For more information, see [“Steps for CSSMTP AUTH configuration” on page 1323.](#)

March 2024 refresh

- Network support for IBM z/OS Container Platform, see the following topics:
 - [“TCPIP.DATA search order” on page 24](#)
 - [“Use of TCPIP.DATA and /etc/resolv.conf” on page 263](#)
 - [“Configuring the local host table \(optional\)” on page 291](#)

Part 1. Base TCP/IP system

Chapter 1. Overview of z/OS Communications Server

z/OS Communications Server provides a set of communications protocols that support peer-to-peer connectivity functions for both local and wide-area networks, including the most popular wide-area network, the Internet. z/OS Communications Server also provides performance enhancements that can benefit a variety of TCP/IP applications.

z/OS Communications Server provides both SNA and TCP/IP protocols for z/OS. The SNA protocols are provided by VTAM and include Subarea, Advanced Peer-to-Peer Networking, and High Performance Routing protocols. For more information about z/OS Communications Server SNA protocols, see [z/OS Communications Server: SNA Network Implementation Guide](#).

Figure 1 on page 4 shows the z/OS Communications Server TCP/IP protocol suite (also called stack), whose functions include associated applications, transport- and network-protocol layers, and connectivity and gateway functions. z/OS Communications Server contains IPv6 support. See [z/OS Communications Server: IPv6 Network and Appl Design Guide](#) for more detailed information.

The z/OS Communications Server protocol suite supports two TCP/IP environments:

- A native MVS environment in which users can exploit the popular TCP/IP protocols in MVS application environments such as batch jobs, started tasks, TSO, CICS® applications, and IMS applications.
- A z/OS UNIX System Services environment that lets you create and use applications that conform to the POSIX or XPG4 standard (a UNIX specification).

Note: z/OS Communications Server exploits z/OS UNIX services even for traditional MVS environments and applications. Prior to using TCP/IP services, therefore, a full-function mode z/OS UNIX environment—including a Data Facility Storage Management Subsystem (DFSMSdfp), a z/OS UNIX file system, and a security product (such as Resource Access Control Facility, or RACF®)—needs to be defined and active before z/OS Communications Server can be started successfully.

z/OS Communications Server

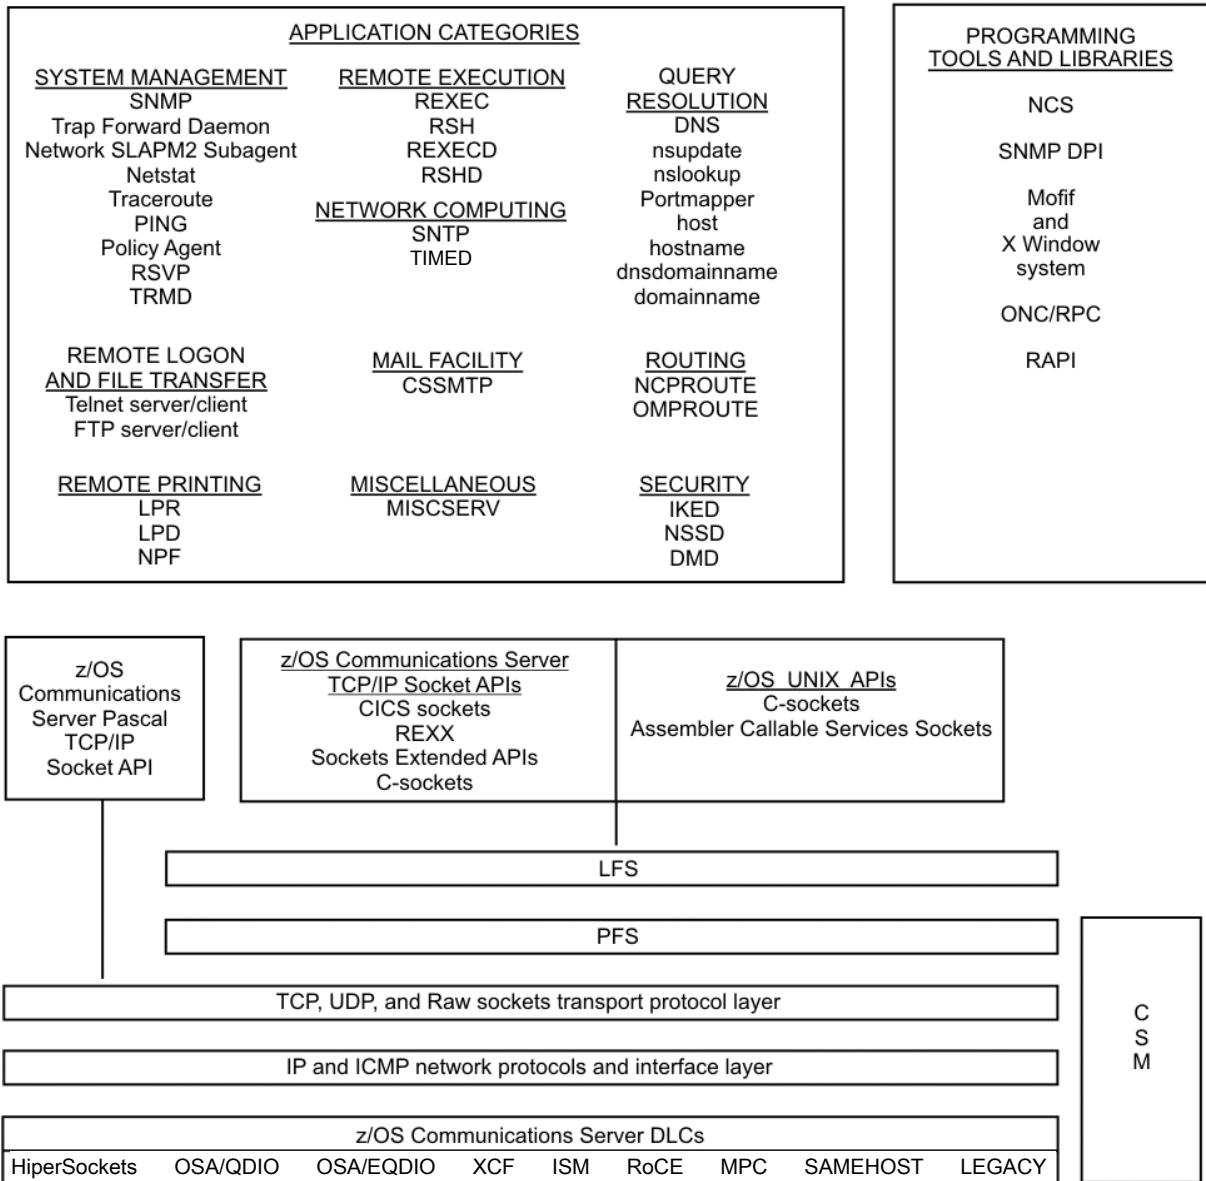

Figure 1. z/OS Communications Server TCP/IP protocol suite

The application categories in [Figure 1 on page 4](#) do not list every application of the TCP/IP protocol suite. z/OS Communications Server TCP/IP protocol-suite functions include the following categories:

- [“TCP/IP protocol stack” on page 5](#)
- [“Connectivity and gateway functions” on page 5](#)
- [“Network protocol layer” on page 7](#)
- [“Transport layer” on page 7](#)
- [“File systems” on page 7](#)
- [“Application Programming Interfaces” on page 8](#)

TCP/IP protocol stack

The Transmission Control Protocol (TCP) and the Internet Protocol (IP) refer to a non-proprietary protocol suite that enables different packet-switched networks to function as a single entity regardless of underlying network topology.

z/OS Communications Server provides robustness and high performance with the following features:

- A fully multiprocessor capable stack
- Exploitation of MVS Reliability, Availability, and Serviceability (RAS) services
- Exploitation of the z/OS architecture to optimize performance, CPU usage, and throughput
- Exploitation of the z/OS Sysplex functions to maximize availability and scalability of TCP/IP workloads

In addition, z/OS Communications Server design includes a tightly integrated storage and I/O model. I/O is provided by multipath channel (MPC) for network communication; storage management is provided by Communications Storage Manager (CSM).

Multipath channel I/O process

The term multipath channel (MPC) describes all z/OS Communications Server I/O driver support. There are specific I/O drivers under this support that are also referred to as MPC (such as MPCPTP).

MPC is a component of the I/O process model. MPC handles protocol headers and data separately and executes multiple I/O dispatchable units of work. MPC provides support for all devices supported by z/OS Communications Server. The MPC I/O process and the CSM facilities that TCP/IP exploits are part of the VTAM component of z/OS Communications Server. As a result, VTAM must be configured and active when starting devices on the TCP/IP stack.

Communications Storage Manager

The Communications Storage Manager (CSM) facility is used by authorized programs to manage subsystem storage pools. CSM reduces data moves by providing a flat storage model that is accessible at multiple layers of the process model and across MVS address space boundaries. In addition, CSM provides the following technical advantages:

- MVS cellpool-like services
- Automatic handling of the contraction and expansion of storage resources
- Handling of different types and sizes of storage requests (for example, pageable and fixed)

Connectivity and gateway functions

TCP/IP connectivity and gateway functions handle the physical interfaces and the routing of IP data packets called datagrams. The following communication interfaces are supported by z/OS Communications Server:

Network Express

The Network Express function provides access to Ethernet for:

- IP connectivity using the Enhanced Queue Direct I/O (EQDIO) architecture. IPv6 is supported on all Ethernet features in the EQDIO mode.

- Remote Direct Memory Access (RDMA) for protocols such as Shared Memory Communications over RDMA (SMC-R).

OSA-Express

OSA-Express provides IP connectivity using the Queue Direct I/O (QDIO) architecture. IPv6 is supported on all Ethernet features in the QDIO mode.

CTC

Provides access to TCP/IP hosts by way of a channel-to-channel (CTC) connection established over a System z® ESCON channel.

MPCIPA

Provides access to:

- TCP/IP hosts that use:
 - OSA Express features
 - HiperSockets: Uses the Internal Queued Direct I/O (iQDIO). HiperSockets provides high-speed, low-latency IP message passing between logical partitions (LPARs) within a single IBM eServer zSeries or later server.
- An ensemble that uses:
 - OSA-Express3 or later feature configured as CHPID type OSX
 - OSA-Express3 or later feature configured as CHPID type OSM

MPCPTP

Provides access to TCP/IP hosts through multipath channel point-to-point (MPCPTP) links. MPCPTP supports IPv4 and IPv6 protocols. MPCPTP can be used in two ways to provide direct connectivity to other mainframe hosts running z/OS Communications Server:

- By using a set of two or more System z channels
- By configuring to use XCF services, if the System z hosts are part of the same sysplex

MPCPTP can also be used to provide the following connectivity options:

- Direct communication between two z/OS Communications Server TCP/IP Services protocol stacks running on the same MVS host without requiring any network attachments
- Connectivity to network attachments such as the IBM 2216 Multiaccess Controller Model 400 or the IBM RS/6000

EZAZCX and EZ6ZCX

The EZAZCX (IPv4) and EZ6ZCX (IPv6) interfaces provide direct communications between the z/OS Communications Server TCP/IP protocol stack and instances of virtual servers executing in the IBM z/OS Container Extensions (zCX) address spaces. The interfaces are dynamically created for IPv4 using DYNAMICXCF or static DEVICE/LINK/HOME, and IPv6 by using INTERFACE VIRTUAL6 for IUTSAMEH, both with at least one VIPARANGE ZCX configured, and connected to the dynamically created VTAM TRLE called IUTZCX4n (IPv4) or IUTZCX6n (IPv6). The last character 'n' represents the instance of the zCX DLC created, where a unique instance of the zCX DLC is created for each TCP/IP stack providing services for zCX workloads.

For information on these interface creation methods and how they support zCX workloads, including VIPARANGE configuration and virtual interface binding, refer to [“IBM z/OS Container Extensions network overview” on page 132.](#)

IBM 10 GbE RoCE Express, RoCE Express2, and RoCE Express3 feature

Enables the use of Remote Direct Memory Access (RDMA) processing by using Shared Memory Communications over RDMA (SMC-R) protocols.

The VTAM component of z/OS Communications Server provides the I/O support for each of these communication interfaces, and requires the creation (dynamically or through definition) of Transport Resource List entries (TRLEs) to represent each interface.

- TRLEs must be defined for the following communication interfaces:

- MPCIPA devices not connected to an ensemble
- MPCPTP

For information about Transport resource list major node, see [z/OS Communications Server: SNA Resource Definition Reference](#).

- For all other communication interfaces, VTAM dynamically creates TRLEs. For information about Resources automatically activated by VTAM, see [z/OS Communications Server: SNA Network Implementation Guide](#).

Network protocol layer

The network protocol layer provides the support for the IP protocol. All TCP and User Datagram Protocol (UDP) data goes through the IP layer when entering and leaving the host. TCP and UDP will use the IPv4 routing layer or the IPv6 routing layer.

The network layer also provides support for the Internet Control Message Protocol (ICMP) and ICMPv6. This is used by the IP layer to exchange information and error messages with IP layers on other hosts and routers. ICMP is used for the IPv4 protocol and ICMPv6 is used for the IPv6 protocol.

Transport layer

The transport layer provides the support for the TCP, UDP, and RAW protocols. All three protocols use IPv4 or IPv6 as the network layer. The TCP protocol provides a connection-oriented, reliable transport layer, whereas UDP provides a simpler, connectionless and unreliable transport layer. The RAW transport layer provides for a more direct interface to the IP layer, which is primarily used by system-management type applications.

File systems

The file system layer provides the main interface between the application programming interfaces (APIs) and the transport layers. The first component of the file system layer is the z/OS UNIX logical file system (LFS). The LFS provides the API layer with a common interface to access files and sockets. In a POSIX-compliant environment, applications can access both files and sockets in a similar fashion. For example, both files and sockets are represented by a 32-bit integer referred to as a descriptor. Common functions can be used to access both file and socket resources.

The layer beneath the LFS is the physical file system (PFS). The PFS layer is where the distinction between files, sockets, and other resources is made. Based on the resource type, the LFS passes the incoming function requests to the appropriate PFS, which handles requests related to resources in the z/OS UNIX file system. For more information about these [FILESYSTYPE](#), see [z/OS UNIX System Services Planning](#).

From a TCP/IP perspective, the AF_INET and the AF_INET6 PFS are of main interest. TCP/IP is enabled for IPv6 by defining an AF_INET6 PFS. Defining the file systems is the responsibility of the installation's z/OS UNIX programmer. The definitions are found in the BPXPRMxx member of SYS1.PARMLIB.

For information about defining AF_INET and AF_INET6 physical file systems, and about customizing BPXPRMxx for INET and CINET systems, see [z/OS UNIX System Services Planning](#).

The AF_INET and the AF_INET6 PFS can be configured in two ways:

Integrated sockets PFS

The integrated sockets PFS can support the AF_INET PFS alone or AF_INET and AF_INET6 PFS together, but not AF_INET6 PFS alone.

Common INET PFS

This configuration is commonly referred to as the C_INET PFS configuration. It enables multiple AF_INET and AF_INET6 transport providers to be configured and active concurrently. Applications using the z/OS UNIX APIs do not know that multiple transport providers exist. For example, multiple TCP/IP Services components of z/OS Communications Server can be configured at the same time.

The C_INET PFS is responsible for selecting the PFS over which to flow the request, based on the IP routing information from each of the AF_INET providers.

Under this configuration, it is also possible for TCP/IP application servers using the z/OS UNIX socket APIs to field incoming client requests from all AF_INET transport providers without knowing the particular transport provider.

Application Programming Interfaces

This information provides a short description of each of the application programming interfaces (APIs) that can be used to interface with the TCP/IP Services protocol stack provided by z/OS Communications Server. All of the APIs, with the exception of the PASCAL API, interface with the LFS layer.

The APIs are divided into the following two categories:

- TCP/IP socket APIs provided by z/OS Communications Server
- z/OS UNIX APIs

TCP/IP socket APIs provided by z/OS Communications Server

z/OS Communications Server provides several APIs to access TCP/IP sockets. These APIs can be used in either or both integrated and common INET PFS configurations. In a common INET PFS configuration, however, they function differently from z/OS UNIX APIs. In this type of configuration, the z/OS Communications Server APIs always bind to a single PFS transport provider, and the transport provider must be the TCP/IP stack provided by z/OS Communications Server.

The following TCP/IP socket APIs are included in z/OS Communications Server:

Pascal API

The Pascal application programming interface enables you to develop TCP/IP applications in Pascal language. Supported environments are normal MVS address spaces. The Pascal programming interface is based on Pascal procedures and functions that implement conceptually the same functions as the C socket interface. The Pascal routines, however, have different names than the C socket calls. Unlike the other APIs, the Pascal API does not interface directly with the LFS. It uses an internal interface to communicate with the TCP/IP protocol stack.

Pascal API supports only AF_INET.

CICS sockets

The CICS socket interface enables you to write CICS applications that act as clients or servers in a TCP/IP-based network. Applications can be written in C language, using the C sockets programming, or they can be written in COBOL, PL/I or assembly language, using the Sockets Extended programming interface.

CICS sockets support AF_INET and AF_INET6.

C sockets

The C sockets interface supports socket function calls that can be invoked from C programs. However, note that for C application development, IBM recommends the use of the UNIX C sockets interface. These programs can be ported between MVS and most UNIX environments relatively easily if the program does not use any other MVS specific services.

C sockets support only AF_INET.

IMS sockets

The Information Management System (IMS) IPv4 socket interface supports client/server applications in which one part of the application executes on a TCP/IP-connected host and the other part executes as an IMS application program.

IMS sockets support AF_INET and AF_INET6.

Sockets Extended macro API

The Sockets Extended macro API is a generalized assembler macro-based interface to sockets programming. It includes extensions to the socket programming interface, such as support for asynchronous processing on most sockets function calls.

The Sockets Extended macro API supports AF_INET and AF_INET6.

Sockets Extended Call Instruction API

The Sockets Extended Call Instruction API is a generalized call-based, high-level language interface to sockets programming. The functions implemented in this call interface resemble the C-sockets implementation, with some extensions similar to the sockets extended macro interface.

The Sockets Extended Call Instruction API supports AF_INET and AF_INET6.

REXX sockets

The REXX sockets programming interface implements facilities for socket communication directly from REXX programs by using an address rxsocket function. REXX socket programs can execute in TSO, online, or batch.

The REXX sockets programming interface supports AF_INET and AF_INET6.

See [z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference](#) for complete documentation of the TCP/IP Services APIs.

z/OS UNIX APIs

The following APIs are provided by the z/OS UNIX element of z/OS and are supported by the TCP/IP stack in z/OS Communications Server:

z/OS UNIX sockets

A set of C language functions provides support for the z/OS UNIX sockets, which are used in the z/OS UNIX environment. Programmers use this API to create applications that conform to the POSIX or XPG4 standard (a UNIX specification). Applications built with z/OS UNIX sockets can be ported to and from platforms that support these standards.

The z/OS UNIX sockets support AF_INET and AF_INET6.

z/OS UNIX assembler callable services

z/OS UNIX assembler callable services is a generalized call-based, high-level language interface to z/OS UNIX sockets programming. The functions implemented in this call interface resemble the z/OS UNIX C sockets implementation, with some extensions similar to the sockets extended macro interface.

The z/OS UNIX assembler callable services support AF_INET and AF_INET6.

For complete documentation of z/OS UNIX sockets, see [z/OS C/C++ Runtime Library Reference](#). For information about z/OS UNIX callable services, see [z/OS UNIX System Services Programming: Assembler Callable Services Reference](#).

Chapter 2. IP configuration overview

The objective of this topic is to help you be better prepared for installation related activities. It is important to understand the terms, relationships, and dependencies presented in this topic as a prerequisite to installation and customization. For additional background information on TCP/IP, see *TCP/IP Tutorial and Technical Overview*, GG24-3376, ISBN 0738421650.

IPv6 support

In this information, there might be no statement of support for a particular function in an IPv6 network. To determine whether a given function is applicable to IPv6, see the [IPv6 support tables](#) in [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

z/OS UNIX System Services concepts

An organization named X/Open documents standards of what to implement for UNIX interfaces in a series of guides that are published as the X/Open Portability Guides (XPG). X/Open owns the term UNIX and certifies different implementations of UNIX according to the UNIX definitions contained in XPG 4.2. z/OS UNIX System Services, or z/OS UNIX, is a certified UNIX system as defined by X/Open in XPG 4.2. z/OS UNIX coexists with traditional MVS functions and traditional MVS data set types such as partitioned data sets and sequential data sets. It enables access to z/OS UNIX files and utilities concurrently by using application programming interfaces (APIs) and the interactive shell environment. Two variants of the z/OS UNIX shell environment are available:

- The z/OS UNIX shell, much like a native UNIX environment
- The ISPF shell, an interface with access to menu-driven command interfaces

With the APIs, programs can run in any environment including batch jobs, in jobs submitted by TSO/E interactive users, and in most other started tasks, or in any other MVS application task environment. The programs can request:

- Only MVS services
- Only z/OS UNIX services
- Both MVS and z/OS UNIX services

The shell interface is an execution environment analogous to TSO/E, with a programming language of shell commands analogous to Restructured eXtended eXecutor (REXX) language. The shell support consists of:

- Programs that are run interactively by shell users
- Shell commands and scripts that are run interactively by shell users
- Shell commands and scripts that are run as batch jobs

Prior to OS/390® V2R5, OS/390 UNIX required APPC/MVS for programs issuing the `fork()` or `spawn()` function. APPC/MVS is no longer required for this purpose. Forked and spawned address spaces are implemented in z/OS for UNIX processing by the Work Load Manager (WLM) component of MVS.

- For a `fork()`, the system copies one process, called the parent process, into a new process, called the child process, and places the child process in a new address space, the forked address space.
- `Spawn()` also starts a new process in a new address space. Unlike a `fork()`, in a `spawn()` call the parent process specifies a name of a program to start the child process.

The types of processes can be:

- User processes, which are associated with a user
- Daemon processes, which perform continuous or periodic functions, such as a web server

Daemons are programs that are typically started when the operating system is initialized and remain active to perform standard services. Some programs that initialize processes for users are considered daemons, even though these daemons are not long-running processes. Examples of daemons provided by z/OS UNIX are cron, which starts applications at specific times, and inetd, which starts applications on demand.

A user or daemon process can have one or more threads. A thread is a single flow of control within a process. Application programmers create multiple threads to structure an application in independent sections that can run in parallel for more efficient use of system resources.

Overview of data sets and UNIX files

Data set and *file* are comparable terms. If you are familiar with MVS, you probably use the term *Data set* to describe a unit of data storage. If you are familiar with AIX® or UNIX, you probably use the term *file* to describe a named set of records stored or processed as a unit. In the TCP/IP environment, in addition to the traditional MVS data set organizations (such as sequential and partitioned), UNIX files are arranged in a hierarchical directory structure.

Some MVS data sets and UNIX files have special importance because of their function. For example, certain data sets and files are used when configuring the TCP/IP environment. Other data sets are used by the Telnet server when performing specific communication functions. For descriptions of the MVS data sets and UNIX files necessary for configuring the TCP/IP environment and the search orders used to find them, see [Table 1 on page 15](#). A search order can include both MVS data sets and UNIX files, and these MVS data sets and UNIX files are collectively referred to as the *configuration files* in this information.

Note: Not all applications support UNIX files.

Hierarchical file system concepts

A hierarchical file system consists of:

- *Files*, which contain data or programs. A file containing a program object, shell script, or REXX program is called an *executable file*. Files are kept in directories.
- *Directories* that contain files, other directories, or both. Directories are arranged hierarchically, in a structure that resembles an upside down tree, with root directory at the top and the branches at the bottom. The *root* is the first directory for the file system at the peak of the tree and is designated by a slash (/).
- Named pipes, links, and other UNIX items, such as character special files like /dev/console that are used by applications like syslogd. See [z/OS UNIX System Services Planning](#) for more information about UNIX items like character special files.

The term *file system* has all of the following meanings:

- A logical collection of files, directories, named pipes, links, and other UNIX items and metadata that are arranged in a hierarchy.
- A particular instance of a logical collection of these items that are arranged in a hierarchy. They might be on local or remote disks or in computer memory.
- A program that is designed to provide the functions and data of one type of file system.

The context indicates which meaning is intended. Often more than one meaning is intended; this is an industry convention.

To the z/OS system, the file hierarchy is a collection of file systems. Additional instances of local or remote file systems might be mounted (logically connected) on directories of the root file system or of additional file systems.

Several types of file systems are supported by z/OS, including the following file systems:

- ZFS (z/OS File System)

Each instance of z/OS File System is in a linear data set.

- TFS (temporary file system)

Each instance of TFS is in computer memory.

- NFS (Network File System)

NFS server provides access to file systems that are on other computers.

For most application programs, these types of file systems are interchangeable. The root file system is the first file system that is mounted. Subsequent file systems can be logically mounted on a directory within the root file system or on a directory within any mounted file system.

References to installation data sets

This information refers to Communications Server installation data sets by their default SMP/E distribution library name. Your installation might, however, have different names for these data sets where allowed by SMP/E, your installation personnel, or administration staff. For instance, this information refers to sample members of the *hlq*.SEZAINST library as SEZAINST(*member*), where the *hlq* value is the high-level qualifier specified during TCP/IP installation. Your installation can choose a data set name of SYS1.SEZAINST, CS390.SEZAINST, or other high level qualifiers for the data set name.

Understanding search orders of configuration information

It is important to understand the search order for configuration files used by TCP/IP functions, and when you can override the default search order with environment variables, JCL, or other variables you provide. This knowledge allows you to accommodate your local data set and file naming standards, and it is helpful to know the configuration data set or file in use when diagnosing problems.

It is important to note that the z/OS Communications Server environment consists of the TCP/IP address space, z/OS Communications Server applications, and the TCP/IP MVS applications. The TCP/IP address space functions are also referred to as the *stack*. The z/OS Communications Server applications refer to those applications using the z/OS UNIX socket API. The TCP/IP MVS applications refer to those applications written to the MVS APIs (for example, C, Sockets-Extended, CICS, IMS, and REXX). The TCP/IP stack and both sets of applications have some common (or global) configuration files, but they also use configuration files that are different.

Another important point to note is that when a search order is applied for any configuration file, the search ends with the first file found. Therefore, unexpected results are possible if you place configuration information in a file that never gets found, either because other files exist earlier in the search order, or because the file is not included in the search order chosen by the application.

Configuration data set naming conventions

When searching for configuration files, you can explicitly tell TCP/IP where most configuration files are by using DD statements in the JCL procedures or by setting environment variables. Otherwise, you can let TCP/IP dynamically determine the location of the configuration files, based on search orders shown in [Table 1 on page 15](#).

For example, in [Table 1 on page 15](#), for the FTP server application, if the installation did not code the //SYSFTPD DD statement, the FTP server would search for *jobname*.FTP.DATA, then file */etc/ftp.data*, then data set SYS1.TCPPARMS(FTPDATA), and finally *hlq*.FTP.DATA.

Dynamic data set allocation

TCP/IP makes extensive use of dynamically allocated data sets using the MVS dynamic data set allocation function to search for configuration files. Multiple versions of a configuration data set can exist, each having a different high-level qualifier or middle-level qualifier. The search order for any configuration file will determine which data set is found and used.

High-level qualifier

High-level qualifiers (HLQ) permit you to associate an application's configuration data set with a particular job name or TSO user ID, or permit you to use a default configuration data set for the application. The possible high-level qualifiers are:

- *userid*

userid is the TSO user ID which invoked the application.

- *jobname*

Jobname is the application's batch JCL job name or the name of the application's started procedure.

- *hlq*

TCP/IP is distributed with a default high-level qualifier of TCPIP. To override the default HLQ used by dynamic data set allocation, specify the DATASETPREFIX statement in the TCPIP.DATA configuration file. For most configuration files, the DATASETPREFIX value is used as the high-level qualifier of the data set name in the last step in the search order. Note that the DATASETPREFIX value is not used as the high-level qualifier of the data set name used as the last step in the search order for the TCPIP.DATA configuration file.

Middle-level qualifiers

Multiple middle-level qualifiers (MLQ) permit the isolation of certain profile and translation table data sets. Two of the possible middle-level qualifiers are:

- Node name

Node name is an MLQ used in the search order for finding the configuration file PROFILE.TCPIP. Node name is determined by the parameters specified during VMCF initialization. For further information on initializing VMCF, see *z/OS Program Directory*.

- Function name

The TCP/IP implementation of multicultural support and double-byte character set (DBCS) support requires the use of multiple translation tables. To facilitate the concurrent use of multiple languages and code pages, TCP/IP uses a middle-level qualifier to designate which server or client uses a particular translation table. STANDARD, the default MLQ, is available for use if a single translation table can be used by multiple servers or clients. The TCP/IP Telnet client and FTP provide a TRANSLATE parameter that permits you to specify your chosen MLQ to replace the function name for that invocation of the command. For example, SRVRFTP is used as an MLQ by the File Transfer Protocol server.

The following data sets are some of the data sets that are only dynamically allocated by TCP/IP in a configuration file search order (you cannot specify them with DD statements in JCL):

ETC.PROTO	ETC.RPC
HOSTS.ADDRINFO	HOSTS.SITEINFO
SRVRFTP.TCPCHBIN	SRVRFTP.TCPHGBIN
SRVRFTP.TCPKJBIN	SRVRFTP.TCPSCBIN
SRVRFTP.TCPXLBIN	STANDARD.TCPCHBIN
STANDARD.TCPHGBIN	STANDARD.TCPKJBIN
STANDARD.TCPSCBIN	STANDARD.TCPXLBIN

For each of these data sets, the fully qualified name is established by using one of the following values as the data set HLQ:

- User ID or job name
- DATASETPREFIX value

Naming conventions for dynamically allocated data sets

A data set that you allocate explicitly (with a DD statement in JCL) can have any valid MVS data set name or z/OS UNIX file name. A data set that you create for the purpose of being allocated dynamically by TCP/IP must use the following naming conventions.

Note: In these examples, xxxx indicates an appropriate high-level qualifier, yyyy indicates an appropriate middle-level qualifier, and zzzz indicates an appropriate low-level qualifier.

- *userid.yyyy.zzzz*

userid is the user ID of the logged on TSO user.

- *TSOprefix.yyyy.zzzz*

TSOprefix is the data set prefix established by the TSO PROFILE command. *userid* is the default value of *TSOprefix*.

- *jobname.yyyy.zzzz*

jobname is the job name specified on the JOB statement for a job stream or the procedure name for a started procedure.

- *hlq.yyyy.zzzz*

hlq is the TCP/IP HLQ distributed as the system default, which can be overridden by the value in the DATASETPREFIX statement.

- *xxxx.nodename.zzzz*

nodename is an MLQ that is used to define the data set name for the TCP/IP stack profile data set.

- *xxxx.function_name.zzzz*

function_name denotes an acronym specifying a particular TCP/IP server (for example SRVRFTP for the FTP server) and is used as an MLQ for the translation table data set for that application.

- *xxxx.private_name.zzzz*

private_name is a user-specified private qualifier that can be specified as an option on some TCP/IP commands.

- SYS1.TCPPARMS(TCPDATA)

The member of a system data set used to find the *configuration file* TCPIP.DATA.

TCP/IP configuration data sets

Table 1 on page 15 lists the configuration MVS data sets and z/OS UNIX files used by the TCP/IP servers and functions. The table includes the name of the sample data set or file that is provided by Communications Server, and the way the data set or file is used.

Table 1. TCP/IP configuration data sets		
Name (search order)	Copied from	Usage
ADNR.CONF The MVS data set or z/OS UNIX file specified on the CONFIG DD statement in the automated domain name registration started procedure	SEZAINST(ADNRCNF)	Contains automated domain name registration configuration statements.
CSSMTP.CONF 1. The MVS data set or z/OS UNIX file referenced by the CONFIG DD statement in the CSSMTP application started procedure 2. <i>jobname.CSSMTP.CONF</i>	SEZAINST(CSSMTPCF)	Contains CSSMTP application configuration statements.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
Defense Manager daemon (DMD) configuration 1. The MVS data set or z/OS UNIX file specified by the DMD_FILE environment variable 2. /etc/security/dmd.conf	/usr/lpp/tcpip/samples/dmd.conf	Contains DMD configuration statements.
Digital certificate access server (DCAS) configuration 1. The MVS data set or z/OS UNIX file that the DCAS_CONFIG_FILE environment variable specified 2. /etc/dcas.conf 3. tsouserid.DCAS.CONF 4. TCPIP.DCAS.CONF	No sample provided.	Contains DCAS configuration statements.
/etc/hosts	No sample provided.	One of the possible local host files used for IPv4 name query. See “Creating /etc/hosts” on page 294.
hlq.ETC.IPNODES	SEZAINST(EZBREIPN)	One of the local host files used for IPv6 name query, or IPv4 and IPv6 name query when COMMONSEARCH is specified in the resolver setup file.
/etc/mail/ezatmail.cf	/usr/lpp/tcpip/samples/ezatmail.cf	Defines sendmail to CSSMTP bridge configuration statements.
ETC.PROTO	usr/lpp/tcpip/samples/protocol	Used to map types of protocol to integer values to determine the availability of the specified protocol. Required by several z/OS Communications Server components. The search order depends on the type of application (z/OS UNIX or native MVS).
ETC.RPC	SEZAINST(ETCRPC)	Defines RPC applications to the Portmapper function.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
ETC.SERVICES	usr/lpp/tcpip/samples/services	Establishes port numbers for servers using TCP and UDP. Required for z/OS UNIX SNMP and OMPROUTE (if the RIP protocol is used). The search order depends on the type of application (z/OS UNIX or native MVS).
/etc/syslog.conf	/usr/lpp/tcpip/samples/syslog.conf	Configuration file for the syslog daemon (syslogd).
FTP.DATA 1. -f command line parameter (FTP client only) 2. The MVS data set or z/OS UNIX file specified on the SYSFTPD DD statement in the FTP server started procedure 3. <i>userid/jobname</i> .FTP.DATA 4. /etc/ftp.data 5. SYS1.TCPPARMS(FTPDATA) 6. <i>hlq</i> .FTP.DATA	SEZAINST(FTCDATA) for the client and (FTPDATA) for the server	Overrides default FTP client and server parameters for the FTP server. For more information about the <i>hlq</i> , <i>jobname</i> , or <i>userid</i> values, see Chapter 12, “Transferring files using FTP,” on page 687.
HOSTS.LOCAL	SEZAINST(HOSTS)	Input data set to MAKESITE for generation of HOSTS.ADDRINFO and HOSTS.SITEINFO.
IKE daemon configuration 1. The MVS data set or z/OS UNIX file specified by the IKED_FILE environment variable 2. /etc/security/iked.conf	/usr/lpp/tcpip/samples/iked.conf	Contains IKE configuration statements.
INETD.CONF The MVS data set or z/OS UNIX file specified on the EXEC DD statement in the INETD started procedure	/samples/inetd.conf	Provides configuration management statements of generic servers for the Internet Daemon (InetD). InetD handles rlogin, telnetd, rshd, rexec, and other applications. For more information about InetD, see z/OS UNIX System Services Planning .

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
LBADV.CONF The MVS data set or z/OS UNIX file specified on the CONFIG DD statement in the z/OS Load Balancing Advisor started procedure	SEZAINST(LBADVCNF)	Contains z/OS Load Balancing Advisor configuration statements.
LBAGENT.CONF The MVS data set or z/OS UNIX file specified on the CONFIG DD statement in the z/OS Load Balancing Agent started procedure.	SEZAINST(LBAGECNF)	Contains z/OS Load Balancing Agent configuration statements.
LPD.CONFIG	SEZAINST(LPDDATA)	Configures the Line Printer Daemon for the Remote Print Server.
MIBS.DATA 1. The name of a z/OS UNIX file or an MVS data set specified by the MIBS_DATA environment variable 2. /etc/mibs.data z/OS UNIX file	No sample provided	Defines textual names for MIB objects for the z/OS UNIX snmp command.
Network security services (NSS) server configuration 1. The name of a z/OS UNIX file or MVS data set specified by the NSSD_FILE environment variable. 2. /etc/security/nssd.conf	/usr/lpp/tcpip/samples/nssd.conf	Contains NSS server configuration statements.
OMPROUTE configuration 1. The MVS data set or z/OS UNIX file specified on the OMPCFG DD statement in the OMPROUTE started procedure. 2. The MVS data set or z/OS UNIX file specified by the OMPROUTE_FILE environment variable 3. /etc/omproute.conf 4. hlq.ETC.OMPROUTE.CONF	SEZAINST(EZAORCFG)	Contains OMPROUTE configuration statements.
OSNMP.CONF 1. /etc/osnmp.conf 2. /etc/snmpv2.conf	/usr/lpp/tcpip/samples/snmpv2.conf	Defines target host security parameters for the osnmp command.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
OSNMPD.DATA 1. The MVS data set or z/OS UNIX file specified by the OSNMPD_DATA environment variable 2. /etc/osnmpd.data file system file 3. The MVS data set z/OS UNIX file specified on the OSNMPD DD statement in the agent started procedure 4. <i>jobname</i> .OSNMPD.DATA, where <i>jobname</i> is the name of the job used to start the SNMP agent 5. SYS1.TCPPARMS(OSNMPD) 6. <i>hlq</i> .OSNMPD.DATA, where <i>hlq</i> either defaults to TCPIP or is specified on the DATASETPREFIX statement in the TCPIP.DATA file being used	/usr/lpp/tcpip/samples/osnmpd.data	Used by SNMP for setting values for selected MIB objects.
PAGENT.CONF 1. File or data set specified with -c startup option 2. File or data set specified with PAGENT_CONFIG_FILE environment variable 3. /etc/pagent.conf	/usr/lpp/tcpip/samples/pagent.conf	Defines Policy Agent configuration parameters and optionally defines QoS service policies (rules and actions).
PROFILE.TCPIP 1. The MVS data set specified on the PROFILE DD statement in the TCP/IP stack started procedure. 2. <i>jobname.nodename</i> .TCPIP 3. TCPIP. <i>nodename</i> .TCPIP 4. <i>jobname</i> .PROFILE.TCPIP 5. TCPIP.PROFILE.TCPIP	SEZAINST(SAMPPROF)	Provides TCP/IP initialization parameters and specifications for network interfaces and routing.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
PW.SRC 1. The MVS data set or z/OS UNIX file specified by the PW_SRC environment variable 2. /etc/pw.src file system file 3. The MVS data set or z/OS UNIX file specified on SYSPWSRC DD statement in the started agent procedure 4. <i>jobname</i> .PW.SRC, where <i>jobname</i> is the name of the job used to start the SNMP agent 5. SYS1.TCPPARMS(PWSRC) 6. <i>hlq</i> .PW.SRC, where <i>hlq</i> either defaults to TCPIP or is specified on the DATASETPREFIX statement in the TCPIP.DATA file being used	No sample provided	Defines a list of community names used when accessing objects on a destination SNMP agent.
Resolver Setup File	SEZAINST (RESSETUP)	Provides configuration statements for the resolver.
RSVPD.CONF 1. File or data set specified with -c startup option 2. File or data set specified with RSVPD_CONFIG_FILE environment variable 3. /etc/rsvpd.conf 4. <i>hlq</i> .RSVPD.CONF	/usr/lpp/tcpip/samples/rsvpd.conf	Defines RSVP Agent configuration parameters.
SMTPNOTE clist System CLIST data set	SEZAINST(SMTPNOTE)	Defines the <i>note</i> parameters for the CSSMTP application.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
SNMPD.BOOTSD 1. The name of a z/OS UNIX file system file or an MVS data set specified by the SNMPD_BOOTSD environment variable. 2. /etc/snmpd.boots	No sample provided	Defines the SNMP agent security and notification destinations. Note: If the SNMPD.BOOTSD file is not provided, the SNMP agent creates the file. If multiple SNMPv3 agents are running on the same MVS image, use the environment variable to specify different SNMPD.BOOTSD files for the different agents. For security reasons, ensure unique engine IDs are used for different SNMP agents.
SNMPD.CONF 1. The name of a z/OS UNIX file system file or an MVS data set specified by the SNMPD_CONF environment variable. 2. /etc/snmpd.conf Note: The first file found in the search order is used.	/usr/lpp/tcpip/samples/snmpd.conf	Defines the SNMP agent security and notification destinations. Note: If the SNMPD.CONF file is found, the PW.SRC file and the SNMPTRAP.DEST files are not used.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
SNMPTRAP.DEST 1. The MVS data set or z/OS UNIX file specified by the SNMPTRAP_DEST environment variable 2. /etc/snmptrap.dest file system file 3. The MVS data set or z/OS UNIX file specified on SNMPTRAP DD statement in the agent started procedure 4. <i>jobname</i> .SNMPTRAP.DEST, where <i>jobname</i> is the name of the job used to start the SNMP agent 5. SYS1.TCPPARMS(SNMPTRAP) 6. <i>hlq</i> .SNMPTRAP.DEST, where <i>hlq</i> either defaults to TCPIP or is specified on the DATASETPREFIX statement in the TCPIP.DATA file being used	No sample provided	Defines a list of managers to which the SNMP agent sends traps.
TCPIP.DATA	SEZAINST(TCPDATA)	Provides parameters for TCP/IP client programs. The search order depends on the type of application (z/OS UNIX or native MVS). For more information about TCPIP.DATA configuration statements, see z/OS Communications Server: IP Configuration Reference .
TNDBCSCN The MVS data set specified on the TNDBCSCN DD statement in the TN3270E Telnet server started procedure	SEZAINST(TNDBCSCN)	Provides configuration parameters for Telnet 3270 Transform support.

Table 1. TCP/IP configuration data sets (continued)

Name (search order)	Copied from	Usage
TRAPFWD.CONF 1. A z/OS UNIX system file or an MVS data set specified by the TRAPFWD_CONF environment variable 2. /etc/trapfwd.conf	No sample provided	Defines addresses to which the Trap Forwarder Daemon forwards traps. Note: If the environment variable is set and if the file specified by the environment variable is not found, the Trap Forwarder daemon terminates.
VTAMLST The VTAM definitions added to the ATCCONxx member of the MVS data set specified on the VTAMLST DD statement in the VTAM started procedure	SEZAINST(VTAMLST)	Defines VTAM applications and associated characteristics. Entries are required for the TN3270E Telnet server.

Configuration files for the TCP/IP stack

Two configuration files are used by the TCP/IP stack, PROFILE.TCPIP and TCPIP.DATA. PROFILE.TCPIP is used only for the configuration of the TCP/IP stack. TCPIP.DATA is used during configuration of both the TCP/IP stack and applications; the search order used to find TCPIP.DATA is the same for both the TCP/IP stack and applications.

PROFILE.TCPIP search order

During initialization of the TCP/IP stack, system operation and configuration parameters for the TCP/IP stack are read from the configuration file PROFILE.TCPIP. As shown in [Table 1 on page 15](#), the search order used by the TCP/IP stack to find PROFILE.TCPIP involves both explicit and dynamic data set allocation as follows:

- //PROFILE DD DSN=aaa.bbb.ccc(anyname)
- jobname.nodename.TCPIP
- TCPIP.nodename.TCPIP
- jobname.PROFILE.TCPIP
- TCPIP.PROFILE.TCPIP

Note: Explicitly specifying the PROFILE DD statement in the TCPIPROC JCL is the recommended way to specify PROFILE.TCPIP. If this DD statement is present, the data set it defines is explicitly allocated by MVS and no dynamic allocation is done. If this statement is not present, the search order continues to use dynamic allocation for the PROFILE.TCPIP.

Examples

These examples show the search order used by TCP/IP to find the configuration file PROFILE.TCPIP. These examples use the sample TCP/IP started procedure, TCPIPROC, installed in the SEZAINST data set.

Example when DD cards are in your TCP/IP startup procedure

In this example, the PROFILE DD cards are specified as follows:

```
//TCPIP  PROC  PARMS='CTRACE(CTIEZB00)'  
//*  
//* z/OS Communications Server  
//* SMP/E Distribution Name: EZAEB01G  
//*  
//*      5694-A01 (C) Copr. IBM Corp. 1991,2001.  
//*      US Government Users Restricted Rights -  
//*      Use, duplication or disclosure restricted  
//*      by GSA ADP Schedule Contract with IBM Corp.  
//*      See IBM Copyright Instructions  
//*  
//TCPIP    EXEC  PGM=EZBTCPIP,  
//          PARM='&PARMS',  
//          REGION=0K,TIME=1440  
//*  
:  
//PROFILE DD  DISP=SHR,DSN=MVSA.PROD.PARMS(PROFILE)  
:  
:
```

Because the PROFILE DD is the first step in the search order, TCP/IP uses the data set MVSA.PROD.PARMS(PROFILE) as the PROFILE.TCPIP configuration file.

Example when no DD cards are in your TCP/IP startup procedure

In this example, the PROFILE DD statement is not specified:

```
//TCPIP  PROC  PARMS='CTRACE(CTIEZB00)'  
//*  
//* z/OS Communications Server  
//* SMP/E Distribution Name: EZAEB01G  
//*  
//*      5694-A01 (C) Copr. IBM Corp. 1991,2001.  
//*      US Government Users Restricted Rights -  
//*      Use, duplication or disclosure restricted  
//*      by GSA ADP Schedule Contract with IBM Corp.  
//*      See IBM Copyright Instructions  
//*  
//TCPIP    EXEC  PGM=EZBTCPIP,  
//          PARM='&PARMS',  
//          REGION=0K,TIME=1440  
//*  
:  
:
```

For the configuration file PROFILE.TCPIP, the search order used is as follows:

1. PROFILE DD
No PROFILE DD exists...search continues.
2. *jobname.nodename*.TCPIP
If *jobname.nodename*.TCPIP is found, the search stops here.
3. TCPIP.*nodename*.TCPIP
If TCPIP.*nodename*.TCPIP is found, the search stops here.
4. *jobname*.PROFILE.TCPIP
If *jobname*.PROFILE.TCPIP is found, the search stops here.
5. TCPIP.PROFILE.TCPIP
TCPIP.PROFILE.TCPIP is searched last if necessary.

TCPIP.DATA search order

The TCP/IP stack's configuration component uses the TCPIP.DATA configuration file during TCP/IP stack initialization to determine the stack's host name. To find the TCPIP.DATA information, the z/OS UNIX

environment search order is used. For a description of this search order, see [“Search orders used in the z/OS UNIX environment”](#) on page 803. This host name value is the value that is returned on gethostname socket function calls processed by this stack for applications not running in IBM z/OS Container Platform environments.

For details on the z/OS UNIX environment and native MVS environment search orders and the usage of z/OS UNIX environment variables, see [“Resolver configuration files”](#) on page 796.

Configuration files for TCP/IP applications

This information describes environment variables, the resolver configuration files that can be used by TCP/IP applications, and the search orders for those files. In addition to resolver files, an application can also have its own configuration files that are specific to that application. For more information about application-specific configuration files, see the descriptions of the individual applications in [Part 2, “Server applications,”](#) on page 591.

Environment variables

Environment variables are case-sensitive named variables with assigned values that various processes in the Communications Server configuration can access. Applications use environment variables to define the characteristics of their specific environment. Many z/OS Communications Server applications use environment variables to provide configuration information to the Language Environment® runtime functions, OMVS, the resolver, and to the application itself.

Use one of the following basic methods to specify environment variables:

- Specify the environment variable in the parameter field of the EXEC JCL statement in the started procedure.

For example:

```
//CONFHFS EXEC PGM=SYSLOGD,REGION=0M,TIME=NOLIMIT,  
//          PARM='ENVAR("TZ=EST5EDT")/-c -i -f /user1/syslogd.conf'
```

This method is useful when only one or two environment variables are required, as the maximum length of the PARM value is limited to 100 characters.

- Specify a file that contains the environment variables, which are processed during initialization of the application.

For example:

```
//CONFHFS EXEC PGM=SYSLOGD,REGION=0M,TIME=NOLIMIT,  
//          PARM='ENVAR("_CEE_ENVFILE_S=DD:STDENV")/-c -i'
```

This method is useful when multiple environment variables are required.

The DD statement STDENV can point to a z/OS file system (zFS) file or to an MVS data set.

- To allocate a zFS file on the STDENV DD statement:

```
//STDENV DD PATH='/etc/syslogd.env',PATHOPTS=(ORDONLY)
```

- To allocate an MVS data set on the STDENV DD statement:

```
//STDENV DD DISP=SHR,DSN=TCPIP.SYSLOGD.ENV(SYSLOGD)
```

When you are using the _CEE_ENVFILE_S environment variable, the data set organization can be a sequential data set or a member of a partitioned data set with a record format of Fixed, Fixed Blocked, Variable, or Variable Blocked. Trailing blank spaces are removed from the end of each record.

Each record that contains an equal sign (=) is considered to be an environment variable. The text before the equal sign is the name of the environment variable. The text after the equal sign is the value of the environment variable. The case of the name and value are not changed.

You can use `_CEE_ENVFILE_COMMENT` as the first environment variable in the file to embed comments in the environment variable file. For example:

```
_CEE_ENVFILE_COMMENT=#
#####
#  SYSLOGD environment variables
#  Last update = 2012/04/25
#####
SYSLOGD_CODEPAGE=IBM_1047
SYSLOGD_DEBUG_LEVEL=0
```

The character that is specified for the `_CEE_ENVFILE_COMMENT` environment variable is then used in column 1 of a record to indicate that the record is a comment record and is to be ignored.

Rule: If you do not define the `_CEE_ENVFILE_COMMENT` environment variable, text strings of the form `name=value` are processed as environment variables. For example, if `#SYSLOGD_CODEPAGE=IBM_1047` is encountered in an environment variable file, the environment variable `#SYSLOGD_CODEPAGE` is defined with the value `IBM_1047`.

For more information about [Using environment variables](#), see *z/OS XL C/C++ Programming Guide*.

Language Environment and UNIX System Services also provide environment variables. For information about these other variables, see [Understanding Shell Variables](#) in *z/OS UNIX System Services User's Guide*.

Table 2 on page 26 lists where to find more information about some common environment variables that z/OS Communications Server and its applications explicitly set or use.

Table 2. Common environment variables		
Environment Variable	Description	Reference
<code>_BPX_JOBNAME</code>	Changes the job name when the application creates a new address space (FTPD)	Commonly used environment variables in z/OS UNIX System Services Planning
<code>_BPXK_SETIBMOPT_TRANSPORT</code>	Requests transport affinity to a specific TCP/IP stack	Requesting transport affinity in z/OS UNIX System Services Planning
<code>_CEE_ENVFILE</code>	The name of an environment file, trailing blanks are left intact	_CEE_ENVFILE in z/OS XL C/C++ Programming Guide
<code>_CEE_ENVFILE_S</code>	The name of an environment file, trailing blanks are removed from each record	_CEE_ENVFILE_S in z/OS XL C/C++ Programming Guide
<code>_CEE_ENVFILE_COMMENT</code>	The character in column 1 of a record of the ENVFILE that indicates that the record is a comment record and is to be ignored	_CEE_ENVFILE_COMMENT in z/OS XL C/C++ Programming Guide
<code>_CEE_ENVFILE_CONTINUATION</code>	The last non-space character in a record that indicates that the environment variable value is continued on the next record	_CEE_ENVFILE_CONTINUATION in z/OS XL C/C++ Programming Guide
<code>RESOLVER_CONFIG</code>	The name of the TCPIP.DATA data set	Specifying TCP/IP address space parameters in z/OS Communications Server: IP Configuration Reference

Table 3 on page 27 lists where to find more information about the environment variables that particular z/OS Communications Server applications explicitly set or use.

MVS-related considerations

This topic includes an overview of MVS-related considerations for configuring z/OS Communications Server.

MVS system symbols

Use of MVS system symbols in TCP/IP profile data sets is automatically supported. This automatic support first attempts to use hiperspace memory files to perform the symbol translation, but if an error occurs, a temporary file is used. The temporary file is created in the directory specified by the TMPDIR environment variable, or in the /tmp directory if the TMPDIR environment variable is not defined.

Use of MVS system symbols in the resolver setup file and the TCPIP.DATA file is also automatically supported. The resolver reads and processes the TCPIP.DATA file on behalf of TCP/IP applications that invoke resolver services. System symbols are resolved as file records are read.

If an MVS system symbol is used with a substitution value that has a length greater than the symbol name, and this substitution causes the record to overflow, then the symbol substitution will fail for the record.

Use of MVS system symbols is also supported in the following cases:

- Values of resolver environment variables, like RESOLVER_CONFIG and RESOLVER_TRACE
- OMPROUTE configuration file
- Communications Server SMTP (CSSMTP) configuration file
- BeginArchiveParms DSNPrefix parameter in the syslogd configuration file

For more information about the use of MVS system symbols, see [What are system symbols?](#) in [z/OS MVS Initialization and Tuning Reference](#).

EZACFSM1 symbol translator utility

For MVS system symbols in other configuration files, use the symbol translator utility, EZACFSM1, to translate the symbols before the files are read by TCP/IP. EZACFSM1 reads an input file and writes to an output file, translating any symbols in the process. The input file and output file can be MVS data sets or z/OS UNIX files; however, do not specify the same file for both the input and output file. For lists of the [Static system symbols](#) and [dynamic system symbols](#) supported by EZACFSM1, see [z/OS MVS Initialization and Tuning Reference](#).

EZACFMS1 returns the following error return codes:

- A return code of 45 if the same file was specified for both the input and the output.
- Errno value from z/OS UNIX fopen() function calls if errors occur opening the input or output file. See [fopen\(\) - Open a file in z/OS C/C++ Runtime Library Reference](#) for a list of the return values for this function call.
- ASASYMBM error return codes. See ASASYMBM and ASASYMBF - Substitute text for symbols in z/OS MVS Programming: Assembler Services Reference ABE-HSP for a list of the return codes for this service.

The following symbol translator JCL is found in SEZAINST(CONVSYM) and is used to start EZACFSM1:

```
//----- JOB (accounting,information),programmer.name,
//          MSGLEVEL=(1,1),MSGCLASS=A,CLASS=A
//*
```

```

/** CS for z/OS
/** SMP/E distribution name: EZACFCSY
/**
/** 5694-A01 (C) Copyright IBM Corp. 1998, 2005
/** Licensed Materials - Property of IBM
/**
/** Function: System Symbols Translator JCL
/**
/** This JCL kicks off a utility that will read from
/** an input file that contains MVS System Symbols
/** and produce an output file which has those symbols
/** replaced with their substitution text, as defined
/** in the appropriate IEASYMxx PARMLIB data set; see MVS
/** Initializaton and Tuning Reference for rules about symbols.
/**
/** This JCL can be run against any of the TCP/IP configuration
/** files that contain MVS System Symbols. An example of how it
/** could be used is this; a customer could have one base TCPIP.DATA
/** file containing MVS System Symbols which they edit and maintain.
/** They would run this utility against this one file the various
/** MVS systems to produce the TCPIP.DATA file for each different
/** system.
/**
/**STEP1 EXEC PGM=EZACFSM1,REGION=0K
/**SYSIN DD DSN=TCP.DATA.INPUT,DISP=SHR
/***SYSIN DD PATH='/tmp/tcp.data.input'
/** The input file can be either an MVS data set or an z/OS
/** UNIX file.
/**
/**
/**SYSOUT DD DSN=TCP.DATA.OUTPUT,DISP=SHR
/***SYSOUT DD PATH='/tmp/tcp.data.output',PATHOPTS=(OWRONLY,OCREAT),
/** PATHMODE=(SIRUSR,SIWUSR,SIRGRP,SIWGRP)
/** The output file can be either an MVS data set or an z/OS
/** UNIX file.
/**
/** The output file cannot be the same file as the input file-
/** doing so will result in a return code of 45.
/**
/** You can mix input and output file types (i.e., the input
/** can be an MVS data set with the output being a z/OS UNIX
/** file or visa versa).
/** Note: Other pathmodes for sysout may be used if needed.

```

The symbol translator utility can be used on any of the TCP/IP configuration files, but because the PROFILE.TCPIP file is automatically translated during TCP/IP initialization, there is no need to run the utility against that file.

Restriction: There is no input line length limitation. However, you must ensure that any symbols that require translation do not end on or span character position 80 or $n*80$ of the line. Otherwise, the utility cannot translate the symbol.

Automatic restart manager

Automatic restart manager (ARM) is an MVS component that can automatically restart the TCP/IP stack after an abnormal end (ABEND).

During initialization, TCP/IP automatically registers with the automatic restart manager using the following options:

```

REQUEST=REGISTER
ELEMNAME=EZAsysclonetcpname
ELEMTYPE=SYSTCPIP
TERMTYPE=ELEMTerm

```

where:

- *sysclone* is a 1– or 2–character shorthand notation for the name of the MVS system. For a complete description of the SYSC clone static system symbol, see [z/OS MVS Initialization and Tuning Reference](#).
- *tcpname* is a 1– to 8–character name of the TCP/IP stack which registers with the automatic restart manager. For example, if the SYSC clone value is 02 and the TCP/IP stack name is TCP CS, the resulting ELEMENT value is EZA02TCP CS.

Rules:

- The TCP/IP stack supports automatic restart only on the same system. Do not explicitly specify TERMTYPE(ALLTERM) in the automatic restart management policy for TCP/IP. A policy that uses the default value ALLTERM is overridden by the TCP/IP stack registration value ELEMTERM.
- To prevent dynamic configuration changes made using the VARY TCPIP,,OBEYFILE command from being lost after restarting TCP/IP, ensure that these configuration changes are part of the normal TCP/IP startup procedure.

For more information about automatic restart manager, see [z/OS MVS Setting Up a Sysplex](#).

Logging of system messages

Syslog daemon (syslogd) is a server process that must be started as one of the first processes in your z/OS UNIX environment. TCP/IP server applications and components use syslogd for logging purposes and can also send trace information to syslogd. Servers on the local system use AF_UNIX sockets to communicate with syslogd; remote servers use AF_INET sockets. z/OS Communications Server components use the local1, local14, local15, daemon, mail, user, and auth facilities names.

Note: Each application activates and deactivates traces in a slightly different manner. For details, see the information about the individual application.

The syslog daemon reads and logs system messages to the MVS console, log files, SMF, other machines, the operlog log stream, or users as specified by the configuration file. If syslogd is not started, log data from some applications will be displayed on the MVS console. For more information on syslogd, see Chapter 5, “TCP/IP Customization,” on page 235.

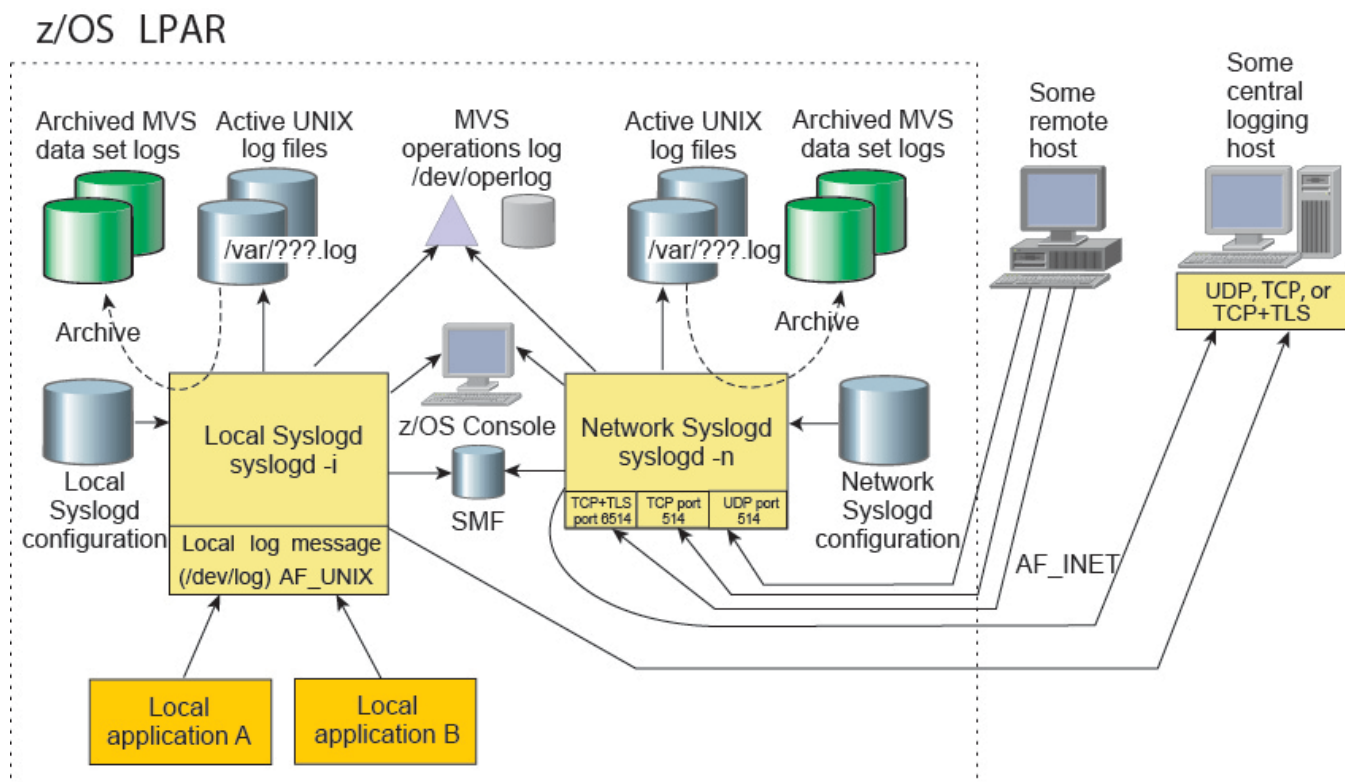

Figure 2. syslogd operation

Note: /var/???log is the file specified in the syslogd.conf file.

The syslogd facility uses a common mechanism for separating messages. [Table 4 on page 31](#) shows the facilities used by z/OS Communications Server functions which write messages to syslogd. The Primary syslog facility column shows the syslog facility used for most messages logged by the application. Some applications use other facilities for certain messages. [Table 4 on page 31](#) also shows any additional facilities.

<i>Table 4. syslogd facilities</i>			
Application	syslogd record identifications	Primary syslog facility	Other syslog facility
Application Transparent Transport Layer Security (AT-TLS)	TTLS	daemon	auth
Automated domain name registration (ADNR)	adnr	daemon	None
Communications Server SMTP (CSSMTP)	CSSMTP	mail	None
Defense Manager daemon (DMD)	DMD	local4	None
FTP server	ftpd, ftps	daemon	None
IKE daemon	IKED	local4	None
Network security services (NSS) server	NSSD	local4	None
Network SLAPM2 subagent	NSLAPM2	daemon	None
OMPROUTE	omproute	user	None
OPORTMAP server	oportmap	daemon	None
OREXCD	rexecd	daemon	auth
ORSHD	rshd	daemon	auth
OTELNETD	telnetd	local1	auth
Policy Agent	Pagent	daemon	None
POPPER	popper	mail	None
PWCHANGE command	pwchange	daemon	None
PWTOKEY command	pwtokey	daemon	None
rpcbind	rpcbind	daemon	None
Simple Network Time Protocol daemon	sntpd	daemon	None
SNMP agent (OSNMPD)	snmpagent	daemon	None
syslogd	syslogd	daemon	None
TCP/IP subagent	M2SubA	daemon	None
TIMED daemon	timed	user	None
TN3270E Telnet subagent	TNSubA	daemon	None

<i>Table 4. syslogd facilities (continued)</i>			
Application	syslogd record identifications	Primary syslog facility	Other syslog facility
Traffic Regulation Management Daemon (TRMD)	TRMD	daemon (used for IDS logging)	local4 (used for IPSEC logging and defensive filter logging) local5 (used for zERT policy-based enforcement logging)
Trap Forwarder daemon	trapfwd	daemon	None
z/OS Load Balancing Advisor	lbadv	daemon	None
z/OS Load Balancing Agent	lbagent	daemon	None

Accounting - SMF records

Installations use Systems Management Facilities (SMF) records for the following reasons:

Performance management

Performance management includes the tasks that are related to verifying that defined service levels are met, and if not, identifying possible causes.

Aggregated information about delivered service, structured by organizational units (for which service levels have been defined) is needed to perform these tasks. These reports are typically time series with varying levels of time intervals, ranging from weeks through days to a time interval that matches the SMF interval. Some examples of potential reports related to performance management are:

- TCP connection elapsed time per server port number per time of day (potentially broken down on source IP address, or netmask)
- Number of TCP connections per server port number per time of day (potentially broken down on source IP address, or netmask)
- Number of inbound/outbound bytes transferred in TCP connections per time of day (potentially broken down in various ways: per destination or source port, per destination IP address, netmask, or in total, etc.)
- TCP retransmission activity per time of day (potentially broken down per destination IP address, or netmask)
- Number of outbound TCP connections per time of day (potentially broken down per destination IP address, or netmask)
- Number of inbound/outbound UDP datagrams per time of day (potentially broken down on server port number)
- Number of discards, error packets, and unknown protocol packets inbound and outbound per time of day (potentially broken down per interface)

Capacity planning

Capacity planning includes tasks that are related to forecasting capacity in terms of central processing power, memory, channel-based I/O subsystem, network attachments, and network bandwidth. Such planning tasks are based on analyzing trends for use of capacity during a preceding period (typically one to two years), and applying forecasting metrics, along with knowledge about planned launches of new applications or use of existing applications, to this trend in order to predict capacity needs during the next one to two year period. Some examples of potential reports related to capacity planning are:

- Total number of TCP connections per reserved server port number per day including analysis of average and variations around average during daily peak periods

- Total number of UDP inbound/outbound UDP datagrams per reserved server port number per day including average and variations around average during daily peak periods
- Number of bytes and/or packets transferred inbound and outbound per interface (LINK) per time of day (potentially broken down into unicasts, broadcasts, and multicasts)
- Size of queue length per interface per time of day

Auditing

Auditing involves tasks that are related to identifying and proving that individual events have taken place. Some examples of potential reports related to auditing are:

- Detailed information about specific TCP connections or UDP sockets, IP addresses, server/client identification, duration, number of bytes, and so on
- Details about activity that involves a specific client or server
- Details about a given application session based on server-specific SMF recording, such as individual Telnet sessions or FTP sessions
- Details about changes to the TCP/IP stack profile and the user that requested the change
- Details about changes to the status of dynamic virtual IP addresses (DVIPAs) and sysplex distributor targets

Compliance

Compliance involves tasks that are related to identifying that certain standards (such as PCI-DSS) are met. The SMF 1154 record is designed to capture compliance evidence from many MVS components and applications. TCP/IP provides specific compliance evidence that can be used in conjunction with other SMF 1154 records to evaluate a system's compliance with one or more standards.

Some examples of potential reports related to compliance are:

- TCP/IP stack configured security settings, such as whether AT-TLS and IPsec are enabled
- Application-level compliance information specific to each individual application, for example:
 - For CSSMTP: Configured security settings, such as TLS protection
 - For FTP: Configured security settings, such as anonymous logon support
 - For TN3270: Configured security settings, such as inactivity timeout values

Accounting

Accounting involves tasks that are related to calculating how much each individual user or organizational unit should be charged for use of the shared central IS resources. Input to such calculations vary, but is often based on CPU cycle use, data quantities, bandwidth usage, and memory use. For TCP/IP additional metrics may be defined, such as type of service used (FTP, LPD, web server, and so on), and TCP connection-related information (number of connections, duration, byte transfer counts, and so on). Some examples of potential reports related to accounting are:

- Aggregated number of connections to a given server from a given source in terms of a specific client IP address, or netmask
- Accumulated connect time to a given server from a given source in terms of a specific client IP address, or netmask.
- Number of bytes transferred to or from a given source in terms of a specific client IP address, or netmask.
- Amount of data protected by specific manual or dynamic tunnels.
- Application-level accounting information specific to each individual server, for example:
 - For Communications Server SMTP (CSSMTP): Information about mail message processing
 - For FTP: Number of transfer operations and bytes retrieved or stored per user ID
 - For IKED: Information about IKE tunnels
 - For TN3270: Number of sessions and session type (TN3270/TN3270E/LINEMODE)

In general, SMF records are created for deferred processing and analysis and are not used for real-time monitoring purposes. In a TCP/IP environment, real-time monitoring is implemented with the SNMP protocol and is based on internal variables that SNMP subagents maintain. However, on z/OS, much of the information that is written in SMF records is also useful from a real-time monitoring perspective. For information about using z/OS Communications Server TCP/IP IPsec NMI to obtain SMF records in real time, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

As can be seen, all disciplines require detailed data as input. Depending on the discipline, certain levels of aggregation is performed on the raw detailed data in order to perform the tasks of that discipline. The objective of the TCP/IP product is to define and generate the lowest level of detail that is needed by all disciplines. How to aggregate and the actual aggregation is performed by other products, such as Performance Reporter for z/OS (PR), MVS Information Control System (MICS), or SAS-based tools or, in many cases, customer-written programs.

TCP/IP– produced SMF records should not be viewed isolated. Other components in MVS produce SMF records for the same purposes as those produced by TCP/IP. An installation is likely to combine information from a series of subsystems in performing detailed performance, or capacity planning, or compliance evaluation. SMF records with information about use of CPU resources and memory resources per address space is, for example, produced by other components in MVS, and TCP/IP produced SMF records should not duplicate that information. Also, compliance with a standard (for example, PCI-DSS) requires data from many components in MVS and various applications.

The events that trigger SMF records to be written and the information included in the SMF records must accommodate the intended purposes. There can be multiple purposes for given SMF records.

SMF records can be cut at multiple levels in the TCP/IP protocol stack, and the type of information that can be included depends on where the SMF record is created:

- At the IP and interface layer, there is information about ICMP activity, IP packet fragmentation and reassembly activity, IP checksum errors, IGMP activity, and ARP activity. At this layer, it is difficult to relate the information to specific users (remote clients, local socket address spaces, and so on), so from an accounting point of view, this information is not very interesting. Because you can aggregate network-layer activity to physical interfaces, the information at the IP and interface layer is an important aspect of both performance and capacity management.
- At the transport protocol layer, there is information about IP addresses, port numbers, and host names. For TCP-related workload, there is information about connections and information that is related to TCP connections, such as byte counts, connection times, reliability metrics, and performance metrics. For UDP-related workload, each UDP datagram is a separate entity; the only way to aggregate information for UDP is on a UDP socket level, where SMF records could be created every time a UDP socket is closed.
- At the application layer, there are more details about what goes on, but every application is different and requires separate SMF record definitions and ability to write the SMF records to implement application-layer SMF recording. Application-layer SMF recording is implemented by some applications, such as the TN3270E Telnet server (Telnet), the FTP server, the IKE daemon, and the CSSMTP daemon.

For more information about the SMF records provided by z/OS Communications Server functions, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Security considerations

Multilevel security is an enhanced security environment that can be configured on a z/OS system. In this environment, the security server and trusted resource managers enforce mandatory access control policies in addition to the usual discretionary access control policies. To participate in a multilevel secure environment, the user IDs associated with z/OS CS tasks and the resource profiles in the SERVAUTH class need to have security labels defined. For more information on the multilevel secure environment and configuring z/OS CS in that environment, see [Chapter 4, “Preparing for IP networking in a multilevel secure environment,”](#) on page 213.

z/OS Communications Server relies on a System Authorization Facility (SAF) to protect several resources:

- Started tasks require access to a STARTED resource. This is documented in the server information in the [z/OS Communications Server: IP Configuration Reference](#). Also, see SEZAINST(EZARACF) for SAF authorizations required for the TCP/IP stack and servers started tasks.
- Restricting access to a network, subnetwork or particular IP address in the network is provided by resources in the SERVAUTH class. Using NETACCESS statements, z/OS CS can map networks, subnetworks and IP addresses to SAF resource names. Users that are not permitted access to a particular SAF resource are not allowed to communicate with the corresponding network, subnetwork, or IP address. See the NETACCESS statement in [z/OS Communications Server: IP Configuration Reference](#) or [“Setting up the System Authorization Facility server access authorization class \(optional\)” on page 291](#) for more information.

You can also use SAF resources in the SERVAUTH class to control which users can create dynamic VIPAs that are specified by VIPARANGE statements, and to restrict access to a specific dynamic VIPA or a specific range of dynamic VIPAs in a VIPARANGE statement. For more information about the VIPARANGE statement, see [z/OS Communications Server: IP Configuration Reference](#). For information about VIPARANGE access control, see [“Defining a security profile for SIOCSVIPa, SIOCSVIPa6, and MODDVIPa” on page 405](#) and [“Defining a security profile for binding to DVIPAs in the VIPARANGE statement” on page 430](#).

Restricting the ability of the users to run applications that access specific TCP and UDP ports is also provided by resources in the SERVAUTH class. z/OS Communications Server provides a one-to-one mapping between port numbers and SAF resource names. See the PORTACCESS statement in the [z/OS Communications Server: IP Configuration Reference](#) or [“Setting up the System Authorization Facility server access authorization class \(optional\)” on page 291](#) for more information.

Similar to the function provided by the PORTACCESS statement, z/OS Communications Server ensures that a user attempting to connect to a TN3270E Telnet server secure port is allowed access to the port. This support is used in conjunction with Telnet client authentication support. See the ClientAuthType parameter of [TTLSEnvironmentAdvancedParms](#) statement in the [z/OS Communications Server: IP Configuration Reference](#) or [“Setting up the System Authorization Facility server access authorization class \(optional\)” on page 291](#) for more information.

Restricting access to the TCPIP stack is also controlled under z/OS CS by defining a resource in the SERVAUTH class. See [“Setting up the System Authorization Facility server access authorization class \(optional\)” on page 291](#) for more information.

- Restricting access to operator commands is provided through the OPERCMDS resource. z/OS Communications Server verifies that users have access to specific OPERCMDS resources before executing the operator command. See the operator commands information in [z/OS Communications Server: IP System Administrator's Commands](#) or [“Setting up the System Authorization Facility server access authorization class \(optional\)” on page 291](#) for more information about limiting access to z/OS Communications Server commands.
- Restricting access to the TSO and UNIX shell Netstat command is provided by SERVAUTH resources. z/OS Communications Server verifies that users have access to specific SERVAUTH resources before executing the Netstat command. See the Netstat command information in the [z/OS Communications Server: IP System Administrator's Commands](#) for more information about limiting access to Netstat command. The security product resource names in the SERVAUTH class do not apply to DISPLAY TCPIP, NETSTAT command. If you want to restrict access to DISPLAY TCPIP, NETSTAT command, you can do so using standard operator command restriction facility, OPERCMDS class profiles. See [z/OS MVS Planning: Operations](#) for more information.

For more information about protecting these resources and other TCP/IP resources from unauthorized access, see [“TCP/IP resource protection” on page 146](#).

Nonreusable ASIDs

The following Communications Server address spaces provide PC-entered services that must be accessible to all address spaces, so a system LX is obtained.

- Resolver

- TCP/IP stack
- TN3270 Telnet server
- VMCF and TNF subsystems

The following applications use these subsystems:

- SNMP Query Engine application
- Pascal Socket Interface
- LPD servers
- TSO TELNET, HOMETEST, TESTSITE, RSH, REXEC, and LPR commands

Unless you specify REUSASID=YES on the START command, the Address Space Identifiers (ASIDs) associated with these address spaces will be nonreusable when these address spaces are stopped or restarted. If these address spaces are stopped enough times and you do not specify REUSASID=YES when you start the address space, all available ASIDs might be exhausted, which prevents a new address space from being created on the system. In this case, an IPL is required. Specifying REUSASID=YES when starting these address spaces ensures that the ASIDs associated with them can be reused and can help avoid an IPL. For more information about tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in [z/OS MVS Initialization and Tuning Reference](#).

Restriction: Do not specify REUSASID=YES when you are starting the VMCF and TNF subsystems or any applications that use these subsystems.

TSO command authorization

You must list the FTP, LPR, MODDVIPA, PING, and TRACERTE commands in the AUTHCMD NAMES section of your IKJTSoxx member of SYS1.PARMLIB.

If a command such as FTP, PING, or TRACERTE is invoked using a method other than a TSO command, you might have to do additional authorization customization, such as adding the program names to the AUTHPGM NAMES section of your IKJTSoxx SYS1.PARMLIB member.

UNIX System Services security considerations

This information describes some security considerations that have a product-wide effect. Descriptions of security considerations that affect specific servers or components are described with the information for each server and component.

Requirement for an OMVS segment

Many TCP/IP Services components in z/OS Communications Server now exploit z/OS UNIX services in both the native MVS environment and in the z/OS UNIX environment. For example, all TCP/IP socket APIs and TCP/IP applications (whether they are provided by z/OS Communications Server, z/OS, other IBM and non-IBM products, or written by users) now make use of z/OS UNIX services.

Use of z/OS UNIX services requires a z/OS UNIX security context, referred to as an *OMVS segment*, for the user ID associated with any unit of work requesting these services. In other words, most user IDs requiring access to TCP/IP functions now require an OMVS segment to be defined in Resource Access Control Facility (RACF).

Note: The tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). If you are using a security product from another vendor, read the documentation for that product for instructions on task performance.

To satisfy the requirement for an OMVS segment in RACF, take one of the following actions:

- Identify all the users in your environment that use TCP/IP services, and define OMVS RACF segments with a unique UID value for the associated user IDs.
- Use the automatic assignment of unique UNIX identities support to automatically generate OMVS segments for user IDs.

For more information about automatic assignment of unique UNIX identities support, see [z/OS UNIX System Services Planning](#). For [Steps for automatically assigning unique IDs through UNIX services](#), see [z/OS Security Server RACF Security Administrator's Guide](#).

Authorization of TCP/IP started task user ID

The TCP/IP address space operates as a transport provider for the INET physical file system. For this to occur, the TCP/IP system address space must connect to z/OS UNIX and become a z/OS UNIX process. Therefore, the started task UID that is assigned to the TCP/IP system address space must have a valid OMVS segment.

As a transport provider, the TCP/IP address space requires superuser privileges in z/OS UNIX. Define the TCP/IP system address space started task UID as UID=0, or define the TCP/IP system address space as a trusted environment in the RACF started class profile for the TCP/IP system address space. Use the following command to assign an OMVS segment to the TCP/IP started task user ID specified as UID=0:

```
ALU tcpip_userid OMVS(UID(0) HOME(/) PGM(/bin/sh))
```

Other user IDs requiring z/OS UNIX superuser authority

When a started procedure is used to start the following servers, daemons, and agents, the user must be a superuser [UID(0)] or permitted to BPX.SUPERUSER class profile.

- Network Print Facility (NPF) queue manager
- SNMP agent (OSNMPD)

The File Transfer Protocol (FTP) daemon requires UID(0). For more information, see [“Security for the FTP server” on page 690](#).

The syslog daemon (syslogd) requires UID(0). For more information, see [“Configuring the syslog daemon” on page 235](#).

The following daemons are managed by the inetd server, and the user specified in file `/etc/inetd.conf` must be defined to RACF with UID(0). For details on inetd, see [z/OS UNIX System Services Planning](#). For details on individual daemons, see [z/OS Communications Server: IP Configuration Reference](#).

- z/OS UNIX remote execution daemon (REXECD)
- z/OS UNIX remote shell daemon (RSHD)
- z/OS UNIX Telnet daemon

BPX.DAEMON FACILITY class profile

Certain z/OS Communications Server TCP/IP Services servers need to change the security environment of the process in which they currently execute. For example, the FTPD daemon creates a new z/OS UNIX process for every FTP client connecting to it. After the new process is created, the daemon changes the security environment of the process so that it is associated with the security context of the logged-in user. The RACF FACILITY class resource BPX.DAEMON is used for this purpose. [Table 5 on page 38](#) contains information about using the BPX.DAEMON resource.

Table 5. BPX.DAEMON	
Task	Details
Decide if you want to activate the BPX.DAEMON level of security by reviewing the information about BPX.DAEMON authority in z/OS UNIX System Services Planning to determine whether this level of security is appropriate for your installation.	<p>This is not required. It is recommended, however, because it provides additional security in the z/OS UNIX environment.</p> <p>The following TCP/IP Services servers and daemons in z/OS Communications Server change the security environment of their processes:</p> <ul style="list-style-type: none"> • FTPD • Network security services (NSS) server • Policy Agent • z/OS UNIX REXECD • z/OS UNIX RSHD • z/OS UNIX TELNETD
Plan the time at which you define BPX.DAEMON carefully.	As soon as you define the BPX.DAEMON resource, MVS will not let programs change the security environment unless the programs are retrieved from a program-controlled library and unless the UID under which the program executes has access to BPX.DAEMON.
If you decide not to define the BPX.DAEMON FACILITY class profile, assign UID(0) for the UIDs associated with these servers and daemons.	This is sufficient for processing. It is described in “Other user IDs requiring z/OS UNIX superuser authority” on page 37 .
If you do decide to define the BPX.DAEMON FACILITY class profile, grant READ access to this profile for the UIDs associated with the listed daemons. Also, enable BPX.DAEMON security by defining the BPX.DAEMON FACILITY class profile in RACF.	<p>To define the BPX.DAEMON FACILITY class profile in RACF, use the following command:</p> <pre>RDEFINE FACILITY BPX.DAEMON UACC(NONE)</pre> <p>Note: You must specify the name BPX.DAEMON in this command. Substitutions for the name are not allowed.</p>

If all the required conditions are not met, your server programs will fail as soon as you define BPX.DAEMON. If the server programs fail, delete BPX.DAEMON, and the setup reverts to its previous state. Check all your definitions, and make the required corrections before trying to define BPX.DAEMON again.

If this is the first FACILITY class profile that your installation is using, activate the FACILITY class using the following commands:

```
SETROPTS CLASSACT(FACILITY) GENERIC(FACILITY) AUDIT(FACILITY)
SETROPTS RACLIST(FACILITY)
```

If you start server programs using MVS start commands or from shell scripts that execute after startup of z/OS UNIX, you must allow the UIDs access to the BPX.DAEMON FACILITY class resource. The following example shows the UID (ftpd_user_ID) with which you can start the FTPD daemon:

```
PERMIT BPX.DAEMON CLASS(FACILITY) ID(ftpd_user_ID) ACCESS(READ)
```

Authorization to change the user security environment is granted only if both of the following two conditions are true:

- The server program is executing under a UID that has READ permission to the BPX.DAEMON FACILITY class profile and a UID=0.

- All programs running in the address space have been retrieved from a controlled library.

Program control

There are additional security concerns when you are loading programs that are considered trusted into the z/OS UNIX file system. Program control facilities in RACF and z/OS UNIX provide a mechanism for ensuring that the z/OS UNIX program loading process has the same security features that APF authorization provides in the native MVS environment.

It is recommended that you enable program control in your installation. If you define the BPX.DAEMON FACILITY class profile, you must enable program control for certain z/OS Communications Server load libraries. Review the information on program control in [z/OS UNIX System Services Planning](#) to decide whether program control is appropriate for your installation.

To enable program control, follow the tasks in [Table 6 on page 39](#).

Table 6. Program control	
Task	Details
Activate program control.	Use the following command: <pre>SETROPTS WHEN(PROGRAM)</pre>
Set the universal access for public library data sets (those in LINKLSTxx) to READ. This allows access to the controlled programs and any other program in those libraries. (MVS opens the LNKLSTxx libraries during IPL and makes these programs public. However, users cannot make changes.)	Use the following commands to create RACF data set profiles: <pre>ADDSD 'cee.version.SCEERUN' UACC(READ) ADDSD 'SYS1.LINKLIB' UACC(READ) ADDSD 'TCPIP.SEZALOAD' UACC(READ) ADDSD 'TCPIP.SEZATCP' UACC(READ)</pre>
Ensure all load modules that are loaded by the BPX.DAEMON servers into an address space come from controlled libraries.	If the MVS contents supervisor loads a module from a noncontrolled library, the address space becomes <i>dirty</i> and loses its authorization. To prevent this from happening, define all the libraries from which load modules can be loaded as program controlled. At a minimum, this should include the C run-time library, the TCP/IP Services SEZALOAD and SEZATCP libraries, SYS1.LINKLIB, and any load libraries containing FTP security exits. Use the following commands: <pre>RDEFINE PROGRAM * ADDMEM('SYS1.LINKLIB'/volser/NOPADCHK) UACC(READ) RALTER PROGRAM * ADDMEM('SYS1.SIEALNKE'/volser/NOPADCHK) RALTER PROGRAM * ADDMEM('cee.version.SCEERUN'/volser/NOPADCHK) RALTER PROGRAM * ADDMEM('TCPIP.SEZALOAD'/volser/NOPADCHK) RALTER PROGRAM * ADDMEM('TCPIP.SEZATCP'/volser/NOPADCHK) RALTER PROGRAM * ADDMEM('db2.DSNLOAD'/volser/NOPADCHK) RALTER PROGRAM * ADDMEM('db2.DSNEXIT'/volser/NOPADCHK) RALTER PROGRAM * ADDMEM('ftp.userexits'/volser/NOPADCHK)</pre> <p>Note: If you define the load libraries as controlled, do not specify a universal access of NONE for the PROGRAM resources. If you do so for your SYS1.LINKLIB programs, you cannot IPL your z/OS system. Be aware also that in z/OS, the <i>volser</i> specification is optional.</p>
Activate RACF changes.	Use the following command: <pre>SETROPTS WHEN(PROGRAM) REFRESH</pre>

Defining TCP/IP as a UNIX System Services physical file system

The TCP/IP services stack in z/OS Communications Server must be defined as a z/OS Communications Server UNIX System Services physical file system (PFS) before it can be started. This involves updating the BPXPRMxx parmlib member. The following sample definition in BPXPRMxx defines TCP/IP as a z/OS Communications Server UNIX System Services PFS, where the network layer is IP Version 4 (IPv4) and communication at the sockets layer is through the AF_INET family:

```
FILESYSTYPE TYPE(INET)  ENTRYPOINT(EZBPFINI)

NETWORK DOMAINNAME(AF_INET)
          DOMAINNUMBER(2)
          MAXSOCKETS(60000)
          TYPE(INET)
```

This sample definition shows how to define a single TCP/IP stack as IPv4 only. To define a single TCP/IP stack as both IPv4 and IPv6, add an additional NETWORK statement in the BPXPRMxx member. The following sample definition in BPXPRMxx defines TCP/IP as a z/OS Communications Server UNIX System Services PFS, where the network layer is IP Version 6 (IPv6) and communication at the sockets layer is through the AF_INET6 family:

```
NETWORK DOMAINNAME(AF_INET6)
          DOMAINNUMBER(19)
          MAXSOCKETS(60000)
          TYPE(INET)
```

The BPXPRMxx member contains additional parameters that are crucial to the correct operation of TCP/IP. Carefully examine and specify these parameters:

- MAXPROCSYS — Specifies the maximum number of z/OS UNIX processes that the system allows.
- MAXPROCUSER — Specifies the maximum number of processes that a single z/OS UNIX user ID can have concurrently active, regardless of how the processes were created.

Guideline: The TN3270E server creates five UNIX processes at initialization and one more process for each BEGINVTAM statement that is used to define a listening port. For example, if 25 ports are defined by BEGINVTAM statements, then the TN3270 server creates at least 30 UNIX processes. If the TN3270E Telnet server is not running as UID(0) and has 20 or more ports defined (BEGINVTAM statements), increase the number of UNIX processes. You can increase the number of UNIX processes by increasing the value for MAXPROCUSER in the BPXPRMxx parmlib member, or by setting the PROCUSERMAX value in the OMVS segment for the TN3270E user ID.

- MAXUIDS — Specifies the maximum number of z/OS UNIX user IDs that can operate concurrently.
- MAXFILEPROC — Specifies the maximum number of descriptors for files, sockets, directories, and any other file system objects that a single z/OS UNIX process can have concurrently allocated. This includes access to both z/OS UNIX files and socket descriptors. In z/OS Communications Server, most TCP/IP applications access TCP/IP sockets, either directly or indirectly, using the TCP/IP socket APIs. You should set the MAXFILEPROC value high enough to accommodate the largest number of sockets that a single TCP/IP application (or z/OS UNIX process) can allocate.

Result: The TN3270E Telnet server running as UID(0) or running with BPX.SUPERUSER authority programmatically raises this limit beyond the MAXFILEPROC value, up to the system-defined maximum.

Guideline: If the TN3270E Telnet server or another application cannot programmatically raise this limit because the application is not running as UID(0) or with BPX.SUPERUSER authority, you can override the MAXFILEPROC limit by using the FILEPROC MAX parameter on the RACF ALTUSER command (or using the appropriate command for your security product).

- MAXPTYS — Specifies the maximum number of pseudo-terminals for the system.
- MAXTHREADTASKS — Specifies the maximum number of MVS tasks that a single process can have concurrently active.
- MAXTHREADS — Specifies the maximum number of threads that a single process can have concurrently active.

- **MAXQUEUEDSIGS** — The sum of **MAXQUEUEDSIGS** and **MAXFILEPROC** multiplied by 2 is the system-wide maximum for the total number of asynchronous z/OS UNIX socket calls that can be outstanding. When you are specifying this number, consider:
 - For every TCP/IP connection that the TN3270E Telnet server has, there is an asynchronous z/OS UNIX socket call outstanding, which is true for both TN3270 and TN3270E clients.
 - Any TCP/IP application, from IBM or supplied by a vendor, that uses either the z/OS UNIX async callable service or the TCP/IP-provided Sockets Extended asynchronous API can have one or more outstanding asynchronous socket calls.

The **MAXSOCKETS** parameter specifies the maximum number of sockets that can be obtained for a particular file system type. You must ensure that this specification is large enough to accommodate your installation workload. For example, each connection to your TN3270E Telnet server or FTP server requires one z/OS UNIX System Services socket. When the maximum number of sockets is allocated, then no more Telnet sessions, FTP sessions, or other applications that require z/OS UNIX System Services sockets can be started.

Note: If multiple **NETWORK** statements are defined, **MAXSOCKETS** can be specified for each **NETWORK** statement and will be enforced separately.

For details on the **BPXPRMxx** member, see:

- [z/OS UNIX System Services Planning](#)
- [z/OS MVS Initialization and Tuning Reference](#)

Performance considerations

Follow the guidelines found in the [z/OS MVS Initialization and Tuning Reference](#). If your installation is running Workload Manager, follow the guidelines found in [z/OS MVS Planning: Workload Management](#).

VTAM, TCP/IP, and some associated server applications must be able to obtain cycles to maintain their network presence. The following dispatching priority guidelines apply for these functions:

- In general, you should set VTAM and TCP/IP to a higher dispatching priority than that of the applications that use their services.
- For server applications such as **OMPROUTE**, **TN3270E** Telnet server, **IKED**, **NSSD**, and **FTPD**, set the priority value to the same value to which TCP/IP is set, or to a priority that is just below that value. If you are using WLM, assign these tasks to the **SYSSTC** service class. Additionally, you can make these tasks non-swappable so they are available during periods of high CPU usage. The MVS default program property table sets Telnet to be non-swappable and privileged, which automatically assigns the task to the **SYSSTC** service class.
- Set non-critical applications, such as Policy Agent and **TRMD**, to a lower priority.
- Set the **SNMP** agent and all the **SNMP** subagents to the same WLM service class so that they all have the same dispatching priority. Timeouts can occur if the **SNMP** subagents are set to a lower dispatching priority than the **SNMP** agent.

On systems with significant FTP activity, you can improve performance by placing the FTP program objects into the dynamic link pack area (LPA). Putting the FTP program objects into the dynamic LPA eliminates the need to load these program objects from DASD for each FTP session. You can place these program objects into the dynamic LPA using either of the following methods:

- Include the following statement in the **PROGxx** member of **SYS1.PARMLIB** and then issue a **SET PROG=xx** command:

```
LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
```

- Issue the following **SETPROG** command:

```
SETPROG LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
```

Tip: You can also place the SET PROG=xx command or the SETPROG command in a COMMNDxx SYS1.PARMLIB member to have the command issued at IPL time.

Requirement: If maintenance is applied to these program objects, you must update the program objects in storage using one of the following methods:

- Issue an LLA refresh command, and then issue a SET PROG=xx command that points to a PROGxx member that contains the following command:

```
LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
```

- Issue an LLA refresh command, and then issue the following SETPROG command:

```
SETPROG LPA,ADD,MODNAME(EZAFTPLS,FTPDNS,EZAFTPLC,FTP),DSNAME(LNKLST)
```

For more information, see [z/OS MVS System Commands](#).

Fast path support

For applications that have strict communications path length requirements, a fast path extension is provided to further reduce z/OS UNIX-to-TCP/IP stack communications. This extension is available to applications that use the UNIX System Services socket API, the z/OS XL C/C++ Runtime Library functions, and the native MVS socket APIs (such as C/C++, EZASMI macro, EZASOKET, REXX, or CICS socket APIs) provided by the Communications Server. It is not available to applications that are using the Pascal API.

With fast path support, communications are reduced for the following socket system calls:

- send()
- recv()
- sendto()
- recvfrom()
- sendmsg()
- recvmsg()

These performance enhancements are also available for the corresponding socket system calls on the z/OS UNIX asynchronous socket interface (BPX1AIO).

Rule: Automatic fast path support is activated by default.

Automatic fast path support does not have the limitations that exist with the fast path support that requires activation (see [“Activating fast path support” on page 42](#)). Most notably, automatic fast path supports POSIX signals.

Restriction: Because automatic fast path supports POSIX signals, applications that cannot handle interruptions by signals must continue to explicitly activate fast path support to use it. For more information about explicitly activating fast path support, see [“Activating fast path support” on page 42](#).

Activating fast path support

You can activate this feature for an entire z/OS UNIX process by using the z/OS UNIX environment variable `_BPXK_INET_FASTPATH`. The value of this variable determines whether a socket application is marked fast path. An XL C/C++ application can set the variable by using the `setenv` function, or you can export the variable to the z/OS UNIX shell environment before the socket application is started. An application that is using the z/OS UNIX API can set this variable by using the `BPX1ENV` service.

Rule: z/OS UNIX environment variables have a process-wide scope only; that is, they usually affect a single MVS address space only. For multiple UNIX processes within a single address space, the setting of this environment variable might vary for each process within the address space. It is not a problem if some of your applications use fast path services and others do not.

If you are using the `_BPXK_INET_FASTPATH` environment variable, the following restrictions apply to applications that are using the UNIX System Services socket API or the z/OS XL C/C++ Runtime Library functions:

- Applications are not compliant with the X/Open Portability Guides (XPG), and POSIX signals are not supported. Applications can be interrupted only with the SIGKILL terminating signal.
- You cannot use the interactive z/OS UNIX DBX debugger to debug an application. However, you can use the DBX debugger to develop and test an application without setting the environment variable, and then run the application in production with the environment variable set.

For environments that do not use common INET, set the value of this variable to the name that is specified on the TYPE parameter of the FILESYSTYPE statement in the BPXPRMxx parmlib member.

For common INET environments, the value that is used to set the environment variable depends on whether the application is using the TCP or UDP protocols. In a common INET environment, set the variable as follows:

- For UDP applications, set it to the name of the TCP/IP stack as specified on the NAME parameter of the SUBFILESYSTYPE statement in the BPXPRMxx parmlib member. The socket application is explicitly associated with the TCP/IP stack name specified in the environment variable. This means that the socket application can communicate with accessible partners only through the specified TCP/IP stack interfaces. For UDP, the environment variable overrides the common INET support. Take this contingency into account before you activate fast path for a UDP application.

Rule: You must use the `_BPXK_INET_FASTPATH` environment variable for UDP applications that require fast path support and affinity to a specific TCP/IP stack. If a UDP application establishes affinity to a specific TCP/IP stack by using other means, such as by setting the `_BPXK_SETIBMOPT_TRANSPORT` environment variable or by using `setibmopt()` or `BPX1PCT`, the setting of the fast path variable is ignored.

- For TCP applications, you can set the variable to an asterisk (*) to associate the application with any TCP/IP stack in the common INET configuration. This method allows all TCP/IP stacks that support the fast path model to obtain the fast path performance benefits automatically. TCP servers are not bound to a specific TCP/IP stack, even if the server specifies a specific TCP/IP stack name on the environment variable; instead, the server can listen for inbound connections across all TCP/IP stacks. When a connection arrives from the TCP/IP stack that is named in the environment variable at the time of the `accept()` call, it is automatically marked as fast path. Connections that arrive from TCP/IP stacks that are not named by the current environment variable value are not marked as fast path.

Guideline: Certain TCP/IP API functions, such as the resolver services [`gethostbyname()`, `gethostbyaddr()`, `getaddrinfo()`, and `getnameinfo()`] and the network interface identification services [`if_nameindex()`, `if_nametoindex()`, and `if_indextoname()`] use UDP sockets internally for their processing. If a specific TCP/IP stack name is specified on the environment variable, these hidden UDP sockets are associated with only the named TCP/IP stack, which might have undesirable effects. For example, any resolver API queries that result in communications with a domain name server occur only over the specified TCP/IP stack. As a result, it is best that TCP applications set the environment variable to the special asterisk (*) value. If the application requires affinity to a specific TCP/IP stack, it can do so by using any of the facilities that are provided by z/OS UNIX, such as `setibmopt()` and `BPX1PCT`. For more information about establishing affinity to a specific TCP/IP stack, see [z/OS UNIX System Services Planning](#).

Applications can also enable fast path processing for a single socket by issuing the `Iocc#FastPath` IOCTL for the socket, or by using the `w_iocctl()` or the `BPX1IOC` APIs. This IOCTL is effective only if it is issued against a socket that is already associated with a specific TCP/IP stack. Sockets are considered associated with a specific TCP/IP stack if they meet any of the following conditions:

- The application has explicit process affinity to a specific TCP/IP stack by setting the `_BPXK_SETIBMOPT_TRANSPORT` environment variable, or by using `setibmopt()`, `BPX1PCT`, or other methods.
- TCP/IP stack affinity is explicitly established for this socket by using the `SIOCSETRTTD` IOCTL.

- A `bind()` is already issued for the socket with a specific IP address, and not the IPv4 `INADDR_ANY` address or the IPv6 unspecified address, `in6addr_any`.
- A TCP streams socket that is connected, which includes TCP sockets that are returned as a result of `accept()` or sockets for which a `connect()` is issued.

The `Ioccc#FastPath` constant is defined in the `BPXYIOCC`. This IOCTL requires a 4-byte argument as input. Set this argument to a nonzero value to activate fast path, or a zero value to disable fast path on the specified socket.

TCP receive window

The z/OS Communications Server implementation calculates the receive window as two times the receive buffer size, minus any data in the receive buffer. The calculated receive window is then limited to the value of the `TCPMAXRCVBUFSIZE` parameter from the `TCPCONFIG` profile statement, unless Dynamic Right Sizing (DRS) is active for the connection.

DRS is a stack performance optimization that allows the TCP receive buffer size to expand because of network conditions. DRS is enabled for connections that meet the following criteria:

- The connections have inbound streaming workload.
- The round trip time (RTT) for network latency is 2 ms or longer.
- The initial receive buffer size is at least 64 KB.

When DRS is active for a connection, the advertised window follows a different set of rules:

- The maximum receive buffer size is changed to 2 MB.
- The receive buffer size is set to the estimated congestion window of the peer.

If CSM high virtual common or fixed storage is constrained and inbound data for a connection is queued in the receive buffer faster than the application can read and process it, DRS is disabled for the connection. You can determine whether DRS is active for a connection by examining the `TcpPrf` field value for the connection on the `Netstat ALL/-A` report output.

If a connection fails to meet the criteria for enabling DRS and thus DRS is disabled, the TCP/IP stack periodically reevaluates the connection characteristics and attempts to reactivate DRS. The TCP/IP stack activates DRS for the connection if the connection subsequently meets the criteria for DRS processing.

Guideline: When you tune for TCP data transmission, you must consider the send buffer size and the receive window size. For the z/OS Communications Server implementation, the amount of data on the network is limited by the smaller of the send buffer size and the receive window size.

TCP send window

The z/OS Communications Server implementation sets the send window to the advertised receive window of the partner. The stack uses the send window and the congestion window to control the outbound packet flow for this connection.

Use the send buffer size to determine the amount of application send data that TCP/IP can buffer for a connection. The connection send buffer size is initialized to the value that is specified on the `TCPSENDBFSIZE` parameter on the `TCPCONFIG` profile statement. An application can explicitly set the send buffer size for a connection to a value in the valid range for the `TCPSENDBFSIZE` by using `SETSOCKOPT()`.

ORS is a stack performance optimization that allows the TCP send buffer size for a connection to expand because of network conditions. ORS is enabled for connections that meet the following criteria:

- The round trip time (RTT) for network latency is 2 ms or longer.
- The initial send buffer size is at least 64 KB.

When ORS is active for a connection, the send buffer size is dynamically managed to optimize throughput up to maximum of 2 MB when the following criteria are met:

- CSM high virtual common or fixed storage is not constrained.
- Data that is appended to any existing data in an application send buffer exceeds the send buffer size.
- The send window and congestion window allow immediate transmission of new data that is beyond the current send buffer size.

When ORS is not active for a connection, the stack monitors the round trip time (RTT) for this connection and activates ORS if network conditions change. You can determine whether ORS is active for a connection by examining the `TcpPrf2` field value for the connection on the Netstat ALL/-A report output.

Guideline: When you tune for TCP data transmission, you must consider the send buffer size and the receive window size. For the z/OS Communications Server implementation, the amount of data on the network is limited by the smaller value of the send buffer size and the receive window size.

Outbound serialization

Sometimes, z/OS Communications Server tailors its processing for certain workloads to improve in-order packet delivery on multiprocessors. This performance optimization, which is called outbound serialization, can reduce CPU consumption and improve throughput. When outbound serialization is enabled for a TCP/IP connection, outbound packets for the connection leave z/OS Communications Server in the correct order. This optimization path reduces out-of-order packet processing on the receiver and minimizes unnecessary retransmissions of packets at the sender.

A connection is eligible for outbound serialization when it meets the following criteria:

- The connection receives four or more consecutive duplicate acknowledgements (ACKs).
- The initial send buffer size is at least 64 KB.

The stack activates outbound serialization for a connection in any of the following conditions:

- The connection has been identified as operating in bulk-data fashion, such as an FTP data connection, and has been registered to the bulk-mode ancillary input queue (AIQ) of an OSA-Express feature that is enabled for inbound workload queuing. Inbound workload queuing is always present (integrated into the base support) for the Network Express feature.
- The connection is eligible for outbound serialization and IPSEC is also enabled for this connection.
- The connection is eligible for outbound serialization, the round trip time for the connection equals or exceeds the specified or defaulted `QUEUEDRTT` parameter value on the `TCPCONFIG` profile statement. The stack determined that a significant number of retransmissions occurred for packets that were delivered out of order initially.

Considerations for multiple instances of TCP/IP

The z/OS Communications Server TCP/IP stack is a multiple-processor capable stack, which means that it can concurrently exploit all available processors on a system. Starting multiple stacks will not yield a significant increase in throughput.

In addition, running multiple z/OS Communications Server TCP/IP stacks requires additional system resources, such as storage, CPU cycles, and DASD. It also adds a significant level of complexity to the system administration tasks for TCP/IP.

For these reasons, it is suggested that in most cases you use the INET configuration, which supports a single TCP/IP stack. However, there are some special situations where running multiple stacks can provide a benefit. For example, you might want to run two separate stacks for intranet and Internet traffic.

Common INET PFS

If you want to run multiple z/OS Communications Server TCP/IP stacks concurrently, you must use the Common INET (CINET) configuration. In this configuration, up to a maximum of eight TCP/IP stacks can be active at any time.

When the CINET configuration is used, the CINET PFS is inserted between the LFS and the TCP/IP PFS for each stack. The CINET PFS maintains an internal copy of each TCP/IP stack's IP configuration, so that it can preroute a socket call to the correct TCP/IP stack. This allows most socket programs to run with multiple stack support with no change to the application. In addition, CINET supports IPv6, and is capable of supporting underlying TCP/IP stacks in IPv4/IPv6 dual mode or in IPv4-only mode.

You can specify your choice of INET (single stack) or CINET (multiple stack) support on the NETWORK, DOMAINNAME, FILESYSTYPE, and SUBFILESYSTYPE statements of SYS1.PARMLIB(BPXPRMxx). For more information about the BPXPRMxx statements, see [“Specifying BPXPRMxx values for a CINET configuration”](#) on page 55 and [z/OS UNIX System Services Planning](#).

Port management overview

When there is a single transport provider, and the relationship of server to transport provider is 1:1, port management is relatively simple. Using the PORT statement, the port number can be reserved for the server in the PROFILE.TCPIP for that single transport provider.

Port management becomes more complex in a CINET environment where there are multiple transport providers (multiple instances of TCP/IP) and a potential for multiple combinations of the same server (for example, z/OS UNIX and TN3270E Telnet servers).

In a multiple transport provider environment, the following questions need to be answered for each server in an installation:

- Is the server generic so that it can communicate with multiple TCP/IPs or does the server have an affinity for one instance of the transport providers and can communicate with only one TCP/IP?
- How can ports be reserved across multiple transport providers? When is the port reservation determined by MVS rather than by the job name, procedure name, or user ID?
- How can you synchronize between BPXPARMS and PORTRANGE for ephemeral port reservation?
- How can TCP/IP distinguish between two different instances of Telnet (z/OS UNIX Telnet and TN3270E Telnet servers)?

Generic server versus server with affinity for a specific transport provider

This information describes the differences between generic servers and servers with affinities for specific transport providers.

Generic server

A generic server, a server without an affinity for a specific transport provider, provides service to any client on the network. (See [Figure 3 on page 47](#).) FTP is an example of a generic server. The transport provider is merely a connection linking client and server. The service File Transfer is not related to the internal functioning of the transport provider, and the server can communicate concurrently over any number of transport providers.

Figure 3. Generic server

Server with an affinity for a specific transport provider

When the service is related to the internal functioning of the transport provider (for example, Telnet, OMPROUTE, OSNMPD, and the Netstat command), there must be an explicit binding of the server application to the chosen transport provider. (See [Figure 4 on page 48.](#)) There must also be a way to specify the single transport to be chosen.

Figure 4. Server with affinity for a specific transport provider

With the exception of applications that use the socket API provided by TCP/IP, other IBM-supplied applications that use the z/OS UNIX socket API and that must bind to a specific transport provider use the z/OS UNIX socket call `setibmopt()` (see [z/OS C/C++ Runtime Library Reference](#)) to specify which TCP they have chosen. A C function `__iptcpn()`, described in the [z/OS C/C++ Runtime Library Reference](#), enables the application to search the TCPIP.DATA file to find the name of the specific TCP/IP. (See [Figure 5 on page 49](#).) An application that uses the z/OS Language Environment run time can also establish stack affinity by setting the environment variable `_BPXK_SETIBMOPT_TRANSPORT`.

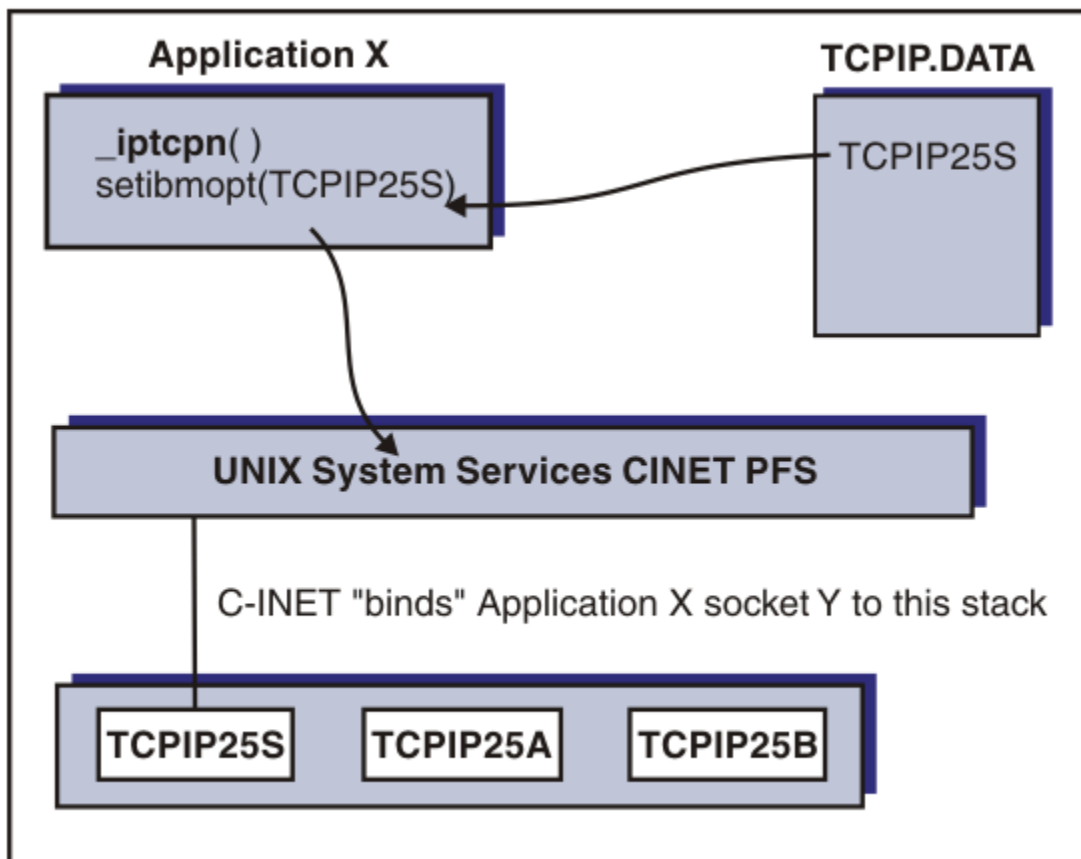

Figure 5. Example of binding an application to a specific transport provider

Generic servers in a CINET environment

In z/OS Communications Server, you can configure multiple TCP/IP stacks in a single MVS image using the CINET feature. In a CINET configuration, an application using the z/OS UNIX socket interface can get transparent access to all the TCP/IP protocol stacks configured under CINET. For example, when an application coded to z/OS UNIX sockets performs a `SOCKET/BIND/LISTEN` in a CINET environment, the request is propagated by CINET to all the TCP/IP stacks. This application can then service client requests that arrive into any of the configured TCP/IP stacks without having any awareness of this fact. This type of application is often referred to as a *generic server* or *daemon*.

The following servers or daemons shipped by z/OS Communications Server are generic:

- DCAS
- FTPD
- NSSD
- Policy Agent
- RPCBIND
- SNTPD
- syslogd
- TIMED
- TN3270E Telnet
- z/OS UNIX POPPER
- z/OS UNIX Portmap

- z/OS UNIX REXECD
- z/OS UNIX RSHD
- z/OS UNIX TELNETD

z/OS UNIX RSHD, REXECD and TELNETD are usually started by the INETD daemon, which is shipped as part of the z/OS UNIX. Because INETD is also a generic daemon, any server processes started by INETD inherently become generic servers as well.

If a server started by INETD (a generic server) requires affinity to a specific stack, this affinity can be accomplished by use of the `_BPXK_SETIBMOPT_TRANSPORT` environment variable. For more information about the `_BPXK_SETIBMOPT_TRANSPORT` environment variable, see [z/OS UNIX System Services Planning](#).

The `_BPXK_SETIBMOPT_TRANSPORT` environment variable, when set, has an effect similar to the `setibmopt()` function call provided by the XL C/C++ compiler and described in the [z/OS C/C++ Runtime Library Reference](#). This variable can be set in the JCL for a started procedure or batch job that executes a z/OS UNIX C/C++ program to indicate which TCP/IP stack instance the application should bind to. TCP/IP applications that require affinity to a specific TCP/IP stack, like OSNMPD and OMPROUTE, use the `setibmopt()` function call directly. The `_BPXK_SETIBMOPT_TRANSPORT` environment variable basically provides the ability to bind a generic server type of application to a specific stack.

For example, if you had two TCP/IP stacks configured under CINET, one named TCPIP and the other TCPIPOE, and you wanted to start an FTPD server instance that was associated with TCPIPOE, you could modify the FTPD procedure to set the `_BPXK_SETIBMOPT_TRANSPORT` environment variable as follows:

```
//FTPD  PROC MODULE='FTPD',PARMS='TRACE'
//FTPD  EXEC PGM=&MODULE,REGION=7M,TIME=NOLIMIT,
//      PARM=('POSIX(ON) ALL31(ON)',
//      'ENVAR("_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE")',
//      '/&PARMS')
//CEEDUMP DD SYSOUT=*
//SYSFTSX DD DISP=SHR,DSN=TCPV34.STANDARD.TCPXLBIN
```

All the parameters specified prior to the slash (/) in the parameter statement are processed by the XL C/C++ run-time library. Parameters to be passed to the FTPD program must appear after the slash (/). Also note how the parameters were split over three lines in this example because they could not fit on a single line.

The following example uses JCL for the started procedure for INETD:

```
//INETD  PROC
//*****
//INETD  EXEC PGM=BPXBATCH,
//*      PARM='PGM /usr/sbin/inetd /etc/inetd.conf'
//      PARM='PGM /usr/sbin/inetd //'USER1.INETD.CONF'''
//*      PARM='PGM /usr/sbin/inetd //'SYS1.TCPPARMS(INETDCNF)'''
//*
//STDERR DD PATH='/tmp/inetd.debug.stderr',
//      PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
//      PATHMODE=SIRWXU
//STDOUT DD PATH='/tmp/inetd.debug.stdout',
//      PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
//      PATHMODE=SIRWXU
//STDENV DD DISP=SHR,DSN=USER1.INETD.ENVIRON
//*STDENV DD DISP=SHR,DSN=SYS1.TCPPARMS(INETDENV)
```

The STDENV data set would contain the `_BPXK_SETIBMOPT_TRANSPORT` variable as follows:

```
_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE
```

In these examples, INETD was also passed its configuration file as a parameter. In our examples, this file is an MVS data set rather than a z/OS UNIX file; therefore, it requires the additional double slash (//) and quotes that the example shows.

Multiple instances of INETD are not allowed, even if each instance is bound to a different TCP/IP stack. This is an INETD restriction, not a TCP/IP restriction. Therefore, if you decide to make INETD have affinity

to a specific stack, then that is the only INETD instance that you will be able to have running in that MVS image.

Notes:

1. The `_BPXK_SETIBMOPT_TRANSPORT` variable should be specified only for a generic server type of application.

If specified for a non-generic server and/or non-z/OS UNIX application it will not have any effect.

2. The name specified for `_BPXK_SETIBMOPT_TRANSPORT` must match the job name associated with the TCP/IP stack.

If the name specified does not match the job name of any TCP/IP stacks defined for CINET, the application will receive a z/OS UNIX return code of X'3F3' and a return value of X'005A' and may be accompanied by the following message:

```
EDC8011I A name of a PFS was specified that either is
not configured or is not a Sockets PFS.
```

If the name specified does not match the job name of any currently active TCP/IP stack defined under CINET, the application will receive a z/OS UNIX return code of X'70' and a return value of X'0296' and may be accompanied by the following message:

```
EDC5112I Resource temporarily unavailable.
```

3. For more detailed information about requesting transport affinity, see [z/OS UNIX System Services Planning](#).

Port reservation across multiple transport providers

When there are multiple transport providers, be sure to synchronize the PORT statements in each of the PROFILE.TCPIP files to ensure that the port reservations for each stack match the port definitions for the servers that will be using that stack.

For more information about reserving ports with the PORT statement, see [Chapter 5, “TCP/IP Customization,” on page 235](#).

Ephemeral ports

When running with multiple transport providers, just as it is necessary to synchronize PORT reservations for specific applications across all stacks, it is required to synchronize reservations for port numbers that will be dynamically assigned across all stacks. These are the ephemeral ports above 1023, which are assigned by the stack when none is specified on the application `bind()`. To reserve a group of ports in the PROFILE.TCPIP, use PORTRANGE. For more information about PORTRANGE, see [Chapter 5, “TCP/IP Customization,” on page 235](#). Specify the same PORTRANGE for every stack. In addition, you must let the z/OS UNIX CINET know which ports are guaranteed to be available on every stack. The following example reserves ports 40000 - 41999 in the two required files:

- PROFILE.TCPIP
 - PORTRANGE 40000 2000 TCP OMVS ; Reserved for OMVS
 - PORTRANGE 40000 2000 UDP OMVS ; Reserved for OMVS
- BPXPRMxx parmlib member
 - NETWORK DOMAINNAME(AF_INET)
 - INADDRANYPORT(40000)
 - INADDRANYCOUNT(2000)

Notes:

1. When IPv6 is configured and there are two NETWORK statements, INADDRANYPORT and INADDRANYCOUNT need to be specified only for the NETWORK statement for AF_INET and not for

AF_INET6. If they are specified for AF_INET6, they are ignored and the values from the NETWORK statement for AF_INET are used if provided. Otherwise, the default values are used.

2. In a CINET environment, you can use IBM Health Checker for z/OS to check whether the range of ports specified by the INADDRANYPORT and INADDRANYCOUNT operands of the BPXPRMxx parmlib member is reserved for OMVS on the TCP/IP stack. For more information about [IBM Health Checker for z/OS](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

Selecting a stack when running multiple instances of TCP/IP

Socket application programs in a multi-stack (CINET) environment must contend with the following questions:

- How the socket program selects which TCP/IP stack to use for its socket communication
- How the TCP/IP resolver code executing in the socket application address space decides which TCP/IP resolver configuration data sets to allocate

Note: If a resolver GLOBALTCPIPDATA setup file is used, a local TCPIP.DATA cannot override any explicit statements in the global file and cannot override any resolver statements. Therefore, in a CINET environment, the TCPIPJOBNAME statement should not be specified in the GLOBALTCPIPDATA file. Also, using the GLOBALTCPIPDATA file with CINET requires that the resolver TCPIP.DATA statements are able to be used by all stacks. For example, the IP addresses specified by the NameServer statement must be accessible from all stacks. If they are not, then the GLOBALTCPIPDATA file should not be used and you should continue with multiple TCPIP.DATA data sets. For details, see [Chapter 13, “The resolver,”](#) on page 753.

To answer these questions, a distinction must be made between standard servers and clients (those that come with the z/OS Communications Server product), and other socket application programs, including those you might have written yourself.

Standard servers and clients

The anchor configuration data set is the TCPIP.DATA data set. This is the base resolver configuration data set with information on host name, domain origin, and so on. It holds the TCPIPJOBNAME statement, which identifies the TCP/IP stack to use, and the DATASETPREFIX statement, which is used by the resolver code and other services when allocating configuration data sets. For more information on these data sets, see [“Configuration files for TCP/IP applications”](#) on page 25.

The key to selecting both a specific stack and resolver configuration data sets is to control which TCPIP.DATA data set a standard server or client address space allocates. Applications that use the z/OS UNIX API can use Common INET to determine which stack an application will use. But, it is important to ensure that the search order and the contents of the resolver configuration data set are understood.

Native MVS servers and clients search for TCPIP.DATA in sequences as described in [“Search orders used in the native MVS environment”](#) on page 808.

z/OS UNIX servers and clients will search for TCPIP.DATA in sequences as described in [“Search orders used in the z/OS UNIX environment”](#) on page 803.

Nonstandard servers and clients

Nonstandard servers and clients (those that do not come with the z/OS CS product) also use TCPIP.DATA to decide which resolver configuration data sets to allocate. Depending on the socket API used, they might or might not use the TCPIPJOBNAME parameter to select a stack.

If you run sockets programs from other products or vendors, you may want to know which sockets API was used to develop the program, and which techniques, if any, the program uses to specify the name of the TCP/IP system address space. As long as application programs that use a TCP/IP socket library do not specify anything specific on calls `setibmopt()`, `Initialize`, or `INITAPI`, the TCPIPJOBNAME from a TCPIP.DATA data set will be used for finding a TCP/IP system address space name.

Table 7 on page 53 depicts the differences that prevail in stack selection depending on the TCP/IP socket API under which you are running the socket program.

<i>Table 7. How your own socket programs select a stack</i>			
C sockets	Callable and Macro	Pascal sockets	REXX sockets
SETIBMOPT or TCPIPJOBNAME from TCPIP.DATA	TCPNAME on INITAPI or TCPIPJOBNAME from TCPIP.DATA	TCPIPJOBNAME from TCPIP.DATA	Service on Initialize or TCPIPJOBNAME from TCPIP.DATA
Callable and Macro programs might have a configuration option to specify the TCP/IP system address space name, or might interrogate the available stacks with the getibmopt() call.			

A Callable or Macro program does not have to call INITAPI. If INITAPI is not called, an implicit INITAPI is performed with the value taken from TCPIPJOBNAME in a TCPIP.DATA data set. If INITAPI is called with the TCPNAME parameter specified as a space, the TCP/IP system address space name results in the TCPIPJOBNAME keyword value.

In a z/OS UNIX INET (single stack) environment, the socket application program is always associated with the single TCP/IP stack. In the z/OS UNIX Common INET (CINET) environment, your application will be associated with multiple TCP/IP stacks unless the application specifically associates with a particular stack using the z/OS UNIX socket call setibmopt(). For other ways of requesting stack affinity in a CINET environment, see [z/OS UNIX System Services Planning](#).

TCP/IP TSO clients

TSO client functions can be directed against any of a number of TCP/IP stacks. Obviously, the client function must be able to find the TCPIP.DATA appropriate to the stack of interest at any one time. Some TSO client commands provide a parameter to specify the stack to be used. For those that do not, the following methods are available for finding the relevant TCPIP.DATA:

- Add a SYSTCPD DD statement to your TSO logon procedure. The issue with this approach is that a separate TSO logon procedure per stack is required, and users have to log off TSO and log on again using another TSO logon procedure in order to switch from one stack to another.
- Use one common TSO logon procedure without a SYSTCPD DD statement. Before a TSO user starts any TCP/IP client programs, the user has to issue a TSO ALLOC command wherein the user allocates a TCPIP.DATA data set to DD name SYSTCPD. To switch from one stack to another, the user has to deallocate the current SYSTCPD allocation (for example, TSO FREE command) and allocate another TCPIP.DATA data set.
- Combine the first and second methods. Use one logon procedure to specify a SYSTCPD DD for a default stack. To switch stacks, issue TSO ALLOC to allocate a new SYSTCPD. To switch back, issue TSO ALLOC again with the name that was on the SYSTCPD DD in the logon procedure. The disadvantage to this approach is that the name that was on the SYSTCPD DD is hidden in the logon procedure and needs to be retrieved or remembered.

The last method can be implemented by creating a small REXX program for every TCP/IP stack on your MVS system. For each stack create a REXX program with the name of the stack (for example, T18A or T18B). Whenever TSO users want to use the T18A stack, they run the T18A REXX program. Any TCP/IP functions invoked thereafter will use the T18A stack for socket communication. If users want to switch to the T18B stack, they run the T18B REXX program. See [Figure 6 on page 54](#) for an example.

```

/* REXX "T18B" */
/*****
/*
/* Switch TSO Address Space to use the T18B Stack.
/* Subsequent NETSTAT command will be directed toward
/* the T18BTCP stack.
/*
/*
*****/
Say 'Switching to T18BTCP stack'

msgstat = msg()
z = msg("OFF")
"FREE FI(SYSTCPD)"
"ALLOC FI(SYSTCPD) DA('TCPIP.T18B.TCPPARMS(TCPDATA)') SHR"
z = msg(msgstat)

exit(0)

```

Figure 6. REXX program to switch TSO user to another TCP/IP stack

Selecting configuration data sets

The resolver code and other services that execute as part of the socket program address space to service calls such as `gethostbyname()`, `getservbyname()` and `getprotobyname()` allocate one or more resolver configuration files to service these calls. All socket programs, including standard servers and clients and homegrown socket programs, need access to resolver configuration files. For information on how the resolver configuration files are found and used, see [“Configuration files for TCP/IP applications”](#) on page 25.

Sharing resolver configuration data sets

The general recommendation is to use separate `DATASETPREFIX` values for each stack and create separate copies of the required configuration data sets; at the very least, create separate copies of the resolver configuration data sets. For a test and a production stack, however, you would probably use different `DATASETPREFIX` values. However, if the stacks are functionally identical, you may share the same `DATASETPREFIX` values and many of the same configuration data sets. You need separate `TCPIP.DATA` data sets because of the two different `TCPIPJOBNAME`s. On the other hand, you may choose to share the resolver configuration data sets between the stacks by using the same `DATASETPREFIX` value in each `TCPIP.DATA` data set.

In addition to separate `TCPIP.DATA` data sets, separate `/etc/resolv.conf` files might also be necessary. If this is the case, use the environment variable `RESOLVER_CONFIG` to point to the appropriate resolver information.

Exercise caution if servers use `DATASETPREFIX` to allocate server-specific configuration data sets. Try to use explicit allocation as far as possible in your server JCL procedures. Most servers allow you to explicitly allocate their configuration data sets using DD statements.

Some servers may use `DATASETPREFIX` to create new data sets. Servers that do create new data sets allow you to specify an alternate data set prefix for the data sets that are created. NPF creates new sequential data sets with captured print data. NPF has a special keyword in `NPF.DATA` for this purpose; it is called `NPFPRINTPREFIX`. If this keyword is specified, NPF will use that as the high-level qualifier for newly created print data sets instead of taking the `DATASETPREFIX` value from `TCPIP.DATA`.

Specifying BPXPRMxx values for a CINET configuration

For a detailed description of parameters in SYS1.PARMLIB(BPXPRMxx), see [z/OS UNIX System Services Planning and z/OS MVS Initialization and Tuning Guide](#).

```
/* AF_INET file system for sockets      */
/* CINET support - BPXTCINT */

FILESYSTYPE TYPE(CINET)
    ENTRYPOINT(BPXTINT) 1
NETWORK DOMAINNAME(AF_INET)
    DOMAINNUMBER(2)
    MAXSOCKETS(10000) 2 TYPE(CINET)
    INADDRANYPORT(40000) 3
    INADDRANYCOUNT(2000)
NETWORK DOMAINNAME(AF_INET6)4
    DOMAINNUMBER(19)
    MAXSOCKETS(10000) 2 TYPE(CINET)
SUBFILESYSTYPE NAME(TCPIP1A) 5
    TYPE(CINET)
    ENTRYPOINT(EZBPFINI) 6
    DEFAULT 7
SUBFILESYSTYPE NAME(TCPIP1B) 5
    TYPE(CINET)
    ENTRYPOINT(EZBPFINI)
```

Figure 7. SYS1.PARMLIB(BPXPRMxx) for CINET

Notes:

1. CINET and BPXTCINT specify the use of CINET.
2. The MAXSOCKETS operand specifies the maximum number of sockets that can be obtained for the given file system type. It should be large enough for the number of sockets needed for applications using z/OS Communications Server. MAXSOCKETS is enforced independently for AF_INET (IPv4 sockets) and AF_INET6 (IPv6 sockets).
3. The INADDRANYPORT and INADDRANYCOUNT operands specify the first ephemeral port number and the range of ports to be used by z/OS UNIX CINET. The port range specified should also be reserved for CINET use in the TCP/IP profile using the port reservation statements. For details, see “Port reservation across multiple transport providers” on page 51. You can use IBM Health Checker for z/OS to check whether the range of ports specified is reserved for OMVS on the TCP/IP stack. For more information about IBM Health Checker for z/OS, see [z/OS Communications Server: IP Diagnosis Guide](#).
4. This additional NETWORK statement is required if you want a TCP/IP stack to also support IPv6. Omit this statement if you do not want the stack to support IPv6 (that is, the stack will support IPv4 only).
5. A transport provider stack for CINET is specified with a SUBFILESYSTYPE statement. The NAME field must match the address space name for the TCP/IP started task as well as the TCPIPJOBNAME parameter in TCPIP.DATA. In our example, the name of the first stack is TCP1A and the name of the second stack is TCP1B.
6. EZBPFINI identifies a z/OS Communications Server TCP/IP stack. For a z/OS Communications Server TCP/IP stack, this is the only valid value.
7. Keyword DEFAULT specifies which transport provider stack is to be used as the default stack for z/OS UNIX. If DEFAULT is not specified, the first active stack will be used as the default stack. The sequence of SUBFILESYSTYPE statements is arbitrary if one stack is identified with the keyword DEFAULT. TCP1A is the default stack in [Figure 7 on page 55](#).

Considerations for Enterprise Extender

The Enterprise Extender (EE) network connection is a simple set of extensions to the existing open high-performance routing (HPR) technology. It performs an efficient integration of the HPR frames using UDP/IP packets. To the HPR network, the IP backbone is a logical link. To the IP network, the SNA traffic is UDP datagrams that are routed without any hardware or software changes to the IP backbone. Unlike gateways, there is no protocol transformation and unlike common tunneling mechanisms, the integration

is performed at the routing layers without the overhead of additional transport functions. The advanced technology enables efficient use of the intranet infrastructure for support of IP-based client accessing SNA-based data (for example, Telnet emulators or web browsers using services such as IBM's Host On-Demand) as well as SNA clients using any of the SNA LU types.

Enterprise Extender seamlessly routes packets through the network protocol *edges*, eliminating the need to perform costly protocol translation and the store-and-forward associated with transport-layer functions. Unlike Data Link Switching (DLSw), for example, there are no TCP retransmit buffers and timers and no congestion control logic in the router because it uses connectionless UDP and the congestion control is provided end system to end system. Because of these savings, the *edge* routers have less work to do and can perform the job they do best, which is forwarding packets instead of incurring protocol translation overhead and maintaining many TCP connections. Data center routers can handle larger networks and larger volumes of network traffic, thus providing more capacity.

Enterprise Extender supports both the IPv4 and IPv6 addressing models. For more information about using Enterprise Extender, see *z/OS Communications Server: SNA Network Implementation Guide* and the EE information in *Migrating Subarea Networks to an IP Infrastructure Using Enterprise Extender* (IBM Redbooks).

You can use QDIO inbound workload queuing on an OSA-Express3 feature (or later feature) to improve throughput for both inbound Enterprise Extender (EE) packets and for inbound non-EE traffic over the same interface. Inbound workload queuing is integrated into the base support and is always present for the Network Express feature. For more information, see “[Inbound workload queuing](#)” on page 75.

Considerations for VIPA

The Internet Protocol (IP) is a connectionless protocol. IP packets are routed from the originator through a network of routers to the destination. All physical adapter devices in such a network, including those for client and server hosts, are identified by an IP Address which is unique within the network. The important point about IP is that a failure of an intermediate router node or adapter will not prevent a packet from moving from source to destination, as long as there is an alternate path through the network.

TCP sets up a connection between two endpoints, identified by the respective IP addresses and a port number on each. Unlike failures of an adapter in an intermediate node, if one of the endpoint adapters (or the link leading to it) fails, all connections through that adapter fail and must be reestablished. If the failure is on a client workstation host, only the relatively few client connections are disrupted and usually only one person is inconvenienced. However, an adapter failure on a server means that hundreds or thousands of connections may be disrupted. On an S/390® or System z server with large capacity, the number may run to tens of thousands.

A Virtual IP Address, or VIPA in TCP/IP for z/OS, alleviates this situation. A VIPA is configured in the same way as a normal IP address for a physical adapter, except that it is not associated with any particular device. To an attached router, the TCP on z/OS simply looks like another router. When the TCP receives a packet destined for one of its VIPAs, the inbound IP function of the stack notes that the IP address of the packet is in the stack's Home list and passes the packet up the stack. Assuming the stack has multiple adapters or paths to it (including XCF from other TCP stacks in a sysplex), if a particular physical adapter fails, the attached routing network will route VIPA-targeted packets to the stack using an alternate route.

While this removes hardware and associated transmission media as a single point of failure for large numbers of connections, the connectivity of a server can still be lost through a failure of a single stack or an MVS image. The VIPA can be configured on another stack with a manual process, but this requires the presence of an operator or programmed automation.

Dynamic VIPA Takeover enables Dynamic VIPAs to be moved without human intervention or programmed automation to allow new connections to a server at the same IP address as soon as possible. This can reduce downtime significantly. With Dynamic VIPA Takeover you can configure one or more TCP/IP stacks to be backups (VIPABACKUP statement) for a particular Dynamic VIPA. If the stack or MVS image where the Dynamic VIPA is active is terminated, one of the backup stacks automatically activates that Dynamic VIPA. The existing connections will be terminated but can be quickly reestablished on the stack that is taking over.

Notes:

1. Because a VIPA is associated with a z/OS TCP/IP stack and is not associated with a specific physical network attachment, it can be moved to a stack on any image in the sysplex, or even to a z/OS TCP/IP stack not in the sysplex as long as the address fits into the installation's network configuration.
2. If using VIPA along with an intelligent bridge or switch, ensure that **Port fast mode** (Cisco) is enabled. This helps to decrease the amount of time the VIPA is unreachable in scenarios where there is dynamic movement of VIPA (dynamic or static). For more information, see your bridge or switch manual.

You may also associate a particular Dynamic VIPA address with an application using the SIOCSVIPA or SIOCSVIPA6 ioctl command or by BINDing explicitly to the Dynamic VIPA address. If the Dynamic VIPA address is within the VIPARANGE profile statement, then this Dynamic VIPA address will be created dynamically. This type of configuration enables a Dynamic VIPA to become an address of an application in a sysplex.

With sysplex distributor you can distribute connection requests destined for Dynamic VIPAs to other stacks in the sysplex. You can use the VIPADISTRIBUTE profile statement to designate up to 32 stacks and 256 ports where connections for a particular DVIPA can be distributed, including the stack where the DVIPA is defined.

The distributing stack (the stack where the VIPADISTRIBUTE statement was coded) might use either WLM or a combination of WLM and Quality of Service (QoS) performance information to determine where to forward new connection requests. If the distributing stack/MVS image fails, connections forwarded to target stacks can be preserved by having the Dynamic VIPA address backed up on another stack.

Similarly, a stack can immediately take back a Dynamic VIPA address from another stack. If the original stack used an address specified with VIPADEFINE with the keyword MOVEABLE IMMEDIATE (the default), then the Dynamic VIPA is moved as soon as the second stack requests ownership. The second stack assumes responsibility for forwarding packets for existing connections to the appropriate stack. If MOVEABLE WHENIDLE was specified, ownership does not pass until all existing connections on the current stack are closed.

For detailed information about VIPA, see [Chapter 7, “Virtual IP Addressing,”](#) on page 389.

Considerations for Fast Response Cache Accelerator

Fast Response Cache Accelerator (FRCA) is a Communications Server function that can significantly improve the performance of the z/OS HTTP Server and the WebSphere® Application Server on z/OS. Web pages are cached within the operating system kernel and requests are handled without traversing the entire kernel or entering the user space. For more information about configuring the WebSphere Application Server to use the FRCA function, see the WebSphere Application Server documentation at http://www.ibm.com/support/knowledgecenter/SSEQTP/mapfiles/product_welcome_was.html.

FRCA also provides the ability to perform content-based quality-of-service (QoS) classification by selecting an appropriate QoS policy for each individual URI in the HTTP request. For more information on specifying individual URIs, see the [Policy Agent and policy applications](#) topic in [z/OS Communications Server: IP Configuration Reference](#).

Use the Netstat CACHINFO/-C commands to display information about FRCA statistics. Statistics are displayed for each listening socket configured for FRCA support. For more information on the Netstat CACHINFO/-C reports, see [z/OS Communications Server: IP System Administrator's Commands](#).

Considerations for extended address volumes

As of Version 1 Release 10, z/OS supports extended address volumes (EAVs). EAVs are volumes greater than 65,520 cylinders. The part of an EAV beyond the first 65,536 cylinders is called the extended address space (EAS). Not all data sets on an EAV can be in the EAS. A data set that could be in the EAS, whether it actually is in the EAS or not, is said to be an EAS-eligible data set.

Rule: Do not allocate data sets that are used by Communications Server as EAS-eligible data sets, except as follows:

- The FTP client and server allow transfer to or from the following types of EAS-eligible data sets:
 - Physical sequential basic format data sets
 - Physical sequential large format data sets
 - Physical sequential extended format data sets
 - Partitioned data sets (PDSs)
 - Libraries
- The following FTP configuration files can be EAS-eligible data sets:
 - ANONYMOUSLOGINMSG
 - ANONYMOUSMVSINFO
 - BANNER
 - FTP.DATA

Restriction: The TSO HOMETEST command cannot process FTP.DATA when it is an EAS-eligible data set.

- LOGINMSG
- MVSINFO
- NETRC
- SOCKSCONFIGFILE

For more information about using extended address volumes, see [z/OS DFSMS Using the New Functions](#).

Considerations for networking hardware attachment

This information provides general networking hardware attachment information and considerations associated with the IBM Z platform. Most of the information included here is associated with the IBM Network Express feature using the EQDIO system architecture and the IBM OSA-Express (OSA) feature using the QDIO system architecture. Both features provide the OSA functions for providing external IP network connectivity directly to the external LAN (Ethernet).

OSA Terminology

The following OSA networking related topics describe capabilities and functions that are provided by a combination of z/OS Communications Server software and the Open Systems Adapter (OSA) firmware or hardware. Most of the functions described in this section apply to both the OSA-Express (QDIO) and the Network Express (EQDIO) features. The Network Express feature continues to provide OSA functionality and general references to OSA apply to both features.

For the purposes of planning the network configuration of the Network Express feature, users can view the configuration requirements for Network Express as being very similar, but simplified, of OSA-Express.

In this section, when an OSA function is being described the following terminology conventions are used:

1. The term OSA is used when the function being described is common to the Network Express feature and the IBM OSA-Express (OSA) feature..
2. The terms OSA-Express, IPAQENET, IPAQENET6, OSD and QDIO are used if the function or task being described is specific to the OSA-Express feature or the QDIO architecture.
3. The terms Network Express, EQENET, EQENET6, OSH and EQDIO are used if the function being described is specific to the Network Express feature or the EQDIO architecture.

Virtual LAN

A local area network (LAN) is a broadcast domain. Nodes on a LAN can communicate with each other without a router, and nodes on different LANs need a router to communicate. A virtual LAN (VLAN) is a configured logical grouping of nodes using switches. Nodes on a VLAN can communicate with each other as if they were on the same LAN, and nodes on different VLANs need a router to communicate.

OSA VLAN

The IBM Open Systems Adapter (OSA) technology provides support for IEEE standards 802.1p/q, which describes priority tagging and VLAN identifier tagging. Deploying VLAN IDs allows a physical LAN to be partitioned or subdivided into discrete virtual LANs. This support is provided by the z/OS TCP/IP stack and the OSA

When you use VLAN IDs, the z/OS TCP/IP stack can have multiple connections to the same OSA feature. One connection is allowed for each unique combination of VLAN ID and IP version (IPv4 or IPv6). Each connection is defined by an INTERFACE statement and uses one channel unit address, or device number, for communication. For IPAQENET, the device number is assigned by VTAM from the DATAPATH parameter of the TRLE definition. For EQENET, the device number is assigned by the DEVNUM parameter on the INTERFACE statement. The configured device and the actual device used for EQENET can differ.

Tip: Each INTERFACE statement appears as a unique IP interface to the stack. When you configure multiple INTERFACE statements to the same OSA feature, each INTERFACE must also appear as a unique IP interface, for example, a unique IP address, VLAN, and subnet.

To configure one or more VLANs for a single OSA feature, take the following steps.

- For an OSA-Express feature, in the TCP/IP profile configure:
 - An IPAQENET INTERFACE statement for each required IPv4 interface.
 - An IPAQENET6 INTERFACE statement for each required IPv6 interface.
- For a Network Express feature, in the TCP/IP profile configure:
 - An EQENET INTERFACE statement for each required IPv4 interface
 - An EQENET6 INTERFACE statement for each required IPv6 interface.

VLANID

Configure a VLANID value on each IPv4 INTERFACE statement and each IPv6 INTERFACE statement on this stack for this OSA feature. Within each IP version, these VLANID values must be unique.

Restriction: The stack supports a maximum of 32 VLAN interfaces per IP version to the same OSA port.

VMAC

Configure the VMAC parameter on each of the INTERFACE statements with the default ROUTEALL attribute.

Requirement: VMAC is required when:

- you configure multiple INTERFACE statements for the same OSA and IP version.
- you configure one or more INTERFACE statements for Network Express.

Requirement: The INTERFACE statement for the Network Express feature requires the VMAC parameter.

When you configure a VMAC you can specify the VMAC address or OSA can generate it.

Rule: If you specify a VMAC address, it must be unique for each INTERFACE statement. The VMAC address also must be unique on the external LAN.

Tip: It can become complicated to coordinate unique user defined VMAC addresses. An OSA generated VMAC address is guaranteed to be unique among all of the OSA features on the LAN. It is recommended to use an OSA generated VMAC address.

Subnet

Configure a unique subnet for each IPv4 interface for this OSA feature, by using the subnet mask specification on the IPADDR parameter on the INTERFACE statement.

Requirement: Subnet is required when:

- The OSA feature is the OSA-Express feature and more than one INTERFACE statement is defined or the INTERFACE statement also defines SMCIPADDR (SMC-Rv2).
- The OSA feature is Network Express.

OMPROUTE

If you are using OMPROUTE and OMPROUTE is not configured to ignore this interface, ensure that the subnet mask value that you configure on the INTERFACE statement in the TCP/IP profile matches the subnet mask that is used by OMPROUTE for this interface. The subnet mask that OMPROUTE uses is the subnet mask value that is defined on the corresponding OMPROUTE statement, OSPF_INTERFACE, RIP_INTERFACE, or INTERFACE, for this interface. If no OMPROUTE statement is specified for this interface, the subnet mask that OMPROUTE uses is the class mask for the interface IP address.

Device selection

Each INTERFACE statement requires a unique device for the associated OSA CHPID. Ensure that a device is (or enough devices are) available. Note. Available means, defined in HCD and online to z/OS. The device used for each interface must be associated with the correct adapter (CHPID). The specific device number used for each interface is arbitrary. Devices are dynamically assigned during INTERFACE activation, typically using the next available device. OSA devices are defined as follows:

- For OSA-Express: DATAPATH parameter in the TRLE definition for each IPv4 interface and for each IPv6 interface for this OSA-Express feature.
- For Network Express: DEVNUM parameter on the EQENET and EQENET6 INTERFACE statements.

Note: The DEVNUM parameter is used by Communications Server to find the available devices for a given OSH CHPID. The next available device is used to activate the interface.

Rule: If you configure multiple INTERFACE statements for the same Network Express feature (CHPID), then all INTERFACE statements must specify the same device number on DEVNUM.

Fixed storage

Ensure that you understand the fixed storage requirements for this configuration; each interface requires its own device, and each device requires fixed storage for read processing. For more information see:

- [“Fixed storage requirements for OSA-Express QDIO and HiperSockets interfaces” on page 79](#)
- [“Fixed storage considerations for Network Express interfaces ” on page 78](#)

Restriction:

- The stack supports a maximum of 32 VLAN interfaces per IP version to the same OSA port. When configuring multiple interfaces, System Fixed storage usage must be taken into consideration.

OSA Inbound Routing

For OSA devices, z/OS Communications Server and the OSA feature provide functions that control how inbound unicast datagrams are routed to the appropriate INTERFACE and TCP/IP stack, especially when the OSA feature is shared by multiple TCP/IP instances. This includes when OSA is shared across multiple LPARs.

Note: The term *OSA inbound routing* does not mean that OSA serves as an IP router. The term OSA routing here means how OSA distributes inbound packets to the proper target stack. The OSA routing provides the ability to share, or virtualize, a physical adapter among multiple users (stacks and LPARs) by routing inbound unicast packets to the appropriate target IP stack and LPAR.

When TCP/IP activates an OSA device, each TCP/IP INTERFACE registers each of its home IP addresses with the OSA feature. TCP/IP also dynamically registers any updates to its set of home IP addresses with

the OSA feature. This enables the OSA feature to route datagrams destined for a registered IP address to the correct TCP/IP instance.

However, when packets are received for IP addresses that are not registered by any TCP/IP stack, OSA needs a method for determining which stack, if any, should receive the packet.

Two functions based on the specific OSA feature are available to accomplish this:

- For Network Express and optionally for OSA-Express: Virtual MAC (VMAC) routing.
- For OSA-Express only: Primary and secondary routing (when not using VMAC).

Requirement: OSA VMAC requirements:

- The Network Express feature requires a VMAC address on the INTERFACE statement.
- The OSA-Express feature only requires a VMAC address when multiple INTERFACE statements are defined for the same OSA feature. For a single INTERFACE for OSA-Express a VMAC address is optional.

OSA sharing (virtualization) and routing are related functions. Relative to sharing OSA features, a quick comparison of the differences in architecture of the OSA features are highlighted here.

1. OSA-Express uses QDIO architecture where a VMAC is optional (required in some cases). z/OS uses QDIO in layer 3 transport mode, meaning OSA primarily routes packets based on IP address, and optionally on a VMAC. Tip: Sharing a physical MAC on OSA-Express is possible, but not recommended. When VMAC is not used, Primary and Secondary router capability is used for routing.
2. Network Express uses EQDIO architecture where a VMAC is required. EQDIO supports layer 2 transport mode only, meaning OSA routes packets based on VMAC. Primary and secondary routing functionality does not apply to EQDIO. This aspect greatly simplifies the routing capabilities and the administrative planning tasks related to the capabilities.

Network Express virtual MAC routing

Network Express supports layer 2 mode only. All Network Express INTERFACES require a VMAC address. The Network Express physical burned in MAC address cannot be used. Each protocol being used (IPv4 or IPv6) must use VMAC.

For IPv4, Network Express provides the ARP offload function. This results in the Network Express feature using the VMAC address for all ARPs sent for that TCP/IP stack's registered IP addresses. The TCP/IP stack will use the VMAC as the source MAC address for all unicast packets sent from that stack.

This simplification is true for IPv6 as well. TCP/IP uses the VMAC address for all neighbor discovery address resolution flows for that stack's IP addresses, and likewise uses the VMAC as the source MAC address for all IPv6 packets sent from that stack. Again, from a network perspective, the OSA-Express feature with this VMAC appears as a dedicated device to that stack.

For IPv6, neighbor discovery processing is done in the TCP/IP stack. TCP/IP uses the VMAC address for all neighbor discovery address resolution flows for that stack's IP addresses, and likewise uses the VMAC as the source MAC address for all IPv6 packets sent from that stack.

From a network perspective, the Network Express feature with a VMAC address per INTERFACE appears as a dedicated device to that stack.

In this way, all routers on the same LAN as the Network Express feature use only the VMAC address as the destination for all packets destined for that specific TCP/IP stack. From a network routing perspective, the Network Express feature with this VMAC appears as a dedicated device to the remote TCP/IP stacks.

The Network Express EQDIO architecture significantly simplifies a shared OSA configuration. The routers on the LAN always send any packets destined for a particular TCP/IP stack to the VMAC defined for that stack. The Network Express feature knows by VMAC address exactly which stack should receive a given packet. Even if the IP address is not registered with the OSA-Express feature, if the packet is destined for that VMAC, the router has determined which stack should be the intermediate router (see Route ALL parameter), and the OSA can forward the packet directly to that stack. If the stack is not an intermediate router, the capability is provided for a stack to indicate to the OSA that it wants to receive packets to registered IP addresses only (see Route Local parameter). This simplification is true for IPv6 as well.

TCP/IP uses the VMAC address for all neighbor discovery address resolution flows for that stack's IP addresses, and likewise uses the VMAC as the source MAC address for all IPv6 packets sent from that stack.

The VMAC address can be defined in the stack (by the administrator), or it can be generated by the OSA. If generated by the OSA, it is guaranteed to be unique from all other physical MAC addresses and from all other VMAC addresses generated by any Network Express feature.

Rule: When VMACs are defined in the stack by an administrator, they should be defined as locally administered MAC addresses, and should be unique addresses for the associated local LAN.

Requirement: If the OSA is configured for both IPv4 and IPv6 for a stack, then you must define one VMAC on the INTERFACE statement for IPv4 usage, and a different VMAC on the INTERFACE statement for IPv6 usage.

The Network Express feature (EQDIO) does not require user defined VTAM TRLE definitions. EQDIO TRLEs are dynamically built when the EQENET INTERFACES are started. This design aspect simplifies the planning and administrative tasks associated with Network Express. There are no associated configuration tasks in VTAM for Network Express INTERFACES and there are no topics in or references to the z/OS Communications Server: SNA Network Implementation Guide. All z/OS configuration planning and guidance associated with Network Express INTERFACES is contained within this IP Configuration Guide. Users must complete the system I/O configuration steps for OSH and devices (HCD).

OSA virtual MAC routing

If multiple TCP/IP instances are sharing an OSA-Express feature, the preferred method of routing is to define or generate a virtual MAC (VMAC) for each stack and for each protocol being used (IPv4 or IPv6). For IPv4, this results in the OSA-Express feature using the VMAC address rather than the physical *burned in* MAC for all ARPs sent for that TCP/IP stack's registered IP addresses, and using the VMAC as the source MAC address for all packets sent from that stack. In this way, all routers on the same LAN as the OSA-Express feature use only the VMAC address as the destination for all packets destined for that specific TCP/IP stack. From a network routing perspective, the OSA-Express feature with this VMAC appears as a dedicated device to that TCP/IP stack.

This simplifies a shared OSA configuration significantly. The routers on the LAN always send any packets destined for a particular TCP/IP stack to the VMAC defined for that stack. The OSA-Express feature knows by VMAC address exactly which stack should receive a given packet. Even if the IP address is not registered with the OSA-Express feature, if the packet is destined for that VMAC, the router has determined which stack should be the intermediate router, and the OSA can forward the packet directly to that stack. If the stack is not an intermediate router, the capability is provided for a stack to indicate to the OSA that it wants to receive packets to registered IP addresses only.

This simplification is true for IPv6 as well. TCP/IP uses the VMAC address for all neighbor discovery address resolution flows for that stack's IP addresses, and likewise uses the VMAC as the source MAC address for all IPv6 packets sent from that stack. Again, from a network perspective, the OSA-Express feature with this VMAC appears as a dedicated device to that stack.

The VMAC address can be defined in the stack, or it can be generated by the OSA. If generated by the OSA, it is guaranteed to be unique from all other physical MAC addresses and from all other VMAC addresses generated by any OSA-Express feature.

Rule: If VMACs are defined in the stack, they should be defined as locally administered MAC addresses, and should be unique addresses for the local LAN on which they are.

Guidelines:

- If the OSA is configured for both IPv4 and IPv6 for a stack, then you must define one VMAC on the INTERFACE statement for IPv4 usage, and a different VMAC on the INTERFACE statement for IPv6 usage.
- A VLAN ID can be associated with an OSA-Express link or interface that is defined with a VMAC. For more information about [configuring VMACs](#), see [z/OS Communications Server: SNA Network Implementation Guide](#).

OSA-Express Primary router

If only one TCP/IP instance is using the OSA-Express device, or when multiple TCP/IP instances are using the same OSA-Express device but you want all instances to share the same physical MAC address of the device, you can optionally have the OSA route unicast packets to unregistered IP addresses by using OSA's primary (PRIROUTER) and secondary (SECROUTER) router support. This function enables a single TCP/IP stack, on a per-protocol (IPv4 and IPv6) basis, to register and act as a router stack on a per-OSA basis. Secondary routers can also be configured to provide for conditions in which the primary router becomes unavailable and the secondary router takes over for the primary router. The primary router stack is the only stack to which OSA forwards packets when the destination IP address has not been previously registered with OSA. If no active TCP/IP instance using this device is defined as the primary router (PRIROUTER) or secondary router (SECROUTER), the device discards the datagram. If the PRIROUTER or SECROUTER value is not specified, the default value is NONROUTER.

Relationship of VLAN and OSA-Express primary router

The OSA primary router support takes into consideration and interacts with the VLAN ID support (VLAN ID registration and tagging). OSA supports a primary and secondary router on a per VLAN basis (per registered VLAN ID). Therefore, if TCP/IP is configured with a specific VLAN ID and also configured as a primary or secondary router, that stack serves as a router for just that specific VLAN. This allows each OSA (CHPID) to have a primary router per VLAN. Configuring multiple primary routers (one per VLAN) has many advantages and preserves traffic isolation for each VLAN.

This support becomes more important when a single OSA is shared by multiple stacks. In this type of configuration, when each stack was configured with a unique VLAN ID, each stack could also be configured as a primary router for its respective VLANs.

OSA also continues to support a primary and secondary router that is not associated with a specific VLAN. This primary router is referred to as the default primary router. It continues to function as the router for inbound packets that are not VLAN ID tagged, or packets that are VLAN ID tagged with a VLAN ID that is not registered to OSA. This is the same primary router support that existed prior to introduction of the VLAN ID support. Therefore, multiple specific VLAN primary routers and a single default primary router can concurrently activate and share a single OSA.

Each VLAN-specific primary and secondary router is subject to the same OSA rules (that is, supporting a single primary router and allowing multiple secondary routers) as the default primary router.

Figure 8 on page 64 shows a configuration where multiple TCP/IP stacks are sharing a single OSA, and multiple VLANs with primary routers are configured.

Various IP networks accessed by z/OSTCP/IP primary routers

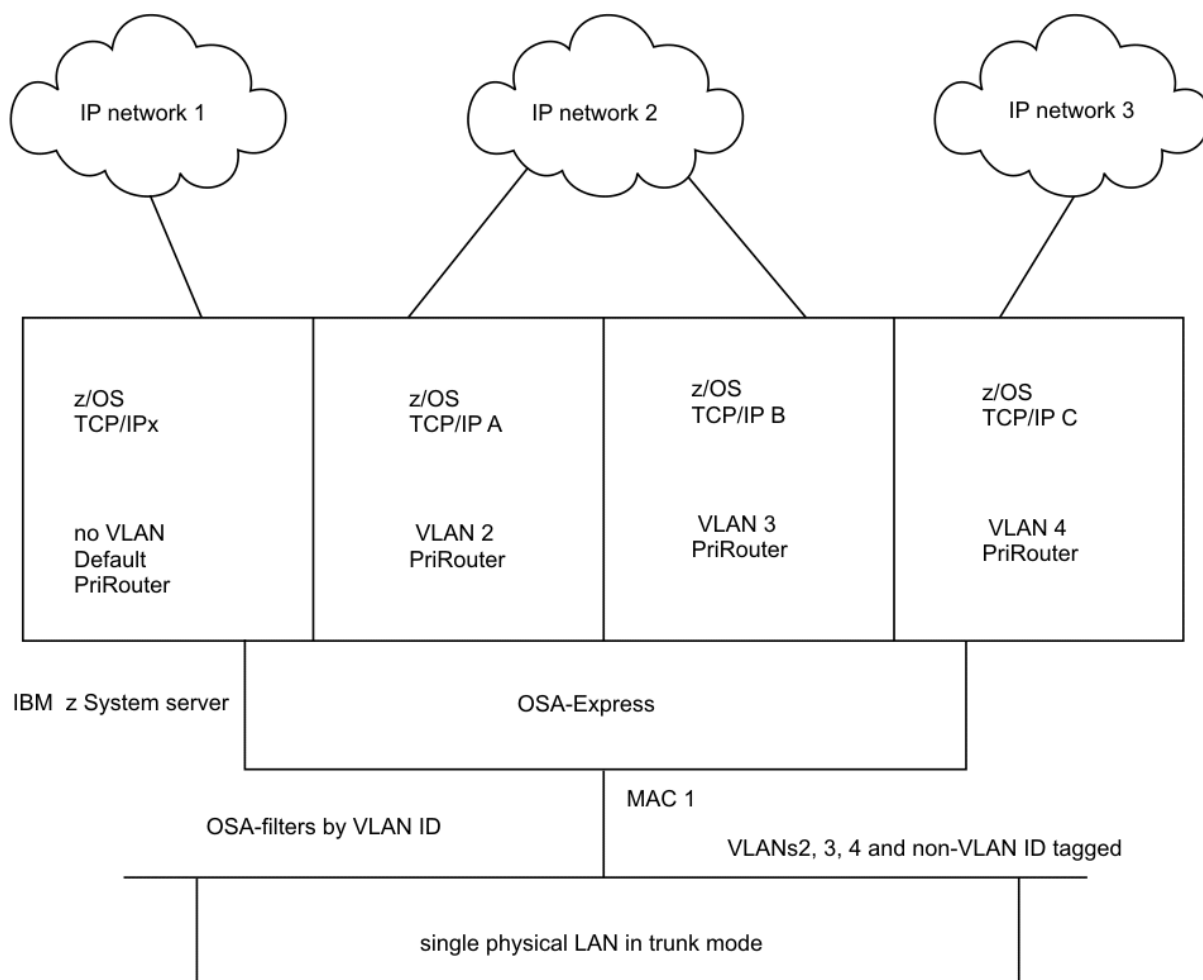

Figure 8. OSA-Express primary router per VLAN (shared OSA-Express with multiple primary routers)

In this example, TCP/IP x serves as the default primary router (PRIRouter without a VLANID configured). The other three TCP/IP stacks serve as a PRIRouter for just their specific VLANs.

For additional information regarding the details and syntax for configuring a VLAN Identifier (VLANID), and how to configure a TCP/IP stack as a primary or secondary router, see [z/OS Communications Server: IP Configuration Reference](#). For IPv4 information on the PRIRouter, SECRouter, NONRouter, and VLANID parameters, see [INTERFACE-IPAQENET OSA-Express QDIO interfaces](#). For IPv6 information regarding these parameters, see [INTERFACE -- IPAQENET6 OSA-Express QDIO interfaces statement](#).

Network configuration strategy with VLAN

The OSA VLAN configuration strategy and networking VLAN principles are the same for both Network Express and OSA-Express.

The VLAN support allows a TCP/IP stack to register a specific VLAN identifier for both IPv4 and IPv6. The VLAN ID for IPv4 must be different from the VLAN ID for IPv6 when the INTERFACE statements apply to the same physical OSA port (or LAN). When a VLAN ID is configured, the following situations occur:

1. TCP/IP becomes VLAN aware or enabled, and this TCP/IP (IPv4 or IPv6 connection) is considered to be part of the configured VLAN.

2. During activation, TCP/IP registers the configured VLAN ID value to OSA.
3. A VLAN ID tag is added to all outbound packets.
4. OSA filters inbound VLAN ID tagged packets based on the configured VLAN ID.
5. For OSA-Express only: if this stack is also configured as a router (for example, PRIRouter), the OSA primary router support is extended to this stack, allowing it to serve as the primary router for the configured VLAN ID.

When configuring a z/OS TCP/IP stack with a VLAN ID, consideration must also be given to how the LAN is partitioned and how the VLAN aware switches are configured.

VLAN switch concepts

In conjunction with the IEEE standards, most VLAN aware switches recognize and support at least two modes, referred to as trunk and access modes. This support is provided on a switch port basis. The general concepts of the two modes are as follows:

Trunk mode

Indicates that the switch should allow all VLAN ID tagged packets to pass through the switch port without altering the VLAN ID. Trunk mode is intended for servers that are VLAN capable, and filters and processes all VLAN ID tagged packets. In trunk mode, the switch expects to see VLAN ID tagged packets inbound to the switch port.

Access mode

Indicates that the switch should filter on specific VLAN IDs and allow only packets that match the configured VLAN IDs to pass through the switch port. The VLAN ID is then removed from the packet before it is sent to the server (that is, VLAN ID filtering is controlled by the switch). In access mode, the switch expects to see packets without VLAN ID tags inbound to the switch port.

For the specific details regarding how to configure VLANs in an Ethernet switch, consult the specific product documentation.

VLAN configuration considerations

When planning and deploying your z/OS TCP/IP VLAN support for OSA you should consider your overall network topology as it relates to your OSA VLAN strategy.

Requirement: The VLAN ID settings of your OSA INTERFACE statements must be consistent with the VLAN settings of the associated Ethernet switch ports. Specific VLAN considerations recommendations are as follows:

- When you define a VLAN ID on the INTERFACE statement the switch port must be configured in “trunk mode”.

Result: Trunk mode means the switch port supports multiple VLAN IDs. When the VLAN ID is configured on the INTERFACE statement, the host is in VLAN aware mode. The VLAN aware “host” (z/OS and OSA) is responsible for VLAN ID processing. The host must tag outbound frames with a valid VLAN ID and filter inbound frames by VLAN ID.

Tip: Considering the potential for sharing an OSA physical port there is a possibility for requiring multiple unique VLAN IDs on each OSA port. Trunk mode offers the most flexibility for many OSA use cases.

- When you do not define a VLAN ID on the INTERFACE statement, the switch port should be configured in “access mode”.

Result: Access mode means the switch port supports a single (transparent to the host) VLAN ID. When the VLAN ID is not configured on the INTERFACE statement, the host is in “VLAN unaware” mode. In this state, the “host” (z/OS and OSA) is not involved with (not responsible for) VLAN processing, tagging (outbound) or filtering (inbound).

Tip: Although access mode should be used for this case, most switches also support trunk mode and allows untagged frames (i.e. trunk mode port setting that “allows untagged frames”). This combination allows a VLAN unaware host to use a port in trunk mode.

Guideline: Additional VLAN considerations are described as follows:

- Multiple OSAs on the same physical LAN

When a z/OS TCP/IP stack has access to multiple OSAs that are on the same physical LAN, and a VLAN ID is configured on any of the OSAs, it is recommended that this stack configure a VLAN ID for all OSAs on the same physical LAN. Do not mix VLAN and no-VLAN on the same physical network when a stack has access to the same LAN through multiple OSAs.

- VLAN ID 1 considerations

Some switch vendors use VLAN ID 1 as the default value when a VLAN ID value is not explicitly configured. It is recommended that you avoid the value of 1 when configuring a VLAN ID value.

[Figure 9 on page 67](#), [Figure 10 on page 69](#), and [Figure 11 on page 71](#) illustrate the preceding recommendations.

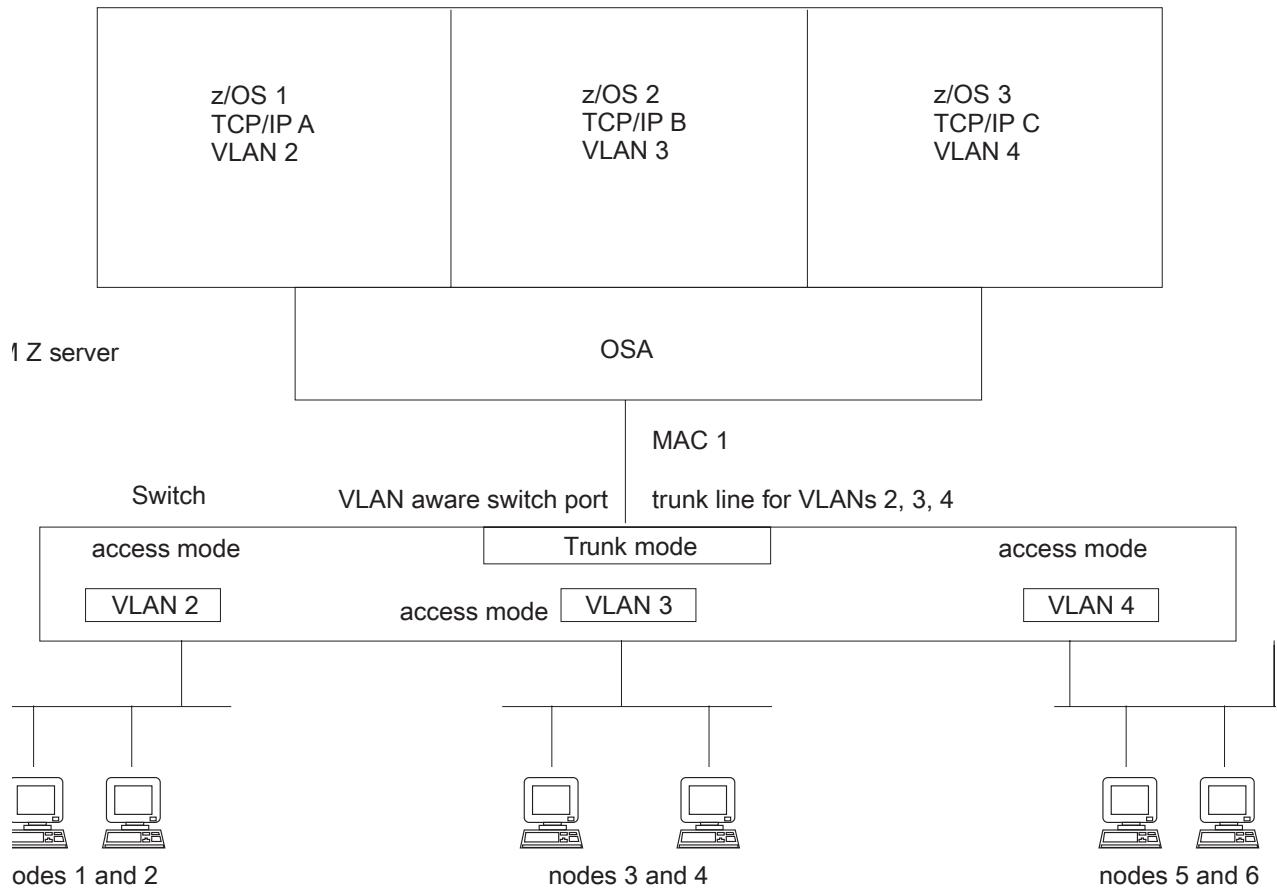

Figure 9. Single OSA and VLAN switch configuration

[Figure 9 on page 67](#) shows the recommended VLAN switch port configuration when a VLAN ID is configured in the TCP/IP stack. A single physical LAN is divided into three separate virtual LANs (2, 3, and 4), the OSA port is configured as a trunk line, and the other ports on the switch are configured in access mode for their specific VLAN.

In [Figure 9 on page 67](#) there are three virtual LANs deployed through the same shared OSA, where each TCP/IP stack appears to have a unique and isolated physical network as follows:

- VLAN 2 - TCP/IP A and nodes 1 and 2
- VLAN 3 - TCP/IP B and nodes 3 and 4
- VLAN 4 - TCP/IP C and nodes 5 and 6

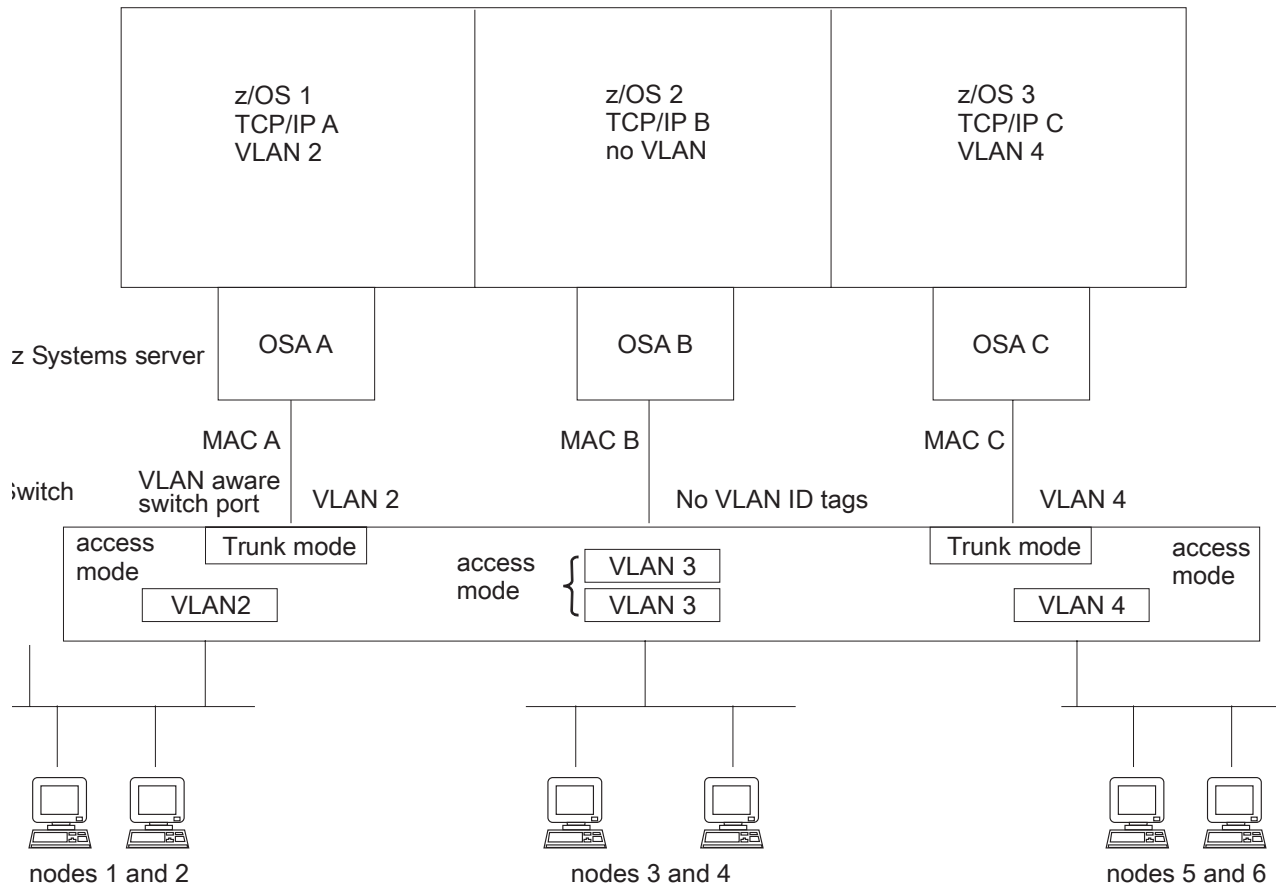

Figure 10. Matching VLAN switch configuration to multiple OSAs (VLAN configuration)

Figure 10 on page 69 illustrates using multiple OSAs and TCP/IP stacks. Three unique VLANs are created. However, TCP/IP stack B will not deploy a VLAN ID, and the corresponding switch port is configured in access mode. No VLAN ID tags will flow to this OSA port.

In Figure 10 on page 69 there are also three virtual LANs deployed. Access to each VLAN is provided through separate OSAs, yet the functionality of having three physical networks is still provided. TCP/IP B is not configured with a VLAN ID, and therefore stack B is unaware of the existence of VLAN 3 (although nodes 3 and 4 on VLAN 3 have access to stack B through OSA B). Note that the switch port for OSA B is configured in access mode, while the other two switch ports are configured in trunk mode.

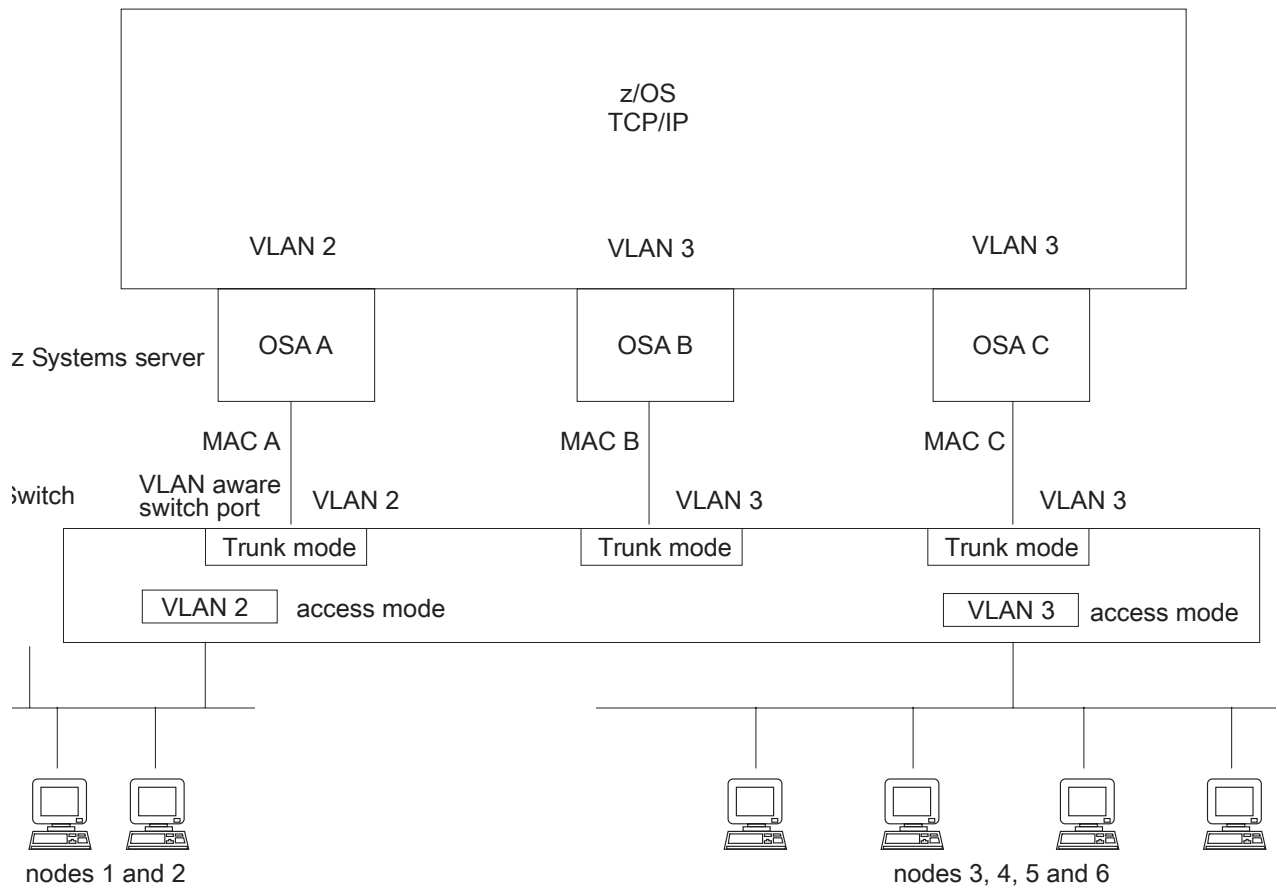

Figure 11. Single stack using multiple OSAs on the same physical network

Figure 11 on page 71 illustrates a single TCP/IP stack using multiple OSAs that are on the same physical network. There are two VLANs deployed, where OSA A is on VLAN 2, and OSA B and OSA C are on VLAN 3.

Configuring OSA B and OSA C with the same VLAN ID has significance for failure or takeover scenarios. The interface takeover (ARP takeover) function, with redundant connectivity onto a LAN, applies within the VLAN. Therefore, if OSA B becomes unavailable, OSA C can take over. Similarly, OSA B can take over if OSA C becomes unavailable. However, OSA A cannot take over for either OSA B or OSA C, because OSA A is on a different VLAN.

In Figure 11 on page 71, a single TCP/IP stack has access to two VLANs through three OSAs, which provides the following network isolation:

- VLAN 2 - through OSA A to nodes 1 and 2
- VLAN 3 - through OSA B and OSA C to nodes 3, 4, 5 and 6

OSA internal routing for a shared OSA physical port

An OSA port can be shared by multiple TCP/IP stacks within the same z/OS instance or across multiple z/OS instances (LPARs). In such a shared OSA port configuration, when a unicast packet is sent over the shared OSA port the packet can be routed internally to the target stack without traversing the external LAN. The “internal routing” or “loopback” technology varies based on the OSA feature:

- OSA-Express: using layer 3 transport mode, when the next-hop IP address is registered by another TCP/IP stack on the same LAN or VLAN that shares the OSA port, then the OSA adapter routes the packet directly to the stack that shares the port, bypassing the external LAN.
- Network Express: using layer 2 transport mode, when the destination VMAC is registered to this adapter by another TCP/IP stack on the same LAN or VLAN sharing the OSA port, then the packet is routed directly to the target stack, bypassing the external LAN

For both features, for multicast and broadcast, the OSA adapter also routes the packet directly to the stack that shares the port, in addition to sending the packet onto the LAN.

OSA connection isolation

OSA connection isolation provides a way to prevent the adapter from internally routing packets directly to a stack that shares the same port. When connection isolation is in effect, the OSA feature discards any unicast packets when the next-hop address is registered by a stack sharing the same port, and prevents any multicast or broadcast packets from being internally routed between the stacks sharing the port.

For direct routing to occur, the OSA feature requires that neither of the stacks that are sharing a port can be isolated. Therefore, for traffic between two stacks that are sharing a port, as long as at least one of the stacks is isolated, then connection isolation is in effect for traffic in both directions between these stacks.

OSA connection isolation can be useful when you want to prevent communication between two stacks that share the same OSA port, and it provides extra assurance against a misconfiguration that might otherwise allow such traffic to flow. OSA connection isolation can also be useful if you want to ensure that traffic flowing through the OSA adapter does not bypass any security features implemented on the external LAN.

Dynamic routing is not aware of OSA connection isolation, which is an issue only if static routes are not used and traffic needs to flow between the two hosts that share the OSA adapter using connection isolation. In this case, a dynamic routing protocol might choose a route between the hosts that includes connection isolation, which would make each host unreachable from the other host. If you want dynamic routing to work between hosts that are using OSA connection isolation, you must ensure in your dynamic routing configuration that the path that includes connection isolation is not chosen to route between the hosts.

Guideline: You can ensure that a path that includes OSA connection isolation is not chosen as the route between two hosts by assigning higher routing costs to isolated interfaces than to other network paths between those hosts (for example dynamic XCF or MPC), so that the other network paths between the hosts are chosen. You can also accomplish this by excluding the interfaces with connection isolation from

the dynamic routing domain, if it is not necessary for them to be reachable from the wider network (for example, by defining them with INTERFACE statements in OMROUTE).

Tip: If you want traffic to flow between two stacks that share an OSA port but you also want to ensure that the traffic flows over an external LAN, take one of the following actions:

- Configure each stack on a separate virtual LAN (VLAN).
- Use a static route with the next-hop address of a router on the LAN.

Result: Using a static route with the next-hop address of a router on the LAN to route to another host on the same LAN can result in excessive ICMP redirect packets from the router to the originating host.

Guideline: If you use this technique, turn off receipt of ICMP redirects on the sharing hosts and, if possible, configure the router to not send ICMP redirects.

ARP offload and VIPA ARP processing

OSA performs all Address Resolution Protocol (ARP) processing for IPv4. The z/OS stack informs the OSA of the IP addresses for which it should perform ARP processing. Because the z/OS stack also supports configurations in which ARPs flow for VIPAs (which you might see on some flat network configurations that use static routing), the stack also informs the OSA of the VIPAs for which it should perform ARP processing. OSA sends gratuitous ARPs for these IP addresses during interface takeover scenarios to provide fault tolerance.

A subnet mask controls the VIPA ARP processing. When you specify a nonzero num_mask_bits value on the IPADDR parameter of the INTERFACE statement, then the stack informs OSA to perform ARP processing for a VIPA only if the VIPA is configured in the same subnet as the OSA (as defined by the resulting subnet mask).

Tip: The OSA-Express ARP processing will be optimized when using subnet mask. For the optional cases, a subnet mask is recommended.

Even in the cases where a subnet mask is not required, it is recommended.

Rule: Network Express requires a subnet mask on the INTERFACE statement.

Checksum offload

When packets are sent or received over OSA, TCP/IP supports offloading most IPv4 and IPv6 inbound and outbound checksum processing (IP header, TCP, and UDP checksums) to the OSA adapter. This is the default behavior.

The TCP/IP stack performs checksum processing in the following cases in which checksum processing cannot be offloaded:

- When data is transmitted that qualifies for TCP segmentation offload (when enabled).
- IPSec-encapsulated packets
- Fragmented and reassembled packets
- Outbound multicast and broadcast packets
- Outbound TCP packets that contain only a TCP header
- IPv6 packets that contain extension headers
- When multipath is in effect (unless all interfaces in the multipath group support checksum offload)

In some cases, you might want to use the NOCHECKSUMOFFLOAD parameter on the IPCONFIG and IPCONFIG6 profile statements to configure the TCP/IP stack to perform all checksum processing.

TCP segmentation offload

You can use TCP segmentation offload support to have the TCP/IP stack offload most IPv4 and IPv6 outbound TCP segmentation processing in the OSA feature. You can configure this function by specifying the SEGMENTATIONOFFLOAD parameter on the IPCONFIG or IPCONFIG6 profile statement. When using

segmentation offload checksum processing will also be offloaded to the OSA feature. The TCP/IP stack performs TCP segmentation processing in the following cases in which segmentation cannot be offloaded:

- Packets that go directly to another stack that shares the same OSA-Express port. Network Express supports segmentation for shared OSA.
- IPSec-encapsulated packets
- When multipath is in effect (unless all interfaces in the multipath group support segmentation offload)
- When the SEGMENTATIONOFFLOAD parameter is not specified on the IPCONFIG or IPCONFIG6 statement

Tip: Applications that use large TCP send buffers will obtain the most benefit from TCP segmentation offload. The size of the TCP receive buffer on the other side of the TCP connection also affects the negotiated buffer size. You can control the size of these buffers using the following mechanisms:

- The TCPSENDBFRSIZE parameter on the TCPCONFIG statement sets the default TCP send buffer size for all applications.
- An application can use the SO_SNDBUF socket option to override the default TCP send buffer size.
- The TCPRCVBUFRSIZE parameter on the TCPCONFIG statement sets the default TCP receive buffer size for all applications.
- An application can use the SO_RCVBUF socket option to override the default TCP receive buffer size.

Dynamic LAN idle timer

z/OS Communications Server can dynamically adjust how frequently an OSAfeature interrupts the host for inbound traffic. By monitoring traffic patterns, the stack can adjust the interrupt-timing values to maximize throughput and optimize CPU cost.

The Dynamic LAN idle function is integrated into the base EQDIO support for Network Express and is not configurable. z/OS Communications Server with EQDIO automatically optimizes the Network Express interrupt-timing

To configure an OSA-Express feature for dynamic LAN idle timer, use the INTERFACE statement with the dynamic inbound performance setting (INBPERF DYNAMIC). For information about dynamic LAN idle timer and the INBPERF parameter, see [INTERFACE-IPAQENET OSA-Express QDIO interfaces](#), and [INTERFACE -- IPAQENET6 OSA-Express QDIO interfaces statement in z/OS Communications Server: IP Configuration Reference](#).

OSA-Express optimized latency mode

One way to improve the performance of an OSA-Express feature in QDIO mode for processing workloads with demanding latency requirements is to configure the OSA-Express feature to operate in optimized latency mode. Optimized latency mode optimizes interrupt processing for both inbound and outbound data, which decreases latency and can provide significant increases in throughput, particularly for high volume, interactive, non-streaming workloads.

To configure an OSA-Express feature to operate in optimized latency mode, use the INTERFACE statement with the OLM parameter. Because optimized latency mode affects both inbound and outbound interrupts, it supersedes other inbound performance settings that the INBPERF parameter sets. For more information about optimized latency mode and the OLM and INBPERF parameters on the INTERFACE statement for [INTERFACE-IPAQENET OSA-Express QDIO interfaces](#) and [INTERFACE -- IPAQENET6 OSA-Express QDIO interfaces statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Because of the operating characteristics of optimized latency mode, two other configuration changes might be required.

- For outbound traffic to gain the benefit of optimized latency mode, direct traffic to priority queues 1, 2, or 3 by using the WLMRIORITYQ parameter on the GLOBALCONFIG statement, or by using Policy Agent and configuring a policy with the SetSubnetPrioTosMask statement.

Although an OSA-Express feature supports multiple outbound write priority queues, outbound optimized latency mode occurs only for traffic on priority queue 1 (priority level 1). The TCP/IP stack combines all the traffic that is directed to priority queues 1, 2, and 3 into priority queue 1 for any OSA-Express feature that is operating in optimized latency mode.

For more information about directing traffic to outbound OSA-Express priority queues by using the WLMRIORITYQ parameter on the `GLOBALCONFIG` statement or using the `SetSubnetPrioTosMask` statement, see *z/OS Communications Server: IP Configuration Reference*.

Guideline: Configure the WLMRIORITYQ parameter with no subparameters, which assigns a default mapping of service class importance levels to OSA-Express outbound priority queues. This default mapping directs traffic that is assigned to the higher priority service class importance levels 1–4 to queues that operate in optimized latency mode, and enables the appropriate types of traffic to benefit from optimized latency mode.

Result: If neither the WLMRIORITYQ or SetSubnetPrioTosMask statements are specified, any packet that has a type of service (ToS) byte with the first 3 bits being 000 or 001 is directed to queue 4 and does not benefit from optimized latency mode.

- To achieve optimal latency for one or more network interfaces that are operating in optimized latency mode, limit the number of network interfaces that can concurrently share an OSA-Express feature.

When at least one network interface is operating in optimized latency mode, ensure that no more than four concurrent network interfaces are sharing an OSA-Express port, and no more than eight concurrent network interfaces are sharing an OSA-Express3 or later channel path identifier (CHPID). The following configurations can result in multiple users that are sharing an OSA-Express feature.

- Multiple LPARs sharing the OSA-Express feature
- Multiple stacks on the same LPAR sharing the OSA-Express feature
- Multiple VLAN interfaces to the OSA-Express feature
- Both an IPv4 and an IPv6 active interface to the OSA-Express feature
- A TCP/IP stack that is enabling the OSA-Express network traffic analyzer (OSAENTA) for the OSA-Express feature

Optimized latency mode is intended for high volume, interactive workloads. Although optimized latency mode can compensate for some mixing of workloads, an excessive amount of high volume, streaming workloads, such as bulk data or file transfer, can result in higher processor consumption.

Guideline: When multipath routing by using the PERPACKET option is enabled, do not configure a multipath group that contains an OSA-Express feature configured with optimized latency mode and any other type of device.

Restrictions:

- Optimized latency mode is limited to OSA-Express Ethernet features in QDIO mode that are running with an IBM System z10® or later server. For more information, see the 2097DEVICE Preventive Service Planning (PSP) bucket.
- Traffic that is either inbound over or being forwarded to an OSA-Express feature configured to operate in optimized latency mode is not eligible for the accelerated routing that HiperSockets Accelerator and QDIO Accelerator provide.
- For an OSA-Express interface configured to operate in optimized latency mode, the stack ignores the configured INBPERF setting and uses the value DYNAMIC.

Inbound workload queuing

The OSA-Express feature with QDIO and the Network Express feature with EQDIO can both perform inbound traffic sorting by placing inbound packets for differing workload types on separate inbound processing queues.

This function is called OSA inbound workload queuing (IWQ). For OSA-Express IWQ must be enabled. For Network Express IWQ is integrated into the base EQDIO support and is not configurable.

With the inbound traffic stream already sorted by the OSA feature, z/OS Communications Server provides the following performance optimizations:

- Finer tuning of read-side interrupt frequency to match the latency demands of the various workloads that are serviced
- Improved multiprocessor scalability, because the multiple OSA input queues are now efficiently serviced in parallel
- Optimized acceleration of traffic, using QDIO (EQDIO) Accelerator processing only for eligible input queues instead of for all input traffic.

Network Express provides the following additional optimizations for each input queue:

- Dynamic storage management based on volume of workload.
- Advanced fairness algorithm to manage processing across multiple workloads.
- Advanced optimizations for the reduction of data copies for acceleration.

z/OS Communications Server and the OSA feature establish a primary input queue and one or more ancillary input queues (AIQs), each with a unique read queue identifier (QID) for inbound traffic. z/OS Communications Server and the OSA feature cooperatively use the multiple queues in the following way:

- Primary input queue: The primary input queue represents IP traffic that is for this z/OS instance and is not directed to a specific Ancillary Input Queue (AIQ) by OSA. In many cases, the primary traffic represents the main business application workloads for this z/OS instance. For OSA-Express, forwarded traffic also defaults to this queue. For Network Express, forwarded traffic can be routed to the IP router AIQ queue described below:

Note: The remaining input queues are AIQs for traffic that is going through z/OS (Sysplex distributed, Enterprise Extender, zCX or IP routed) or traffic that might benefit from unique processing (bulk, Enterprise Extender, IPSec, or zCX). Separating this unique type of traffic from the primary traffic allows the primary traffic to be optimized or “streamlined” avoiding delays from unpacking, sorting and data copies. The AIQs are described along with a brief description of the associated benefits of each AIQ.

- Sysplex distributor AIQ: The OSA feature directs an inbound packet (received on this interface) that is to be forwarded by the sysplex distributor to the sysplex distributor AIQ. z/OS Communications Server then tailors its processing for the sysplex distributor queue, notably by using the multiprocessor to service sysplex distributor traffic in parallel with traffic on the other queues. The sysplex distributor queue is eligible for Accelerator processing.
- Bulk data AIQ: The TCP layer automatically detects connections operating in a bulk-data fashion (such as the FTP data connection), and these connections are registered to the receiving OSA feature as bulk-mode connections. The OSA feature then directs an inbound packet (received on this interface) for any registered bulk-mode connection to the TCP bulk- data AIQ. z/OS Communications Server tailors its processing for the bulk queue, notably by improving in-order packet delivery on multiprocessors, which likely results in improvements to CPU consumption and throughput. Interrupt processing using dynamic LAN idle settings and storage provisioning are also optimized for this AIQ. Like other AIQs, processing for data on the bulk queue can be in parallel with traffic on the other queues.
- Enterprise Extender (EE) AIQ: The OSA feature directs an inbound Enterprise Extender packet (received on this interface) to the Enterprise Extender AIQ. This allows z/OS Communications Server to process inbound traffic on the Enterprise Extender queue in parallel with inbound traffic on the other queues for this interface. A key optimization of the EE AIQ is the use of CSM dataspace memory for the subsequent VTAM (SNA) stack processing avoiding data copies.
- IPSec AIQ: The OSA feature directs inbound AH packets, ESP packets, and UDP-encapsulated ESP packets that are received on this interface to the IPSec AIQ. This allows z/OS Communications Server to process inbound traffic on the IPSec queue in parallel with inbound traffic on the other queues for this interface. A key benefit of this processing is the use of zIIP processing for this input data (when IPSec zIIP is configured).

An IPSec packet can also be GRE-encapsulated when using VIPAROUTE for sysplex distribution. Network Express can recognize a GRE-encapsulated IPSec packet and direct it to the IPSec input

queue on the target host allowing it to benefit from IPSec input queue zIIP processing. For OSA-Express, GRE-encapsulated IPSec traffic is directed to the primary (default) input queue.

- **zCX AIQ** The OSA feature directs inbound packets (received on this interface) that are destined to a zCX server to the zCX AIQ. This allows z/OS Communications Server to process inbound traffic on the zCX queue in parallel with inbound traffic on the other queues for this interface. Additionally, it also allows for this inbound traffic to be processed on a System z® Integrated Information Processor (zIIP).

GRE encapsulation is used for zCPA (zCX) forwarded traffic. Both OSA-Express and Network Express support directing the forwarded zCPA GRE traffic to the zCX input queue in the target host.

- **IP Router AIQ (Network Express only):** The Network Express feature directs inbound packets that do not match any other ancillary input queue, default traffic to an IP router AIQ. If the packet is to be forwarded it can be processed by the Accelerator. This allows z/OS Communications Server to separate IP forwarded traffic from the primary traffic. Accelerator processing can be targeted to the IP router and sysplex distributor AIQs avoiding the cost of accelerator processing on the primary input queue.

The IP Router input queue is created for a Network Express feature when datagram forwarding is enabled (DATAGRAMFWD on the IPCONFIG statement), QDIO Accelerator is enabled (QDIOACCELERATOR on the IPCONFIG statement), and ROUTEALL is configured for this interface (VMAC ROUTEALL on the INTERFACE statement).

- The primary and bulk data input queues are always used (activated). The remaining input queues are only activated if the specific function or type of workload associated with the input queue is detected.

Restrictions:

- IWQ is not supported for a z/OS guest on z/VM® using simulated (virtual) devices, such as virtual switch (VSWITCH) or guest LAN.
- Bulk-mode TCP connection registration is supported only in configurations in which a single inbound interface is servicing the bulk-mode TCP connection. If a bulk-mode TCP connection detects that it is receiving data over multiple interfaces, IWQ is disabled for the TCP connection and inbound data from that point forward is delivered to the primary input queue.
- The support for internally routed IWQ traffic over a shared OSA port differs based on the generation of the OSA feature as follows:
 - OSA-Express QDIO IWQ is not supported for traffic over a shared OSA port; this traffic is placed on the primary input queue of the target host.
 - Network Express EQDIO IWQ is supported for internally routed traffic over a shared Network Express port.

Guidelines: IWQ requires an additional amount of fixed 4K CSM HVCOMMON storage per active AIQ. The storage provisioned for IWQ is managed differently based on the generation of OSA as follows:

- **OSA-Express IWQ storage management:** The WORKLOADQ parameter enables IWQ and requires an additional amount of fixed 4K CSM HVCOMMON storage per AIQ. The amount of storage consumed per AIQ is based on the amount of storage defined for READSTORAGE for this interface. The bulk AIQ is always backed with this additional CSM storage. The remaining AIQs are not backed with the additional CSM storage until the specific function (EE, SD, IPSec or zCX) is used. The EE AIQ is backed by fixed 4K CSM DSPACE64 storage (instead of HVCOMMON). To verify the amount of CSM storage that is being used for each input queue, display the VTAM TRLE name that is associated with the interface. The WORKLOADQ parameter also requires an additional 36K of ECSA per AIQ.
- **Network Express IWQ storage management:** IWQ is integrated in the base support Network Express EQDIO and is not configurable. IWQ requires fixed 4K CSM HVCOMMON for each active AIQ. Storage required for Network Express inbound (read) processing is dynamically managed. The READSTORAGE parameter does not apply to Network Express interfaces. For additional information about the usage and monitoring of fixed storage for Network Express, see [“Fixed storage considerations for Network Express interfaces”](#) on page 78.

Tip: The additional CSM storage consumed by each OSA interface using IWQ also consumes fixed (real) storage. It is recommended that you verify that the additional fixed storage required by IWQ (per OSA interface) will not approach any of the following system limits:

- The CSM FIXED MAXIMUM value used by Communications Server (use the D NET, CSM command and see the CSM FIXED MAXIMUM value defined in IVTPRM00)
- The actual real storage available to this z/OS system (see D M=STOR or D M=HIGH)

Guideline: IWQ is integrated in the base support Network Express and is not configurable. IWQ for OSA-Express must be enabled using the WORKLOADQ parameter. IWQ requires an additional amount of fixed 4K CSM HVCOMMON. For additional considerations for QDIO IWQ fixed storage requirements, see [“Steps for enabling OSA-Express QDIO inbound workload queuing”](#) on page 78.

Steps for enabling OSA-Express QDIO inbound workload queuing

Use QDIO inbound workload queuing (IWQ) to establish a primary input queue and one or more ancillary input queues (AIQs). QDIO IWQ provides performance optimizations, such as the processing of data on one queue in parallel with traffic on the other queues. IWQ is integrated into EQDIO and IWQ enablement (WORKLOADQ) does not apply to Network Express

About this task

Procedure

Perform the following steps to enable QDIO IWQ:

1. Review the storage requirements for QDIO IWQ as discussed in “Inbound Workload Queuing”.
2. Specify the INBPERF parameter with the DYNAMIC setting on the INTERFACE statement for the IPAQENET or IPAQENET6 interface. In addition, you must specify the WORKLOADQ subparameter and the VMAC parameter.

Tip: In addition to enabling QDIO IWQ, the INBPERF DYNAMIC setting also dynamically tunes the read-side interrupt frequency for the OSA-Express feature.

Results

You know you are done when the Workloadqueuing field of the Netstat DEvlinks/-d report is set to Yes, indicating that QDIO IWQ is enabled. You can also obtain this information with a GetIfs request for the TCP/IP callable NMI (EZBNMIFR).

You can use the Netstat ALL/-A report to determine whether any TCP connections are registered to the TCP bulk data ancillary input queue (AIQ); the Ancillary Input Queue field is set to Yes and the BulkDataIntfName field is set to the interface name. You can also obtain this information with a GetConnectionDetail request for the TCP/IP callable NMI (EZBNMIFR).

You can use the Netstat STATS/-S report to display the total number of TCP segments that are processed on the TCP bulk data AIQ; this number is displayed in the Segments Received on OSA Bulk Queues field. You can also obtain this information with a GetGlobalStats request for the TCP/IP callable NMI (EZBNMIFR).

For more information about the [Netstat](#) command, see [z/OS Communications Server: IP System Administrator's Commands](#). For more information about [EZBNMIFR](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Since IWQ is always on for Network Express, the relative IWQ status information described here is always available.

Fixed storage considerations for Network Express interfaces

Each Network Express interface requires fixed storage for read processing. If you define a large number of interfaces (for example, by configuring multiple VLANs to one or more Network Express features), then you need to consider how much fixed storage your configuration requires.

For Network Express EQDIO interfaces, z/OS Communications Server supports dynamic storage management. A summary of the EQDIO dynamic storage management is described as follows:

- The administrator is not required to configure a static storage value for EQENET or EQENET6 INTERFACE statements (the ReadStorage parameter is N/A for EQENET interfaces).
- The VTAM start option QDIOSTG does not apply to EQDIO interfaces.
- When managing EQDIO storage, Communications Server will:
 - Use CSM 4k HVCOMMON (64bit) fixed storage.
 - Set initial storage values based on OSA port bandwidth and the type of input queue.
 - Dynamically increase and decrease storage usage on a per input queue basis as workload demands change on each input queue.

Additional information about current storage utilization for each EQENET interface is provided as follows:

- NetStat DEvlinks report provides a total read storage in use per interface.
- Display TRLE provides additional detail about storage usage for the interface on a per input queue basis along with minimum and maximum storage usage.

Tip: Consider periodically monitoring your fixed CSM storage usage during steady state and peak periods using:

1. Netstat DEvlinks for each EQENET interface and optionally create a total of fixed storage used for all interfaces.
2. D NET,TRLE provides storage usage detail on a per input queue basis.
3. D NET,CSM for HVCOMM and FIXED MAX.

Compare the running totals to your FIXED MAX defined for CSM in IVTPRM00.

Fixed maximum storage for CSM buffers

The IVTPRM00 parmlib member defines parameters for CSM. The default value of the FIXED MAX setting is 512 MB. This setting defines the maximum amount of storage that is dedicated to fixed CSM buffers.

Tip: If you use OSA interfaces with at least 25 GbE of bandwidth and are using a FIXED MAX setting lower than the default value, you should consider increasing the FIXED MAX setting in your IVTPRM00 parmlib member to 512 MB. If you increase this setting, you should also review your HVCOMMON setting in IEASYSxx and determine whether you need to increase this value to account for the fact that the system reserves a larger portion of this storage for CSM buffers.

Fixed storage requirements for OSA-Express QDIO and HiperSockets interfaces

Each OSA-Express QDIO and HiperSockets interface requires fixed storage for read processing (which is allocated by VTAM). If you define a large number of these interfaces (for example, by configuring multiple VLANs to one or more OSA-Express features), then you need to consider how much fixed storage your configuration requires.

For information about how much fixed storage VTAM allocates by default for each OSA-Express QDIO and HiperSockets interface, how to control the amount of this storage allocation using the VTAM QDIOSTG start option (for OSA-Express QDIO) and the VTAM IQDIOSTG start option (for HiperSockets), and considerations for the IVTPRM00 parmlib member, see [z/OS Communications Server: SNA Resource Definition Reference](#).

You can also override the global QDIOSTG or IQDIOSTG value and control the amount of fixed storage for a specific OSA-Express QDIO or HiperSockets interface by using the READSTORAGE parameter on the INTERFACE statements.

Fixed storage considerations for OSA-Express 25 GbE interfaces

OSA-Express7S with 25 GbE bandwidth

The OSA-Express7S feature has 25 GbE bandwidth compared to a maximum of 10 GbE for earlier generation OSA-Express features. The z/OS Communications Server default value for read storage in previous releases is insufficient to accommodate a high-volume workload over a 25 GbE adapter and could result in packet loss and sub-optimal performance.

For OSA-Express interfaces with at least 25 GbE of bandwidth, z/OS Communications Server uses higher read storage values for the keywords MAX, MIN, and AVG and a higher default value than for interfaces with less than 25 GbE of bandwidth. For details on the read storage values used for the various keywords, see [QDIOSTG start option in z/OS Communications Server: SNA Resource Definition Reference](#).

Obtaining 8 MB of fixed read storage

The largest amount of read storage that can be allocated for an OSA-Express QDIO interface is 8 MB.

Guideline: If you expect a high-volume workload over an interface with at least 25 GbE of bandwidth, you should run with 8 MB of read storage to achieve optimal performance.

You can obtain 8 MB of fixed CSM 4K HVCOMMON of read storage for an OSA-Express QDIO interface which has at least 25 GbE of bandwidth in one of the following ways:

- Use the default QDIOSTG value of MAX in the VTAM start options and use the default READSTORAGE value of GLOBAL on the INTERFACE or LINK statement for an OSA with 25 GbE bandwidth.
- Specify a READSTORAGE value of MAX on the INTERFACE or LINK statement for any OSA. This will override the global QDIOSTG setting for that OSA.
- Specify a VTAM start option of QDIOSTG=126 and specify (or default) the READSTORAGE value on the OSA INTERFACE statement to GLOBAL. This will make 8 MB the default for all OSA-Express features. To get a lower value for a specific OSA interface, you will need to configure a value other than GLOBAL on the READSTORAGE parameter on the INTERFACE statement for that OSA.

Tips:

- To see the amount of read storage in MB being used for a specific QDIO interface, use the **Netstat Devlinks/-d** command.
- The OSA-Express Enhanced Inbound Blocking function is dependent on the READSTORAGE setting for your interface, the QDIOSTG VTAM start option, and the QDIOEIB start option. For more information about the OSA-Express EIB function and using the VTAM QDIOEIB and QDIOSTG start options, see the [VTAM Start Options in z/OS Communications Server: SNA Resource Definition Reference](#). For more information about the READSTORAGE interface setting, see [z/OS Communications Server: IP Configuration Reference](#).
- For a list of all related OSA Express Best Practices for optimizing your performance for your OSA interface configuration, see [IBM z/OS Communications Server and OSA Express Best Practices](#).

Additional fixed storage for OSA interfaces using 8 MB of read storage

For OSA interfaces which have a bandwidth of at least 10 GbE and which are using 8 MB of read storage, z/OS Communications Server allocates additional fixed CSM 4K HVCOMMON storage for work element processing. If the interface is not using IWQ, the additional storage is 96 KB (plus another 32 KB if QDIO Accelerator is enabled). If the interface is using IWQ, the additional storage is 224 KB (plus another 96 KB if QDIO Accelerator is enabled).

Fixed maximum storage for CSM buffers

The IVTPRM00 parmlib member defines parameters for CSM. The default value of the FIXED MAX setting is 512 MB. (In releases prior to z/OS V2R4 Communications Server, the default value was 200 MB.) This setting defines the maximum amount of storage that is dedicated to fixed CSM buffers.

Tip: If you use OSA-Express interfaces with at least 25 GbE of bandwidth and are using a FIXED MAX setting lower than the default value, you should consider increasing the FIXED MAX setting in your IVTPRM00 parmlib member to 512 MB. If you increase this setting, you should also review your HVCOMMON setting in IEASYSxx and determine whether you need to increase this value to account for the fact that the system reserves a larger portion of this storage for CSM buffers.

OSA configuration recommendations

For planning your external network access, both Network Express and OSA-Express features can be viewed as OSAs. z/OS Communications Server supports the mixing of Network Express with OSA-Express features for external connectivity. If you plan to mix OSA feature types and use QDIO Accelerator, then refer to the QDIO Accelerator topic.

Consideration should be given to the speed of each OSA. If your configuration includes OSA interfaces with different speeds (for example 10 GbE and 25 GbE), you should consider how you plan to use these interfaces in your network configuration.

Note: EQDIO interfaces do not use any VTAM settings, including VTAM start option QDIOSTG. Since there are no VTAM configuration tasks required for EQDIO storage there are no references to the z/OS Communications Server: SNA Resource Definition Reference.

Note: EE workloads do not support 64bit storage within the VTAM (SNA) stack. The EE input queue uses CSM common access data space (CADS) storage.

Guideline: In general, you should avoid mixing interfaces with different speeds (especially when you expect a heavy workload over these interfaces) in the following configurations:

- In the same multipath group
- In the same LAN group
- In a sysplex distributor environment where traffic reaches the distributor stack over a higher bandwidth OSA and is distributed to the target stack over a lower bandwidth OSA

Tip: You can display the speed of an active OSA-Express QDIO interface by using either **Netstat DEvlinks/-d** or the **DISPLAY TCPIP, ,OSAINFO** command.

Mixing OSA types - configuration recommendation

For planning your access to the external network, both Network Express and OSA-Express features can be viewed as OSAs. z/OS Communications Server supports the mixing of Network Express with OSA-Express features for external connectivity for both load balancing and high availability. If you plan to mix OSA feature types and use QDIO Accelerator, then refer to [“QDIO Accelerator” on page 122](#).

Consideration should be given to the speed (bandwidth) of each OSA. If your configuration includes OSA interfaces with different speeds (for example 10 GbE and 25 GbE), you should consider how you plan to use these interfaces in your network configuration.

Guidelines: In general, you should avoid mixing interfaces with different speeds (especially when you expect a heavy workload over these interfaces) in the following configurations:

- In the same multipath group.
- In the same LAN group.
- In a sysplex distributor environment where traffic reaches the distributor stack over a higher bandwidth OSA and is distributed to the target stack over a lower bandwidth OSA.

Note: In a sysplex distributor environment where bulk traffic is distributed to the target stack using VIPAROUTE, sysplex distribution encapsulates the bulk traffic. If the target stack is using a Network Express feature, the GRE bulk traffic is directed to the bulk input queue. If the target stack is using an OSA-Express feature, the GRE bulk traffic is directed to the primary input queue.

Tip: You can display the speed of an active OSA-Express QDIO interface by using either **Netstat DEvlinks/-d** or the **DISPLAY TCPIP, ,OSAINFO** command

Displaying OSA interface information

You can use the following commands to display information about OSA interfaces:

- Netstat DEvlinks/-d

This command displays configured and runtime information from the TCP/IP stack for an OSA interface.

- DISPLAY TCPIP,,OSAINFO

This command displays configured and runtime information from the OSA feature for the data subchannel device of the interface.

For information about the syntax and output of these commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

Configuring the OSA interface statement

The section covers general guidance and considerations about configuring the OSA interface statements for both the Network Express and OSA-Express features for both IPv4 and IPv6. Some migration considerations are also included. For specific syntax information about the INTERFACE statements and their various parameters refer to [z/OS Communications Server: IP Configuration Reference](#).

Network Express feature in EQDIO mode

The INTERFACE statement types for the Network Express feature are:

1. EQENET (Enhanced QDIO for Ethernet) for IPv4 and
2. EQENET6 (Enhanced QDIO for Ethernet) for IPv6

Use the INTERFACE statement to configure EQENET for IPv4 and EQENET6 for IPv6 definitions for the Network Express feature in EQDIO mode. Each INTERFACE statement creates a unique interface into Network Express, can be independently operated, and consumes a separate device.

The Network Express feature supports channel (CHPID) type OSH, Open Systems Adapter for Hybrid Networks.

The Network Express feature with EQDIO architecture:

- Supports a single physical port. OSH does not require or allow a port number to be configured anywhere, in z/OS or the System I/O configuration (HCD or IOCDs).
- Does not use control devices. The concept of MPC (Multi-Path Channel) architecture is eliminated from EQDIO. EQDIO uses a single device per interface, which is defined with the device number (DEVNUM) parameter on the INTERFACE statement. Both control signals and data are exchanged over a single EQDIO device.
- Operates at Layer 2 mode using (virtual) MAC addresses. All packets exchanged between z/OS and OSA (EQDIO) are based on the (virtual) MAC address contained in fully formed IEEE standard Ethernet frames. Although this layer 2 aspect is fundamentally transparent to the user, a virtual MAC is required for EQDIO interfaces (when configuring EQENET).
- Provides the same off-loaded functions as QDIO, such as ARP, CHKSUM and Segmentation.

z/OS Communications Server simplifies the Interface configuration for Network Express by eliminating or simplifying some of the more complex parameters used for QDIO. Some key examples of the z/OS simplification for EQDIO are:

- EQDIO interfaces do not use or require a user defined TRLE statement defined in VTAM. Each EQENET or EQENET6 interface statement dynamically creates a separate TRLE per interface when the interface is started. Each INTERFACE statement (and associated dynamic TRLE) uses a single device defined by the INTERFACE DEVNUM parameter. The configured device number for DEVNUM must apply to a device defined with an OSH CHPID. The actual device number used under the OSH CHPID is arbitrary. The next available device configured for z/OS is selected.

Tip: Since there are no associated configuration tasks in VTAM for Network Express INTERFACES there are no topics in or references to the z/OS Communications Server: SNA Network Implementation Guide. All configuration planning and guidance associated with Network Express INTERFACES is contained within this IP Configuration Guide.

Guideline: One OSH device is consumed per INTERFACE statement during activation. It is recommended that you configure multiple or extra OSA devices to each z/OS instance. For example, consider configuring at least one additional device than you anticipate needing.

Tip: The Netstat report for EQENET and EQENET6 interfaces displays the configured and the actual device number used for each interface.

Requirement: When you define multiple interfaces for the same OSH CHPID, each interface must be defined with the same device number. The next available device is selected, and is unique per interface. For additional configuration rules when configuring multiple OSH interfaces for the same OSH CHPID, see the DEVNUM parameter topic on the EQENET and EQENET6 INTERFACE statements in the [z/OS Communications Server: IP Configuration Reference](#).

- EQDIO interfaces do not use or require a user defined TRLE statement defined in VTAM. Each EQENET or EQENET6 interface statement dynamically creates a separate TRLE per interface when the interface is started. Each INTERFACE statement and the associated dynamic TRLE uses a single device defined by the INTERFACE DEVNUM parameter. The configured device number for DEVNUM must apply to a device defined with an OSH CHPID. The actual device number used under the OSH CHPID is arbitrary. The next available device configured for z/OS is selected.

Tip: The Network Express feature (EQDIO) does not require user defined VTAM TRLE definitions. EQDIO TRLEs are dynamically built when the INTERFACES are started. This design aspect simplifies the planning and administrative tasks associated with Network Express. Since there are no associated configuration tasks in VTAM for Network Express INTERFACES there are no references to the z/OS Communications Server: SNA Network Implementation Guide. All configuration planning and guidance associated with Network Express INTERFACES is contained within this IP Configuration Guide.

- Network Express supports a single physical port. The port number definition is not applicable to OSH and is not configured anywhere in z/OS or HCD.
- Inbound Workload Queuing is integrated into the base EQDIO support and is always present.

Result: Inbound Workload Queueing (IWQ) consumes additional storage for each interface. Users who have a large number (e.g. greater than 4) of OSA IPAQENET or IPAQENET6 INTERFACE statements not using IWQ (i.e. did not specify WORKLOADQ), who are planning to replace OSA-Express interfaces with Network Express EQENET or EQENET6 interfaces (with IWQ built into the base), will see a storage increase. The amount of the increase varies depending on how many input queues apply to your configuration. To better understand and plan for this potential storage increase see the Guidelines under the *Inbound Workload Queuing* topic.

- The Inbound Performance (INBPERF) parameter and all related sub-parameters such as Inbound Workload Queuing and Dynamic LAN Idle are eliminated. The related functions are integrated into the base z/OS EQDIO support.
- The ReadStorage parameter is eliminated. EQDIO read storage is dynamically managed.

Tip: Storage consumption can be monitored on a per EQDIO INTERFACE basis using the **NETSTAT DEVLINKS/-d** command and using the **D NET,TRL,TRLE=trle** command for the dynamic EQDIO TRLE.

- The following QDIO parameters are eliminated from EQDIO:
 - CHPIDTYPE. OSH is the only possible CHPID type.
 - PriRouter, including the router function, primary, secondary and nonrouter.
 - DYNVLANREG.
 - OLM.

A summary of the differences in the IPAQENET (QDIO) and IPv4 EQENET (EQDIO) and IPAQENET6 (QDIO) and the IPv6 EQENET6 (EQDIO) interface statements are shown below in the following tables.

Table 8. Summary of differences in IPAQENET (QDIO) and IPv4 EQENET (EQDIO)

Keyword	IPAQENET (OSD) (default)	EQENET (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
define	IPAQENET	EQENET	INTERFACE type: You can migrate IPAQENET (OSD) to EQENET6 (OSH) with the Auto-Migrate function using the devnum keyword.
CHPIDTYPE	OSD OSX	N/A	CHPID (hardware) TYPE. Eliminated for OSH, as there is only one possible CHPID type for OSH.
Portname	value	N/A	Defines the specific OSD physical port (PCHID) with the user statically defined VTAM TRLE (VTAM definition). The TRLE is defined with a matching portname value. A group of devices are defined in the TRLE definition, which must match the HCD. The VTAM arbitrarily assigns the first available device to each interface. Portname is obsolete for OSH. User defined TRLEs are also obsolete, as the TRLE is dynamically created. Portname is replaced by devnum. For more information, see devnum .
devnum	Value	value	Defines any valid OSH device for a given CHPID: VTAM uses devnum to find a specific CHPID, then finds any available device under that CHPID for the interface. New for 2.5 and 3.1 only: When DEVNUM is defined for OSD it is ignored on pre z17 machines. DEVNUM is used on z17 machines to migrate the IPAQENET statement to EQENET with the Auto-Migrate function .
IPADDR	value	value	Static IP address of this interface: No changes. For more information, see TEMPPIP .
num_mask_bits	mask	mask	Subnet mask: Optional for OSD, but required for some cases. For example, if there are multiple interfaces for the same OSA port or SMC. Subnet mask is required for OSD when using the Auto-Migrate function to IPAQENET with devnum. Subnet mask is required for OSH.

Table 8. Summary of differences in IPAQENET (QDIO) and IPv4 EQENET (EQDIO) (continued)

Keyword	IPAQENET (OSD) (default)	EQENET (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
TEMPIP	No parameters	No parameters	Defines an Interface without an IP Address. Allows dynamic IP address definition over interface using DHCP. When the DHCP flows complete, the interface is restarted with a new IPADDR. No changes for OSH.
Prirouter	NonRouter PriRouter SecRouter	N/A	Pri/Sec/Non Router: Applied to OSD only when not using VMAC. Obsolete for OSH, as VMAC is required for OSH.
VLANID	value	value	VLANID value: When the defined host is VLAN aware. No change for OSH. This is required when multiple interfaces are defined for the same physical port.
INBPERF	Balanced Dynamic MINCPU MINLATENCY	N/A	Defines Inbound Performance characteristics (complex variations): Balanced, Dynamic, MINCPU or MINLATENCY settings. Keyword is obsolete for OSH. OSH always uses DYNAMIC mode.
INBPERF DYNAMIC	NOWORKLOADQ WorkloadQ	N/A	Controls IWQ: Dynamic NOWORKLOAD WORKLOADQ (IWQ) Keyword is obsolete for OSH. OSH always uses IWQ.
VMAC	VMAC VMAC value	VMAC VMAC value	Defines Virtual MAC: Optional for OSD, but required for some cases. OSH requires VMAC, as VMAC is required for OSD to use the Auto-Migrate function. OSH continues to support user defined VMACs, though OSA generated VMAC is recommended.
VMAC	RouteALL RouteLocal	RouteAll RouteLocal	Controls OSA inbound routing: RouteALL: OSD Default - All packets are routed inbound RouteLocal: Only packets destined for IP Addresses in the home list are routed inbound. No changes for OSH.

Table 8. Summary of differences in IPAQENET (QDIO) and IPv4 EQENET (EQDIO) (continued)

Keyword	IPAQENET (OSD) (default)	EQENET (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
SMCR	SMCR	SMCR	Controls SMCR eligibility for this interface. SMCR remains the default, and NOSMCR disables SMCR for the interface. No changes for OSH.
SMCR	PFID SMCRIPADDR SMCRMTU	PFID SMCRIPADDR SMCRMTU	SMC-Rv2 Parameters: Enables and defines SMC-Rv2 for this IP interface. PFID and IP addr are both required: PFID (specific RNIC), RoCEv2 IPv4 addr, optional MTU, which defaults to 1k. No changes for OSH.
SMCD	SMCD	SMCD	Controls SMCD eligibility for this interface. SMCD remains the default, and NOSMCD disables SMCD for the interface. No changes for OSH.
Sourcevipa interface	vipa_name	vipa_name	Defines the source VIPA. No changes for OSH.
MTU	value	value	Defines the MTU for this interface. The OSD default value is 8992. MTU can be defined in multiple places. The OSH default value is 9000.
Readstorage	Global Max, Min, AVG	N/A	Defines the static value for the amount of read storage for inbound processing. The OSD default GLOBAL setting uses the VTAM setting. Not available for OSH because storage is dynamically managed.
IPBCAST	IPBCAST	IPBCAST	Defines (enables) IPBCAST over this interface. No changes for OSH.
SECCLASS	255 sec_class	255 sec_class	Defines the security class for IP filtering. No changes for OSH.
NoMonSysplex	NoMonsysplex MonSysplex	NoMonsysplex MonSysplex	Defines interface for sysplex autonomies monitoring. No changes for OSH.
DynVLANReg	NoDynVLANReg	N/A	Defines (enables) dynamic VLAN switch registration. Not supported for OSH.

Table 8. Summary of differences in IPAQENET (QDIO) and IPv4 EQENET (EQDIO) (continued)

Keyword	IPAQENET (OSD) (default)	EQENET (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
OLM	NonOLM OLM	N/A	Defines Optimized Latency Mode for OSD. Not supported for OSH.
ISOLATE	NoISOLATE ISOLATE	NoISOLATE ISOLATE	Defines (enables) LP-LP traffic within the CPC, rather than forcing all traffic to flow externally. No change for OSH.

Table 9. Summary of differences in IPAQENET (QDIO) and IPv6 EQENET (EQDIO)

Keyword	IPAQENET6 (OSD) (default)	EQENET6 (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
DEFINE	IPAQENET6	EQENET6	INTERFACE type: You can migrate IPAQENET6 (OSD) to EQENET6 (OSH) with the Auto-Migrate function using the DEVNUM keyword.
DELETE	interface_name	interface_name	Specifies that the interface should be deleted from the list of interfaces.
ADDADDR	value	N/A	Allows the addition of IP addresses to an existing interface definition. Eliminated for OSH.
DELADDR	Value	N/A	Allows the deletion of IP addresses from an existing interface definition. Eliminated for OSH.
DEPRADDR	Value	N/A	Allows the deprecation of IP address on an existing interface definition. Eliminated for OSH.
ADDTEMPPREFIX	Value	N/A	Allows the addition of prefixes to the list of temporary prefixes on an existing interface definition. Eliminated for OSH.
DELTEMPPREFIX	Value	N/A	Allows the deletion of prefixes from the list of temporary prefixes on an existing interface definition. Eliminated for OSH.
CHPIDTYPE	OSD OSX	N/A	CHPID (hardware) TYPE. Eliminated for OSH, as there is only one possible CHPID type for OSH. An error is generated if CHPIDTYPE OSX is specified on an IPAQENET statement that also specifies DEVNUM.

Table 9. Summary of differences in IPAQENET (QDIO) and IPv6 EQENET (EQDIO) (continued)

Keyword	IPAQENET6 (OSD) (default)	EQENET6 (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
PORTNAME	value	N/A	<p>Defines the specific OSD physical port (PCHID) with the user statically defined VTAM TRLE (VTAM definition). The TRLE is defined with a matching PORTNAME value. A group of devices are defined in the TRLE definition, which must match the HCD. VTAM arbitrarily assigns the first available device to each interface.</p> <p>PORTNAME is obsolete for OSH. User defined TRLEs are also obsolete, as the TRLE is dynamically created. PORTNAME is replaced by DEVNUM. For more information, see DEVNUM.</p>
DEVNUM	value	Value	<p>Defines any valid OSH device for a given CHPID:</p> <p>VTAM uses devnum to find a specific CHPID, then finds any available device under that CHPID for the interface.</p> <p>New for 2.5 and 3.1: When DEVNUM is defined for OSD, it is ignored on pre z17 machines, and is used on z17 machines to migrate IPAQENET6 statement to EQENET6 with the Auto-Migrate function.</p>
IPADDR ipv6_addr	values	values	<p>Static IP addresses of this interface: Optional for OSD. For more information, see INTFID.</p> <p>No changes for OSH.</p>
INTFID	value	Value	<p>Optional 64-bit interface identifier in colon-hexadecimal format. If specified, allows forming the link-local address for the interface and appended to manually configured prefixes to form complete IPv6 addresses on the interface.</p> <p>No changes for OSH.</p>
TEMPPREFIX	ALL NONE prefix/ prefix_length	ALL NONE prefix/ prefix_length	<p>A set of prefixes for which temporary IPv6 addresses can be generated. Allows dynamic IP address definition over interface using DHCPv6.</p> <p>No changes for OSH.</p>
PRIROUTER	NONROUTER PRIROUTER SECROUTER	N/A	<p>PRI/SEC/NONROUTER: Only applied to OSD when not using VMAC.</p> <p>Obsolete for OSH, as VMAC is required for OSH.</p>

Table 9. Summary of differences in IPAQENET (QDIO) and IPv6 EQENET (EQDIO) (continued)

Keyword	IPAQENET6 (OSD) (default)	EQENET6 (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
VLANID	value	Value	VLANID value: When the defined host is VLAN aware. No change for OSH. This is required when multiple interfaces are defined for the same physical port.
INBPERF	BALANCED DYNAMIC MINCPU MINLATENCY	N/A	Defines Inbound Performance characteristics (complex variations): BALANCED, DYNAMIC, MINCPU or MINLATENCY settings. Obsolete for OSH, as OSH always uses DYNAMIC mode.
INBPERF DYNAMIC	NOWORKLOADQ WorkloadQ	N/A	Controls IWQ: Dynamic NOWORKLOAD WORKLOADQ (IWQ) Keyword is obsolete for OSH. OSH always uses IWQ. A potential service mode only control is to be determined.
VMAC	VMAC VMAC value	VMAC VMAC value	Defines Virtual MAC: Optional for OSD, but required for some cases. OSH requires VMAC, as VMAC is required for OSD to use the Auto-Migrate function. VMAC ROUTEALL is used as the default value if the VMAC is not specified for use with the Auto-Migrate function. OSH continues to support user defined VMACs, though OSA generated VMAC is recommended.
VMAC	ROUTEALL ROUTELOCAL	ROUTEALL ROUTELOCAL	Controls OSA inbound routing: ROUTEALL: OSD Default - All packets are routed inbound ROUTELOCAL: Only packets destined for IP Addresses in the home list are routed inbound. No changes for OSH.
SMCR	SMCR	SMCR	Controls SMCR eligibility for this interface. SMCR remains the default, and NOSMCR disables SMCR for the interface. No changes for OSH.
SMCR	PFID SMCRIPADDR SMCRMTPU	PFID SMCRIPADDR SMCRMTPU	SMC-Rv2 Parameters: Enables and defines SMC-Rv2 for this IP interface. PFID and IP addr are both required: PFID (specific RNIC), RoCEv2 IPv4 addr, optional MTU, which defaults to 1k. No changes for OSH.

Table 9. Summary of differences in IPAQENET (QDIO) and IPv6 EQENET (EQDIO) (continued)

Keyword	IPAQENET6 (OSD) (default)	EQENET6 (OSH)	Keyword Definition - OSH Applicability, Changes and Notes
SMCD	SMCD	SMCD	Controls SMCD eligibility for this interface. SMCD remains the default, and NOSMCD disables SMCD for the interface. No changes for OSH.
SOURCEVIPA INTERFACE	vipa_name	vipa_name	Defines the source VIPA. No changes for OSH.
MTU	value	value	Defines the MTU for this interface. OSD default is 9000. MTU can be defined in multiple places. No changes for OSH.
READSTORAGE	Global Max, Min, AVG	N/A	Defines the static value for the amount of read storage for inbound processing. The OSD default GLOBAL setting uses the VTAM setting. Not available for OSH because storage is dynamically managed.
SECCLASS	255 sec_class	255 sec_class	Defines the security class for IP filtering. No changes for OSH.
NOMONSYSPLEX	NOMONSYSPLEX MONSYSPLEX	NOMONSYSPLEX MONSYSPLEX	Defines interface for sysplex autonomic monitoring. No changes for OSH.
DYNVLANREG	NODYNVLANREG	N/A	Defines (enables) dynamic VLAN switch registration. Not supported for OSH.
OLM	NonOLM OLM	N/A	Defines Optimized Latency Mode for OSD. Not supported for OSH.
ISOLATE	NoISOLATE ISOLATE	NoISOLATE ISOLATE	Defines (enables) LP-LP traffic within the CPC, rather than forcing all traffic to flow externally. No changes for OSH.
DUPADDRDET1	value	Value	Optional, defines the number of times to attempt duplicate address detection. The minimum value is 0, maximum is 2, and default is 1. No changes for OSH.

Network Express Auto-Migrate function

When planning your migration to Network Express, z/OS Communications Server provides a migration aid called “**Auto-Migrate**” that should be considered.

When you plan to migrate to Network Express, z/OS Communications Server provides a migration aid called “Auto-Migrate” that should be considered.

When migrating to Network Express, there are two options to define your EQENET Interface statements:

1. Define new EQENET interface statements from scratch.
2. When possible, reuse your existing IPAQENET interface statements using the Auto-Migrate function.

If you plan to replace your existing OSA-Express features with Network Express features, the external networking related OSA parameters such as IP address, subnet mask, and VLAN typically will remain the same. For this common use case, the Auto-Migrate function allows administrators to make only a minor change to their existing IPAQENET interface statements in order to use Network Express.

The EQDIO Auto-Migrate function automatically converts your IPAQENET and IPAQENET6 interface settings to EQENET and EQENET6 interface statements. The migrated interface dynamically changes your interface to EQENET in the running system, but Auto-Migrate does not alter your IPAQENET INTERFACE definition in your TCPIP PROFILE.

Auto-Migrate applies to both IPv4 and IPv6 interface statements. The information and examples shown in the remainder of this section describes only the IPv4 IPAQENET INTERFACE statement.

Requirement: To use the Auto-Migrate function on an existing IPAQENET interface statement, the following must be specified on your IPAQENET interface statement:

1. *subnet mask* must be defined and
2. *DEVNUM*, a new parameter, must be added and defined with a valid device number of the associated OSH CHPID. The *DEVNUM* parameter initiates the Auto-Migrate function.

Result: When *DEVNUM* is configured on IPAQENET it is applied as follows:

1. *DEVNUM* is ignored if it is executed on a System Z generation prior to the IBM z17 . In this case, the *PORTNAME* parameter continues to be used to find the user defined TRLE and associated OSA-Express feature.
2. When executed on a z17 generation of System Z, *DEVNUM* is used to automatically migrate the interface to EQENET. The configured device number must be associated with a Network Express feature. In this case, *PORTNAME* is ignored.

When the IPAQENET interface statement is automatically migrated to EQENET, the obsolete IPAQENET parameters are ignored, and some parameters are automatically used. Auto-Migrate only changes the INTERFACE settings in your active system. Auto-Migrate does not change your actual IPAQENET INTERFACE definition in your TCPIP PROFILE.

Note: IPAQENET INTERFACE dynamically switches to EQENET INTERFACE when activated on z17.

Figure below illustrates the main concepts of Auto-Migrate switching.

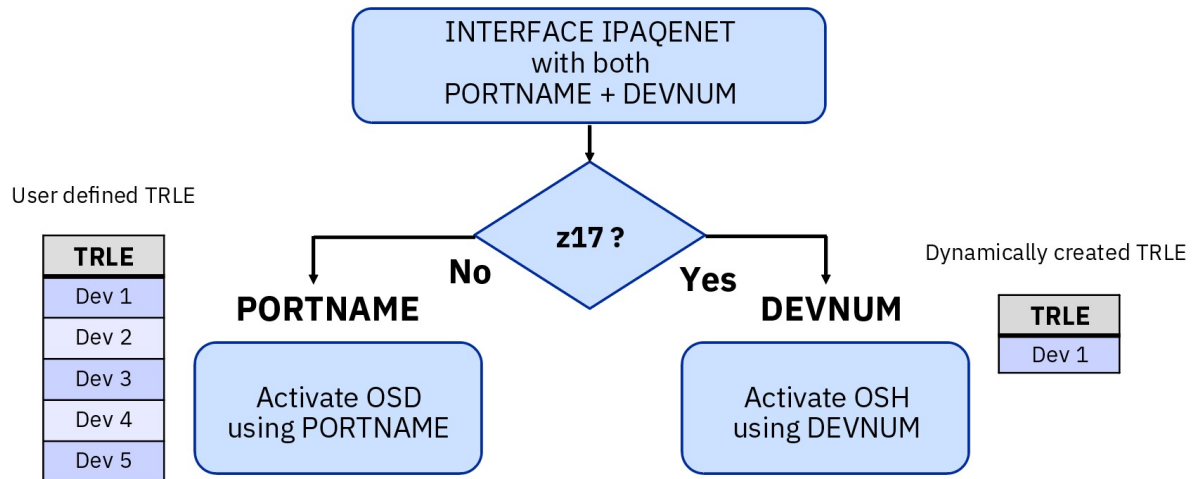

Figure 12. Network Express Auto-Migrate concepts

The Auto-Migrate (DEVNUM) capability allows a user to move a z/OS system to and from different generations of System z while continuing to use the same IPAQENET INTERFACE statement.

Result: The NetStat display for EQENET interfaces indicates when an interface is migrated to EQENET with the Auto-Migrate function and displays the applicable EQENET INTERFACE options that were used for the migrated interface.

Result: When executing on z17, Auto-Migrate attempts to activate an interface on Network Express and does not support switching between OSA-Express and Network Express. When the device number specified for DEVNUM on IPAQENET is invalid or not available, the OSH activation fails. This can occur if the device is not defined, is not associated with a valid OSH CHPID, or is defined but all devices are in use. If a valid OSH device is defined but is offline, the activation waits, (IST1631I) pending an online status change.

Steps for capturing the results of an EQENET INTERFACE statement created with Auto-Migrate

When you are ready to finalize your auto-migrated EQENET INTERFACE statement into a permanent EQENET INTERFACE statement, you have the option to capture the auto-migrated EQENET INTERFACE definition in your running system to create a permanent EQENET INTERFACE definition in your TCPIP PROFILE.

About this task

After an IPAQENET INTERFACE is successfully converted to EQENET, you can capture the syntax of the dynamically created EQENET INTERFACE statement by completing the following steps.

Procedure

Once your IPAQENET INTERFACE is successfully auto-migrated to EQENET and the EQENET INTERFACE has become active, you can follow this procedure.

1. Use NETSTAT DEVLINKS to confirm the state of the migrated EQENET interface. Ensure that the INTERFACE is active and successfully communicates with external hosts over Network Express.

Tip: Consider testing the auto-migrated EQENET INTERFACE for a period of time before finalizing to a permanent EQENET INTERFACE definition.

2. While running with an auto-migrated INTERFACE, you can dump the TCP/IP address space and use the TCIPCS PROFILE subcommand to display the configuration information for the EQENET INTERFACE.
3. Compare the existing IPAQENET INTERFACE definition in your TCPIP PROFILE that is using DEVNUM for Auto-Migrate to your migrated EQENET INTERFACE definition obtained from the previous step.
4. Use the dynamically built auto-migrated EQENET INTERFACE definition to define your final EQENET INTERFACE in your TCPIP profile.

Results

For information about the TCPIP profile (PROFILE.TCPIP) and configuration information for IPAQENET and EQENET, see the [z/OS Communications Server: IP Configuration Reference](#).

OSA-Express feature in QDIO mode

Use the INTERFACE statement to configure both IPv4 and IPv6 definitions for the OSA-Express feature in QDIO mode.

For an overview of the [OSA-Express feature](#) and QDIO mode, and how to configure VTAM to use the OSA-Express feature in this mode, see [z/OS Communications Server: SNA Network Implementation Guide](#).

When you configure an OSA-Express feature for IPv4 using the INTERFACE statement and also configure the same OSA-Express feature for IPv6, then the z/OS TCP/IP stack has two connections to the OSA-Express feature and requires two DATAPATH devices.

Steps for converting from IPv4 IPAQENET DEVICE, LINK, and HOME definitions to the IPv4 IPAQENET INTERFACE statement

Use the INTERFACE statement to configure IPv4 definitions for OSA-Express QDIO, rather than using the DEVICE, LINK, and HOME statements. The INTERFACE statement improves stack configuration for IPAQENET interfaces, and some functions like multiple VLAN support require that the QDIO interface is defined with the INTERFACE statement.

Procedure

Perform the following steps to convert your TCP/IP profile so that it uses the INTERFACE statement to configure IPv4 definitions for OSA-Express QDIO.

1. Convert the IPv4 IPAQENET DEVICE, LINK, and HOME statements to an IPv4 IPAQENET INTERFACE statement.

The values used in the following sub-steps are based on the sample profile that appears after the sub-steps.

- a. Copy the LINK name (QDI04101L in the example) and specify this name as the interface name on the INTERFACE statement.

Tip: When you use the original LINK name as the new INTERFACE name, you do not have to make changes to the static route definitions, OMPROUTE definitions, PKTTRACE statement, and PRIMARYINTERFACE statement.

- b. Copy the IPAQENET parameter from the LINK statement and specify this parameter after the DEFINE parameter of the INTERFACE statement.
- c. Copy the remaining LINK parameters and values (INBPERF DYNAMIC in the example) to the INTERFACE statement.
- d. Copy the DEVICE name (QDI04101 in the example) and specify this name on the PORTNAME parameter of the INTERFACE statement. This PORTNAME value must match the corresponding PORTNAME value in the SNA TRLE definition.
- e. Copy the remaining DEVICE parameters (PRIROUTER in the example) to the INTERFACE statement.
- f. Copy the HOME list entry IP address (172.16.1.1 in the example) and specify this address on the IPADDR parameter of the INTERFACE statement.

- g. Append a value (/24 in the example) to the end of the IP address to define the subnet mask.
- h. Remove the HOME list entry.

Example of the profile before conversion:

```
DEVICE QDIO4101 MPCIPA PRIROUTER
LINK QDIO4101L IPAQENET QDIO4101
INBPERF DYNAMIC
;
HOME
172.16.1.1 QDIO4101L
```

Example of the profile after conversion:

```
INTERFACE QDIO4101L
DEFINE IPAQENET
INBPERF DYNAMIC
IPADDR 172.16.1.1/24
PORTNAME QDIO4101
PRIROUTER
```

Tip: Optionally, you can dump the TCP/IP address space and use the CONVERT parameter on the TCIPCS PROFILE subcommand to display the configuration information at the time of the dump. The resulting output reflects your IPAQENET DEVICE, LINK, and HOME definitions in INTERFACE statement format, which might be helpful in converting your profile to use INTERFACE statements. You should review the output before you implement any changes. For more information about using the CONVERT parameter on the TCIPCS PROFILE, see [z/OS Communications Server: IP Diagnosis Guide](#).

For more information about the INTERFACE-IPAQENET OSA-Express QDIO interfaces, see [z/OS Communications Server: IP Configuration Reference](#).

2. Remove any BSDROUTINGPARMS entries for the interface.
3. If you have configured the SOURCEVIPA parameter on the IPCONFIG statement, perform the following steps:
 - a) Find the IPAQENET LINK in the original HOME list and search backwards to locate the static VIPA (if any) that is located closest to this link in the HOME list.
 - b) If you find a static VIPA, add the SOURCEVIPAINTERFACE parameter to the IPv4 INTERFACE statement. Use the static VIPA link name as the SOURCEVIPAINTERFACE value.
4. If you are using the START statement to start the IPv4 device, change the START statement to specify the name of the IPv4 INTERFACE.
5. If you also have an IPAQENET6 definition for the OSA, perform the following steps:
 - a) If you configure the same virtual MAC address (VMAC) on both the IPAQENET LINK statement and IPAQENET6 INTERFACE statement, either change one of the VMAC addresses so that they are unique or let OSA generate the VMAC addresses.
 - b) Ensure that the corresponding TRLE definition has at least two DATAPATH devices available so that one device is available for the IPv4 interface and one device is available for the IPv6 interface.

Results

For information about the TCP/IP profile, see [z/OS Communications Server: IP Configuration Reference](#).

The following examples show some additional changes that you might need to make to the definitions for OSA-Express QDIO.

Example of the profile before conversion:

```
IPCONFIG
SOURCEVIPA
;
DEVICE VIPA4811 VIRTUAL 0
LINK VIPA4811L VIRTUAL 0 VIPA4811
;
DEVICE QDIO4101 MPCIPA PRIROUTER
LINK QDIO4101L IPAQENET QDIO4101
```

HiperSockets concepts and connectivity

HiperSockets is a System z hardware feature that provides high performance internal communications between LPARs within the same central processor complex (CPC), without the use of any additional or external hardware equipment (for example, channel adapters and LANs). When the processor supports HiperSockets and the CHPIDs are configured in HCD (IOCP), TCP/IP connectivity can occur for two reasons:

- DYNAMICXCF is configured on the IPCONFIG (IPv4) or the IPCONFIG6 (IPv6) statements.
- A user-defined HiperSockets (MPCIPA) DEVICE and LINK (IPv4) or INTERFACE (IPv4 or IPv6) is configured and started.

Therefore, there are two types of HiperSockets devices:

- DYNAMICXCF HiperSockets device or interface (TRLE IUTIQDIO and an MPC group of subchannel devices)

The PORTNAME is IUTIQDxx, where xx is the IQD CHPID that VTAM uses (for example, IUTIQDFD when using IQD CHPID x'FD').

- A user-defined HiperSockets device or interface consisting of an MPC group of subchannel devices and one of the following definitions:
 - TRLE IUTIQDxx for INTERFACE (IPv6) and DEVICE/LINK (IPv4)
 - TRLE IUTIQ4xx for INTERFACE (IPv4)

The PORTNAME is not applicable for these TRLEs.

When HiperSockets is configured with a DEVICE and LINK definition, the z/OS TCP/IP stack has only one connection to the HiperSockets CHPID. You define this connection with a combination of the DEVICE, LINK, and HOME statements for IPv4, an INTERFACE statement for IPv6, or both. This single connection uses one DATAPATH device from the TRLE definition that VTAM creates to represent this HiperSockets CHPID. Both IPv4 and IPv6 traffic share this one connection and DATAPATH device. For more information about DATAPATH devices and TRLEs, see [z/OS Communications Server: SNA Network Implementation Guide](#).

If you configure a HiperSockets (IQD) CHPID for IPv4 using the INTERFACE statement and also configure the same HiperSockets CHPID for IPv6, then the z/OS TCP/IP stack has two connections to the IQD network represented by the IQD VCHID and requires two DATAPATH devices.

Steps for converting from IPv4 IPAQIDIO DEVICE, LINK, and HOME definitions to the IPv4 IPAQIDIO INTERFACE statement

Use the INTERFACE statement to configure IPv4 definitions for HiperSockets, rather than using the DEVICE, LINK, and HOME statements. The INTERFACE statement simplifies stack configuration for IPAQIDIO interfaces, and some functions like multiple VLAN support require that the HiperSockets interface is defined with the INTERFACE statement.

Procedure

Perform the following steps to convert your TCP/IP profile so that it uses the INTERFACE statement to configure IPv4 definitions for HiperSockets.

1. Convert the IPv4 IPAQIDIO DEVICE, LINK, and HOME statements to an IPv4 IPAQIDIO INTERFACE statement.

The values used in the following substeps are based on the sample profiles shown in [Figure 13 on page 98](#) and [Figure 14 on page 98](#).

- a. Copy the LINK name (HSINTF1 in the example) and specify this name as the interface name on the INTERFACE statement.

Tip: When you use the original LINK name as the new INTERFACE name, you do not have to change the static route definitions, OMPROUTE definitions, PKTTRACE statement, and PRIMARYINTERFACE statement.

- b. Copy the IPAQIDIO parameter from the LINK statement and specify this parameter after the DEFINE parameter of the INTERFACE statement.
- c. Copy the remaining LINK parameters and values (IPBCAST in the example) to the INTERFACE statement.
- d. Copy the xx portion of the DEVICE name (FE in the example) and specify this value on the CHPID parameter of the INTERFACE statement.

- e. Copy the HOME list entry IP address (200.16.1.1 in the example) and specify this address on the IPADDR parameter of the INTERFACE statement.
- f. Append a value (/24 in the example) to the end of the IP address to define the subnet mask.
- g. Remove the HOME list entry.

Tip: Optionally, you can dump the TCP/IP address space and use the CONVERT parameter on the TCIPCS PROFILE subcommand to display the configuration information at the time of the dump. The resulting output reflects your IPAQENET, IPAQIDIO, and VIRTUAL DEVICE, LINK, and HOME definitions in INTERFACE statement format, which might be helpful in converting your profile to use INTERFACE statements. Review the output before you implement any changes. For more information about using the CONVERT parameter on the TCIPCS PROFILE, see [z/OS Communications Server: IP Diagnosis Guide](#).

For more information about the IPv4 IPAQIDIO INTERFACE statement, see [z/OS Communications Server: IP Configuration Reference](#).

2. Remove any BSDROUTINGPARMS entries for the interface.
3. If you configured the SOURCEVIPA parameter on the IPCONFIG statement, perform the following steps:
 - a) Find the IPAQIDIO LINK in the original HOME list and search backwards to locate the static VIPA (if any) that is located closest to this link in the HOME list.
 - b) If you find a static VIPA, add the SOURCEVIPAINTERFACE parameter to the IPv4 INTERFACE statement. Use the static VIPA link name as the SOURCEVIPAINTERFACE value.
4. If you are using the START statement to start the IPv4 device, change the START statement to specify the name of the IPv4 INTERFACE.
5. Ensure that your HCD configuration is sufficient for the resulting dynamic TRLE definitions. DEVICE/LINK and IPv6 INTERFACE definitions use the IUTIQDxx TRLE and the new IPv4 INTERFACE definitions use the IUTIQ4xx TRLE where xx is the HiperSockets CHPID. If you use a combination of these definitions for a HiperSockets CHPID that requires both TRLEs, configure an additional set of 10 IQD devices in HCD for the new TRLE. If you are converting from DEVICE/LINK to IPv4 INTERFACE and are not using IPv6, you can reuse the same set of IQD devices for the new TRLE. However, if VTAM is still active from your previous definitions such that the IUTIQDxx TRLE was created, recycle VTAM to reuse that set of IQD devices for the new IUTIQ4xx TRLE. For more information about dynamic TRLEs, see [Resources automatically activated by VTAM](#) in [z/OS Communications Server: SNA Network Implementation Guide](#).

Results

For information about the TCP/IP profile, see [z/OS Communications Server: IP Configuration Reference](#).

The following examples show some additional changes that you might need to make to the definitions for HiperSockets.

Figure 14. Example IPv4 IPAQIDIO profile after conversion

Concepts and considerations for the IQD CHPID

The HiperSockets hardware device is represented by the IQD CHPID and its associated subchannel devices. All LPARs that are configured (HCD) to use the same IQD CHPID have internal connectivity and therefore have the capability to communicate using HiperSockets. If the system supports multiple channel subsystems, and if HiperSockets connectivity is required across multiple channel subsystems, the IQD CHPID must also be configured (HCD) to span the applicable channel subsystems. The IQD CHPID can be viewed as a logical LAN within the CPC. The HiperSockets hardware allows up to four (16 with systems that support multiple channel subsystems) separate IQD CHPIDs to be defined per CPC, creating the capability of having four (16 with systems that support multiple channel subsystems) separate logical LANs within the same CPC. [Figure 15 on page 99](#) and [Figure 16 on page 100](#) illustrate this concept:

System z CPC

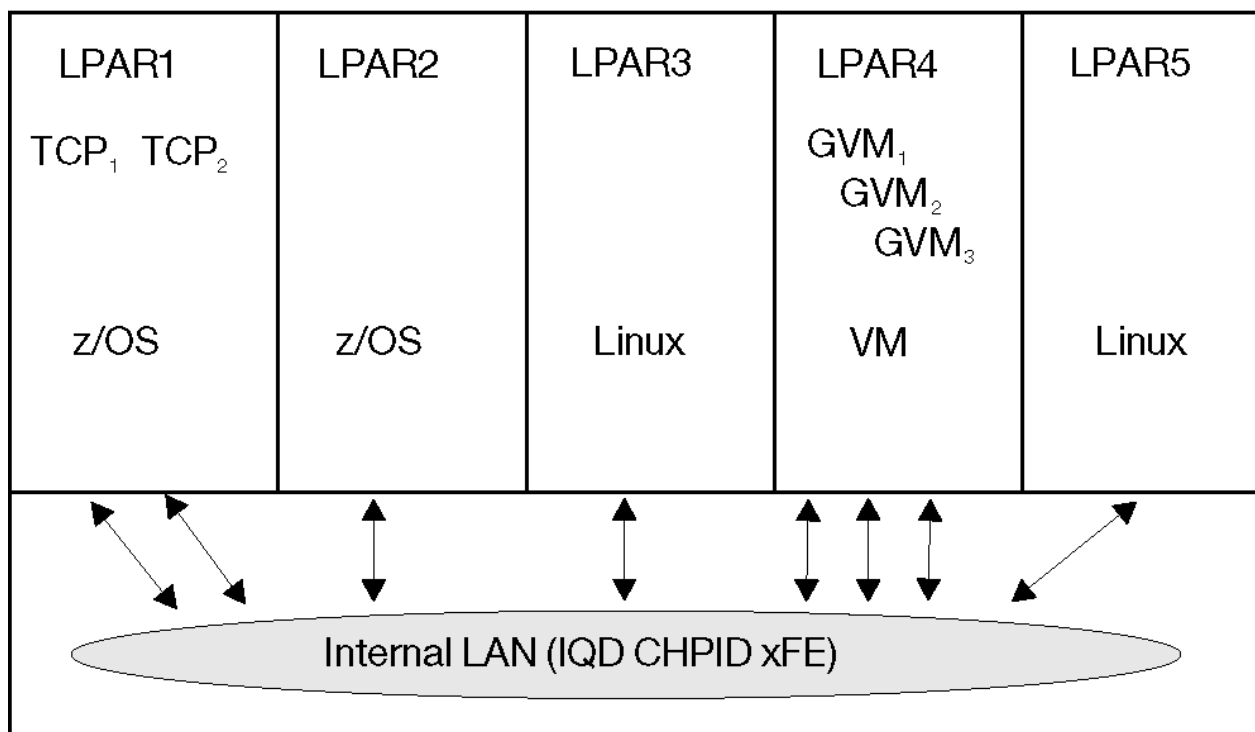

Figure 15. HiperSockets internal LAN

Figure 16. HiperSockets multiple internal LANs

With this capability, the system administrator can logically separate (or control) the internal connectivity. This is accomplished by controlling which specific LPARs are allowed to internally connect using HiperSockets. Further examples of this are as follows:

- SYSPLEX 'A' LPARs running on LPs 1 through 4 could use IQD CHPID x'FC'.
- SYSPLEX 'B' LPARs running on LPs 5 through 8 could use IQD CHPID x'FD'.
- A VM LPAR runs in LP 9 running various second level systems (Linux and z/OS) which use IQD CHPID x'FE'.
- Combinations of these examples could be:
 - Another set of LPARs on LPs 10 through 12 which are not using DYNAMICXCF (non SYSPLEX) are connected to IQD CHPIDs x'FE' and x'FF'.
 - Subsets of LPARs 1 through 8 are using both the DYNAMICXCF IQD CHPIDs and a non-DYNAMICXCF IQD CHPIDs.
 - Some LPARs are connected to all four IQD CHPIDs.

In a HiperSockets CHPID, IP addresses of the HiperSockets interfaces can be in the same subnet or in different subnets. Some applications can detect when HiperSockets IP addresses are in different logical subnets and might issue warning or error messages. For further subdivision of connectivity in the HiperSockets CHPID using virtual LANs, see [“HiperSockets and VLAN” on page 100](#).

HiperSockets and VLAN

HiperSockets supports VLANs, which means you can logically subdivide the internal LAN for a HiperSockets CHPID into multiple virtual LANs. Therefore, two stacks that configure the same VLAN ID for the same CHPID can communicate over HiperSockets, while two stacks that configure different VLAN IDs cannot. For HiperSockets interfaces that share a single DATAPATH device, the VLAN ID provided applies to both IPv4 and IPv6 connections.

Guideline: If you configure a VLAN ID on a stack using a HiperSockets CHPID, configure a VLAN ID for all other stacks using the same CHPID.

When you use VLAN IDs, the z/OS TCP/IP stack can have multiple connections to the same HiperSockets CHPID. One connection is allowed for each unique combination of VLAN ID and IP version (IPv4 or IPv6). Each connection is defined by an INTERFACE statement and uses one DATAPATH device from the TRLE definition created by VTAM. To configure one or more VLANs for a single HiperSockets CHPID, see [“Steps for configuring virtual LANs for a HiperSockets CHPID” on page 101](#).

Restrictions:

- A stack can support a maximum of 8 VLAN interfaces per IP version to the same HiperSockets CHPID.
- If multiple stacks on the same z/OS image are using the same HiperSockets CHPID, then those stacks can collectively activate a maximum of 8 VLAN interfaces per IP version for that CHPID.

Steps for configuring virtual LANs for a HiperSockets CHPID

You can logically subdivide the internal LAN for a HiperSockets CHPID into multiple virtual LANs (VLANs).

Procedure

Perform the following steps to configure one or more VLANs for a single HiperSockets CHPID:

1. Configure the interfaces.

Configure each IPv4 interface for this HiperSockets CHPID in the TCP/IP profile using the INTERFACE statement for IPAQIDIO, rather than the DEVICE, LINK, and HOME statements.

Configure each IPv6 interface for this HiperSockets CHPID in the TCP/IP profile using the INTERFACE statement for IPAQIDIO6.

2. Configure a VLANID value on each IPv4 INTERFACE statement and each IPv6 INTERFACE statement on this stack for this HiperSockets CHPID.

Within each IP version, these VLANID values must be unique.

3. Configure a unique subnet for each IPv4 interface for this HiperSockets CHPID, using the subnet mask specification on the IPADDR parameter on the INTERFACE statement.

4. If you are using OMPROUTE and OMPROUTE is not configured to ignore this interface, ensure that the subnet mask value that you configure on the INTERFACE statement in the TCP/IP profile matches the subnet mask that is used by OMPROUTE for this interface.

The subnet mask that OMPROUTE uses is the subnet mask value that is defined on the corresponding OMPROUTE statement (OSPF_INTERFACE, RIP_INTERFACE, or INTERFACE) for this interface. If no OMPROUTE statement is specified for this interface, the subnet mask that OMPROUTE uses is the class mask for the interface IP address.

5. Ensure that you understand the fixed storage requirements for this configuration.

Each interface requires its own DATAPATH device, and each DATAPATH device requires fixed storage for read processing. For more information, see [“Fixed storage requirements for OSA-Express QDIO and HiperSockets interfaces” on page 79](#)

Planning for IQD CHPID spanning

Figure 17 on page 102 illustrates how an IQD CHPID can span both logical channel subsystem 0 and logical channel subsystem 1.

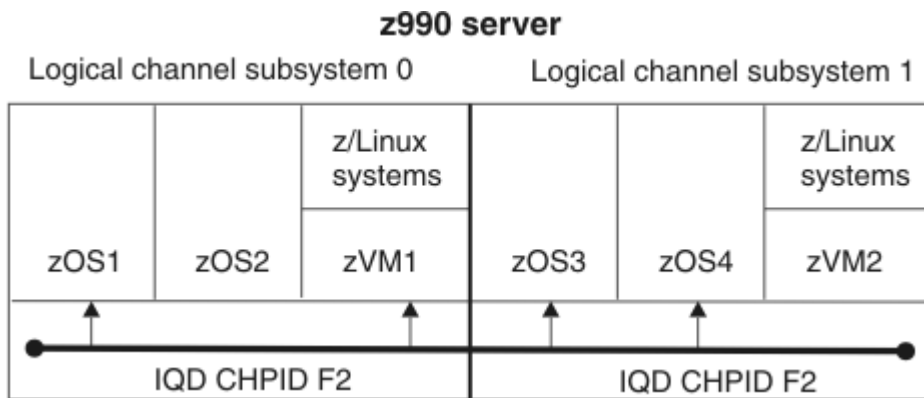

Figure 17. Spanned IQD (HiperSockets) CHPID

In Figure 17 on page 102, note:

- CHPID spanning is applicable to servers that support multiple channel subsystems, such as the IBM z990 server.
- IQD CHPIDs and their spanning attributes are configured using HCD.
- Logical channel subsystem 0 and logical channel subsystem 1 are both using IQD CHPID F2, which was configured (in HCD) to span.
- All images can exploit IQD CHPID spanning.
- Using HiperSockets support along with IQD spanning support, logical partitions in both logical channel subsystem 0 and 1 have internal connectivity.
- Specific logical partitions can be configured to have access to the spanned IQD CHPID. In this example:
 - IQD CHPID F2 is configured to span both logical channel subsystem 0 and logical channel subsystem 1.
 - In logical channel subsystem 0, zOS1 and zVM1 have connectivity (through IQD CHPID F2) to zOS3 and zOS4 in logical channel subsystem 1.
 - zOS2 and zVM2 do not have access to IQD CHPID F2.
- Up to 16 IQD CHPIDs can be configured in HCD.
- There are no TCP/IP or VTAM configuration changes required (spanning support is transparent to z/OS Communications Server).

Tip: TCP/IP Dynamic XCF support uses HiperSockets connectivity when the remote system is reachable through HiperSockets. This is dynamically determined, and this internal logic also handles a spanned IQD CHPID.

To configure a spanned IQD CHPID, see [z/OS HCD User's Guide](#).

The HiperSockets MPC group

For a specific IQD CHPID, VTAM builds a single HiperSockets MPC group, using the subchannel devices associated with that IQD CHPID. VTAM requests up to 10 devices from the I/O subsystem if they are defined to the CHPID being initialized, regardless of how many will be required for the number of TCP/IP stacks to be used in the LPAR. VTAM requires two subchannel devices for the read and write control devices, and 1 to 8 devices for data devices, one device for each of up to 8 TCP/IP stacks.

Therefore, to build the MPC group, there must be a minimum of 3 subchannel devices defined (within HCD) and associated with the same IQD CHPID. The maximum number of subchannel devices that VTAM will use is 10 (supporting 8 data devices or 8 TCP/IP stacks) per LPAR or MVS image. The subchannel devices must be configured for the LPAR and online prior to when the TCP/IP stack is initialized. Generally, the number of HiperSockets subchannel devices you should configure to HCD per LPAR is:

$$+ \quad 2 \quad \begin{array}{l} \text{(read / write control devices)} \\ \text{(where N = number of TCP/IP stacks)} \end{array}$$

```

-----
      N+2      (total subchannel devices per LPAR)
Example (LPAR 1 starts two TCP/IP stacks and both stacks use HiperSockets):

- define 4 subchannel devices on the same IQD CHPID
- where 2 are used for read / write control and 2 data devices are available

```

Tip: The HCD configuration is the only way to control the number of devices that VTAM uses for HiperSockets.

The first TCP/IP stack within the LPAR to initialize dynamic XCF support (DYNAMICXCF) causes the IUTIQDIO HiperSockets MPC group to be dynamically created. The first TCP/IP stack within the LPAR to initialize a user-defined HiperSockets device (TRLE IUTIQDxx) causes the IUTIQDnn HiperSockets MPC group to be dynamically created.

Each TCP/IP stack can then start the HiperSockets device, and each stack is assigned a unique (dedicated) subchannel data device from the IUTIQDIO or IUTIQDnn MPC group.

Guideline: Configure the IQD CHPIDs using CHPIDs x'F0' through x'FF' (but any valid CHPID value x'00' through x'FF' can be configured as TYPE = IQD). See [z/OS HCD Planning](#) and [Appendix D, “Using HCD,”](#) on page 1369 for additional details.

HiperSockets maximum frame size

The HiperSockets hardware supports four different frame sizes referred to as the HiperSockets MFS (maximum frame size). Using HCD (or IOCP), the HiperSockets MFS is configured on the IQD CHPID using the 'OS=' parameter. All LPARs communicating over the same IQD CHPID will then use the same IQD MFS. The MFS affects the largest packet that TCP/IP can transmit. TCP/IP will adjust the MTU (Maximum Transmission Unit) based on the MFS, which is discovered during activation.

The following table depicts the four possible TCP/IP MTU sizes resulting from the HiperSockets frame sizes:

OS=value	HiperSockets frame size	TCP/IP MTU size
00 (default)	16 KB	8 KB
40	24 KB	16 KB
80	40 KB	32 KB
C0	64 KB	56 KB

The default HiperSockets MFS is 16 KB. However, in cases in which increased bandwidth is required (such as large file transfers, file backup), a larger MFS could be used. In most workload environments the default size will result in better storage and CPU usage.

```

*****
* OS values are '00'=16K, '40'=24K, '80'=40K and 'C0'=64K. *
*
* Need at least 3 addresses per z/OS, maximum of 10:
* - 2 addresses for control
* - 1 address for data for each TCP stack (between 1 and 8) *
*****

See [z/OS HCD Planning and Appendix D, “Using HCD,” on page 1369](#) for additional details.

Modifying HiperSockets connectivity [TCP/IP device and link and the VTAM HiperSockets MPC group (IUTIQDIO)]

Certain modifications can be made to the HiperSockets device (MPC group) without disrupting an active TCP/IP stack.

z/OS supports dynamic I/O for the HiperSockets CHPID and subchannel devices, allowing subchannel devices to be added or removed to or from an LPAR which has already been IPLed.

TCP/IP supports the STOP and START command for the DYNAMICXCF HiperSockets device (IUTIQDIO). However, the commands are supported only when the (internal) start (activation) was successful during stack initialization. TCP/IP also supports the STOP and START command for the user-defined HiperSockets devices (IUTIQDxx). Because a user-defined HiperSockets device is supported as an MPCIPA device, STOP and START function just as they would for other MPCIPA devices.

VTAM supports a MODIFY VTAMOPTS command that you can use to change the initial setting of the IQDCHPID start option.

Therefore, it is possible to make certain changes to the DYNAMICXCF HiperSockets MPC group (IUTIQDIO) without restarting VTAM or an active TCP/IP stack. Examples of changes that can be made are (STOP/START device required):

- Alter which specific IQD CHPID is used for DYNAMICXCF (for example, move from the x'FC' CHPID to the x'FD' CHPID).
- Add or remove subchannel devices (for example, from the current IQD CHPID).
- Alter the IQD MFS which alters the TCP/IP MTU (for example, increase the current IQD CHPID from 16k to 64k).

Although VTAM supports modifications to the start option IQDCHPID (and the modification will be immediately displayed), the effects will vary depending on what the current usage was and the change (from or to) that was made. For example:

- When MODIFIED from ANY (or CHPID) to NONE, there is no effect on current usage but blocks subsequent activations of the DYNAMICXCF HiperSockets device.
- When MODIFIED from NONE to ANY (or CHPID), there is no effect on current usage but allows subsequent activations.
- When MODIFIED from CHPID_X to CHPID_Y, there is no effect on current usage.

Note: VTAM uses the CHPID value only when building the IUTIQDIO MPC group.

To change CHPIDs for an active MPC group, take the following steps:

1. TCP/IP IUTIQDIO devices and IQDIOINTF6 interfaces that are changing must be stopped.
2. Make any necessary HCD/IOCDS changes.
3. Verify new subchannel devices are varied online.
4. Verify the MPC group has deactivated (with no usage it times out after approximately 2 minutes).
5. Modify IQDCHPID = CHPID (to new CHPID).
6. Restart the TCP/IP IUTIQDIO devices and IQDIOINTF6 interfaces.

To use HiperSockets communications, the processor must have the necessary hardware support. If the processor does not support HiperSockets communications, modifications to this start option will not be accepted, and the IQDCHPID option will not be displayed (displayed as ***NA***).

HiperSockets connectivity and routing

For each pair of stacks within a sysplex that are not on the same MVS image, if all of the following conditions are true, the stacks will use HiperSockets DYNAMICXCF connectivity (versus standard XCF connectivity):

- The two stacks must be on the same CPC.
- For the DYNAMICXCF HiperSockets device (IUTIQDIO):
 - The two stacks must be using the same IQD CHPID.
 - If running on a system that supports multiple channel subsystems and the two stacks are also in different channel subsystems, the IQD CHPID must be configured (HCD) to span.
- Both stacks must be configured (HCD) to use HiperSockets.
- For IPv4 HiperSockets connectivity, both stacks must be at the z/OS V1R2 level, or a later release. For IPv6 HiperSockets connectivity, both stacks must be at the z/OS V1R7 level.
- The initial HiperSockets activation must complete successfully.

When an IPv4 DYNAMICXCF HiperSockets device and link are created and successfully activated, a subnet route is created across the HiperSockets link. The subnet is created by using the DYNAMICXCF IP address and mask. This allows any LPAR within the same CPC to be reached, even ones that are not within the sysplex. For example, an LPAR that is running z/Linux or z/VM® that does not support joining the sysplex can still be reached. The z/Linux or z/VM LPAR must define at least one IP address for the HiperSockets endpoint that is within the subnet defined by the DYNAMICXCF IP address and mask.

Similarly, when an IPv6 DYNAMICXCF HiperSockets interface is created and successfully activated, a prefix route is created across the HiperSockets interface (if `prefix_route_len` is specified on DYNAMICXCF). This allows any LPAR within the same CPC to be reached, even ones that are not within the sysplex. For example, an LPAR that is running z/Linux or z/VM that does not support joining the sysplex can still be reached. The z/Linux or z/VM LPAR must define at least one IP address for the HiperSockets endpoint that uses the same prefix as the DYNAMICXCF IP address.

Therefore, TCP/IP can communicate with other LPARs within the CPC over the HiperSockets connectivity created by DYNAMICXCF even when the TCP/IP in the other LPAR is not part (joins or supports) of the sysplex. You can also elect to manually configure a HiperSockets device for non-sysplex communications.

When multiple stacks are within the same LPAR that supports HiperSockets, both IUTSAMEH and HiperSockets links or interfaces will coexist. In this case, it is possible to transfer data across either link or interface. Because IUTSAMEH links or interfaces have better performance, it is better to always use them for intra-stack communication. A host route will be created by DYNAMICXCF processing across the IUTSAMEH link or interface but not across the HiperSockets link or interface. To avoid using the HiperSockets link or interface for communication within the same host, the following rules should be observed:

- Specify DYNAMICXCF IP addresses in a separate subnet than that of VIPA addresses (IPv4) or using a separate prefix than that of VIPA addresses (IPv6).
- Do not specify static IUTSAMEH links or interfaces.

It is also possible with multiple stacks in the same LPAR to end up with both XCF and HiperSockets links or interfaces. This occurs when the availability of the (preferable) HiperSockets link or interface changes as each TCP stack (within the same LPAR) is started. For example, stack A is started with HiperSockets available and later stack B is started with HiperSockets unavailable. This type of configuration should be avoided.

Efficient routing using HiperSockets Accelerator

Communications Server leverages the technological advances and high performing nature of the I/O processing offered by HiperSockets with the IBM Z servers and the IBM OSA-Express feature using QDIO architecture by optimizing IP packet forwarding processing that occurs across these two types of links. This function is referred to as HiperSockets Accelerator. It is a configurable option, and activated by configuring the `IQDIORouting` option on the `IPCONFIG` statement.

Restrictions:

- HiperSockets Accelerator is IPv4 only.
- You cannot enable HiperSockets Accelerator if you enable IP security on the stack.
- You cannot enable HiperSockets Accelerator if IP forwarding is disabled on the stack.
- Network Express (OSH) EQDIO does not support HiperSockets Accelerator. EQDIO supports acceleration from and to EQDIO interfaces only.

When configured, it allows unicast IPv4 packets that are received over a HiperSockets link and are to be forwarded over a QDIO link (or received over QDIO and are to be forwarded over HiperSockets) to be forwarded by the z/OS Communications Server HiperSockets device driver. That is, the IP forwarding function is pushed down as close to the hardware [or to the lowest software DLC (Data Link Control)] layer as possible so that these packets do not have to be processed by the TCP/IP stack or address space. Therefore, valuable TCP/IP resources (storage and machine cycles) are not expended for purposes of routing and forwarding packets. [Figure 18 on page 106](#) illustrates a configuration before the use of HiperSockets Accelerator.

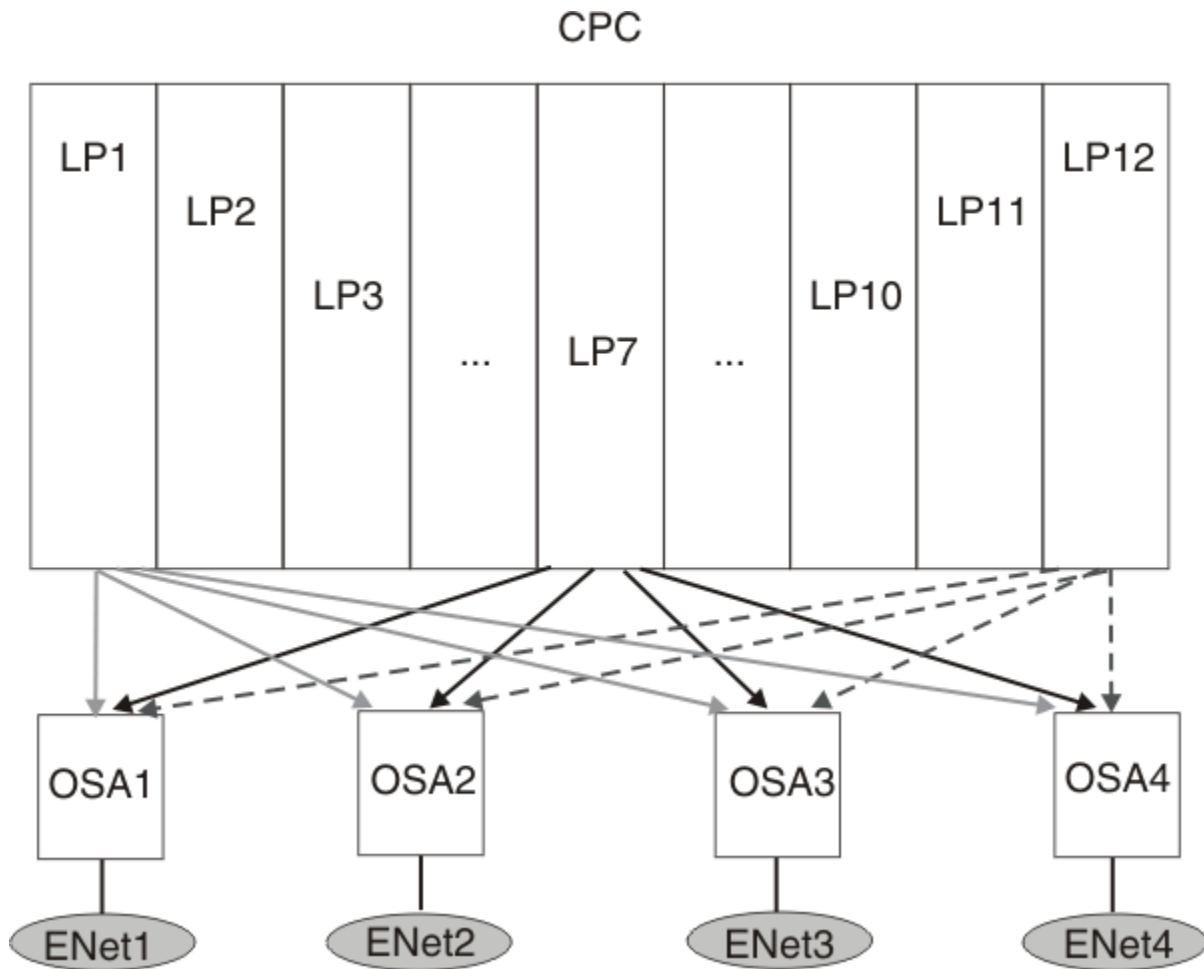

Figure 18. Candidate configuration for HiperSockets Accelerator

HiperSockets Accelerator presents a different configuration and approach to obtain full connectivity, as shown in [Figure 19 on page 107](#).

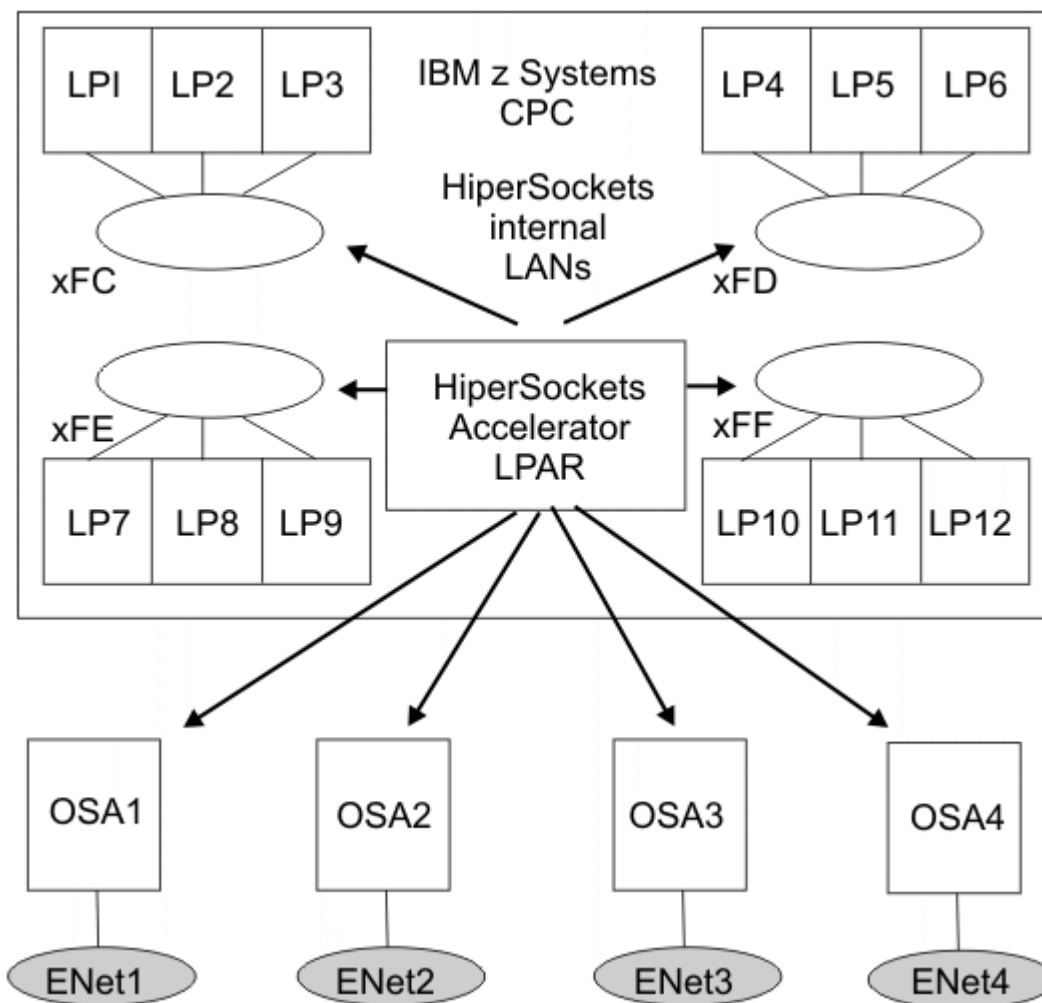

Figure 19. HiperSockets Accelerator configuration

This function allows a user to position a specific or single TCP/IP stack which has direct physical connectivity to the OSAs LANs as the HiperSockets router. This stack can then connect to all remaining TCP/IP stacks in other images (LPARs) within the same CPC that require connectivity to the same OSA LANs using HiperSockets connectivity.

This approach becomes more beneficial as the number of LPARs within a given CPC increase. Instead of attempting to directly attach each LPAR to each physical network attachment using an OSA LAN, a smaller number of OSAs could be concentrated through a single z/OS LPAR. From a performance perspective, HiperSockets Accelerator attempts to make the intermediate (or router) TCP/IP stack appear as if it did not exist in the path. Instead, each LPAR will appear as if each were directly attached to the physical network (for example, packets are forwarded without traversing the router TCP/IP stack). There are no additional routing configuration tasks required by the user. The prerouting occurs automatically. The TCP/IP stack automatically detects IP packet forwarding is occurring across a HiperSockets eligible route (QDIO/HiperSockets or HiperSockets/QDIO), and dynamically creates a HiperSockets Accelerator route entry. All subsequent packets will then take the optimized device driver path, and will not traverse the TCP/IP stack.

The dynamically created HiperSockets Accelerator routing entries can be displayed by the Netstat ROUTE/-r report option with the IQDIO modifier. VTAM tuning statistics are provided to allow the user to monitor or measure prerouting activity.

QDIOPriority (IQDIORouting option) is an optional choice that allows the user to specify which of the four priority queues should be used when prerouting packets from a HiperSockets link outbound to a QDIO link. The default is 1 (highest priority), and in most cases should be sufficient.

For additional details regarding the IQDIORouting configuration option, see the IPCONFIG statement in [z/OS Communications Server: IP Configuration Reference](#).

Tips:

- If packet trace is enabled, then packets that are accelerated by HiperSockets Accelerator do not appear in the packet trace (either inbound or outbound). If you want function similar to that of the packet trace in conjunction with HiperSockets Accelerator, you can use the OSA-Express network traffic analyzer (OSAENTA) to trace these packets that are accelerated to or from OSA-Express QDIO. For more details on OSAENTA, see [“OSA-Express network traffic analyzer trace”](#) on page 125.
- QDIO Accelerator provides all of the function supported by HiperSockets Accelerator, and provides accelerated forwarding for other combinations of traffic involving QDIO devices, including sysplex distributor. QDIO Accelerator can also interoperate with IP security. For more information, see [“QDIO Accelerator”](#) on page 122.

HiperSockets multiple write

The HiperSockets multiple write facility moves multiple output data buffers in a single write operation. This facility might reduce CPU usage, and might provide a performance improvement for large outbound messages that are typically generated by traditional streaming workloads such as file transfer, and interactive web-based services workloads such as XML or SOAP.

To enable the HiperSockets multiple write facility on all HiperSockets interfaces, including interfaces created for dynamic XCF, add the IQDMULTIWRITE parameter to the GLOBALCONFIG statement. For more information about the GLOBALCONFIG statement and the HiperSockets multiple write facility, see [z/OS Communications Server: IP Configuration Reference](#).

Restriction: HiperSockets multiple write is effective only on an IBM System z10 or later server when z/OS is not running as a guest in a z/VM environment.

HiperSockets multiple write assist with IBM zIIP

When your system is an IBM System z10 or later server and the HiperSockets multiple write facility is enabled, an additional assist for large outbound TCP messages is available through the IBM Z Integrated Information Processor (zIIP) on a System z9® or later server. To enable HiperSockets write processing for large outbound TCP messages on available zIIPs, specify the ZIIP IQDIOMULTIWRITE parameter on the GLOBALCONFIG statement.

When your system is an IBM System z10 or later server that does not have zIIPs configured, you can use the zIIP HiperSockets multiple write facility to project the percentage of existing HiperSockets workload currently running on central processors that would be eligible to run on zIIPs, if zIIPs were available on the z/OS image. To perform such projection analysis, specify the following parameters on the GLOBALCONFIG statement:

- IQDMULTIWRITE parameter
- ZIIP parameter with the value IQDIOMULTIWRITE

In addition, you must also specify PROJECTCPU= YES in the IEAOPTxx member of SYS1.PARMLIB. Then run your HiperSockets workload, and SMF provides accounting information regarding zIIP-eligible workload.

Guideline: Remove GLOBALCONFIG ZIIP IQDIOMULTIWRITE from your TCP/IP profile after you have completed your zIIP performance projection runs. TCP/IP consumes slightly more central processing resources when no zIIPs are online and you have coded GLOBALCONFIG ZIIP IQDIOMULTIWRITE.

For information about configuring the PROJECTCPU parameter in the IEAOPTxx member of SYS1.PARMLIB, see [z/OS MVS Initialization and Tuning Reference](#). For information about accounting for zIIP eligibility in SMF record types 30 and 7x, see [z/OS MVS System Management Facilities \(SMF\)](#). For information about zIIP-related reporting updates, see [z/OS Resource Measurement Facility Report Analysis](#).

z/OS HiperSockets connectivity

[“HiperSockets concepts and connectivity”](#) on page 95 describes how in z/OS HiperSockets can be used for two unique purposes with each option that have unique configuration requirements summarized here as follows:

Dynamic XCF (dynamically defined HiperSockets)

Dynamic XCF links provide connectivity to other z/OS instances within the same sysplex. When other z/OS instances within the sysplex are also running on the same central processor complex (CPC), HiperSockets interfaces are (optionally) dynamically created to those instances.

User-defined HiperSockets interface (non XCF-related HiperSockets)

User-defined (static) HiperSockets interface definitions provide connectivity to other z/OS or Linux instances running within the same CPC that are unrelated to sysplex (or the IP subnet of the dynamic XCF interface). In this use case, the administrator manually configures the user-defined HiperSockets IPv4 or IPv6 interface by using DEV/LINK or INTERFACE statements.

HiperSockets uses the Internal Queued Direct I/O (IQD) channel architecture on IBM Z. IQD channel path IDs (CHPIDs) and their related subchannel devices are defined in hardware configuration definition (HCD). The IQD system firmware is based on QDIO system architecture. QDIO architecture defines the following two connectivity modes of internal system connectivity for the internal routing of network traffic as follows:

Layer 3 (L3) mode

IQD firmware routes packets to other hosts using the same IQD CHPID based on the (next hop) IP address.

Layer 2 (L2) mode

IQD firmware routes packets to other hosts using the destination MAC address (unaware of the L3 protocol).

Each IQD CHPID serves as a unique internal (IBM Z) isolated network. Each internal IQD network can optionally be configured with a single physical network identifier (PNetID).

Operating systems running on the same CPC that require HiperSockets connectivity must:

- Connect to the same IQD channel (CHPID).
- Use the same QDIO (L2 or L3) mode.
- Use the same VLAN (when VLANs are used).

z/OS HiperSockets (IQD) interfaces created by both DYNXCF and user-defined interfaces support L3 mode only and the mode is not configurable in z/OS. The next topic introduces a different configuration approach that does use QDIO L2 mode.

HiperSockets Converged Interface overview

z/OS Communications Server provides the capability to integrate HiperSockets connectivity with your external LAN. HiperSockets connectivity converged with the external LAN is referred to as the z/OS Communications Server HiperSockets Converged Interface (HSCI) function.

Within each central processor complex (CPC), you can define a specific Internal Queued Direct I/O (IQD) channel path ID (CHPID) for HiperSockets to provide connectivity that is associated with your designated external LAN. You must configure the designated IQD CHPID by using a channel parameter in the hardware configuration definition (HCD), which enables the IQD External Bridge channel function of HiperSockets. The IQD External Bridge function is a channel function and is not a new CHPID type. When the IQD External Bridge function is configured, the single IQD CHPID is integrated with your designated external LAN; for communications within the CPC, the External Bridge function enables secure and high-performance network access using the designated IQD CHPID.

The z/OS HSCI function transparently converges a HiperSockets interface with your OSA interfaces providing transparent and dynamic usage of HiperSockets. HSCI is supported by both OSA-Express (OSD) and Network Express (OSH) features.

HSCI provides z/OS users with a third HiperSockets hands free usage (administrative) model. The HSCI inherits all of the OSA network-related attributes (for example, IP route, IP address, subnet, VLAN, VMAC, and so on).

The HSCI configuration option is managed with a single TCP/IP global configuration option called AUTOIQDC (automatically create, converge, operate, and manage the IQD interface). HSCI is intended to replace the (need for) static user-defined HiperSockets interfaces. The HSCI function is unrelated to and independent of DYNXCF-related HiperSockets.

The key benefits of the HSCI are:

- Combines the existing high-performance attributes of HiperSockets for intra-CPC communications with your external LAN providing a single IP network administrative model.
- z/OS HiperSockets administrative usability improvements provide:
 - Dynamic configuration and reconfiguration of HiperSockets interfaces.
 - Automatic provisioning and connectivity to the IQD network without requiring operational actions such as Start or Stop Interface commands.
 - Dynamic discovery of and communications with peer hosts that have access to the same IQD network.
- Converges OSA connectivity and HiperSockets connectivity into a single logical network interface. The single interface simplifies network management by reducing the number of resources that are required to represent individual unique networks, including the following resources:
 - IP interfaces
 - IP subnetworks (VLANs when applicable)
 - IP addresses
 - IP routes
- z/OS mobility improvements:

When a z/OS instance is moved to another CPC as your OSA interfaces are started, TCP/IP automatically and dynamically reconnects to HiperSockets on the new CPC without requiring any TCP/IP configuration or configuration changes.
- Linux Layer 2 (L2) mode connectivity for HiperSockets providing compatibility with Linux instances using the z/VM Virtual Switch Bridge environment (requires L2 mode).
- Enables sysplex network traffic to transparently use HiperSockets connectivity for VIPAROUTE processing over OSA interfaces.
- Single IP network topology:

HSCI provides a single seamless LAN topology where your internal IQD networks within each CPC are no longer unique and isolated IP subnets. With the HSCI function, your IQD network becomes part (an extension) of your external LAN (creating a single IP subnet). This architectural model is similar to what a switch Bridge port provides, bridging separate networks and creating a single logical network topology. The single network model simplifies many network administrative tasks. The concepts of the single network are illustrated in the following figures.

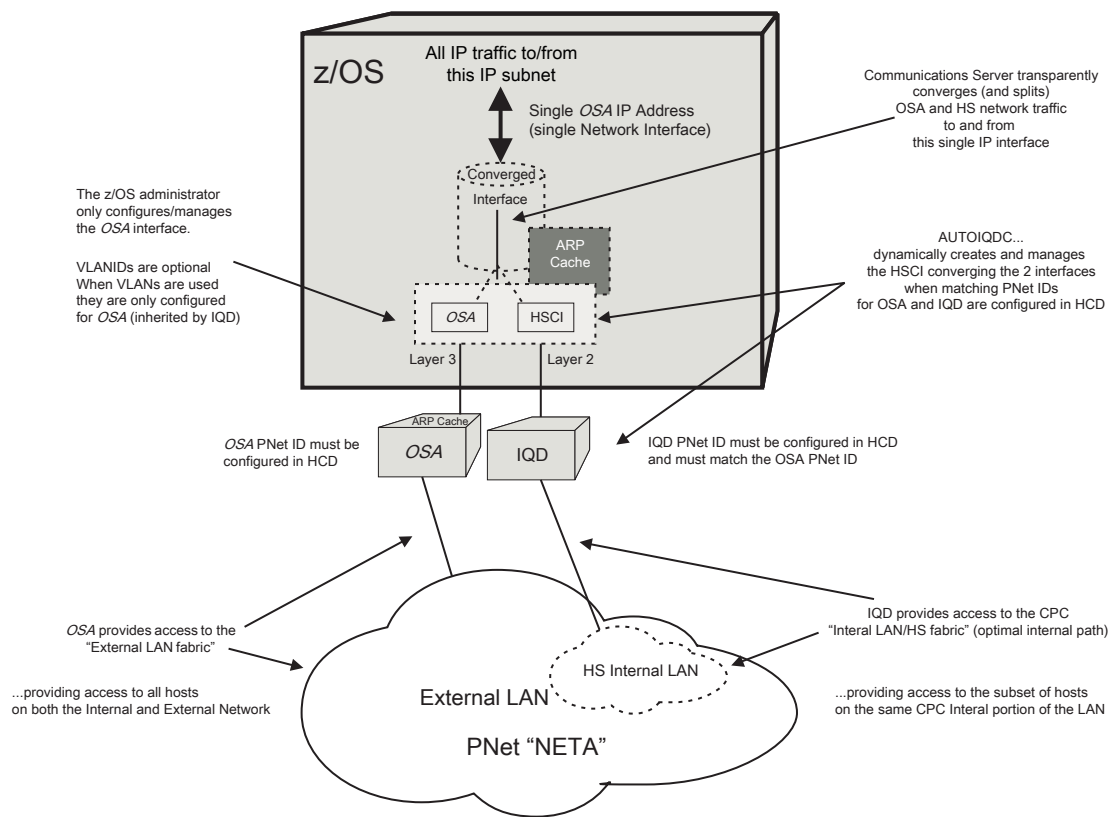

Figure 20. HiperSockets Converged Interface overview

Figure 20 on page 111 shows the key concepts of the HSCI function. HSCI logically converges the network interfaces provided by IQD with OSA CHPID types into a single logical interface. HSCI is transparent to the application layer. The upper layers of the TCP/IP software stack only have visibility to a single OSA interface that has a single IP address and IP subnet.

The z/OS Communications Server HSCI function is controlled with a single TCP/IP Global Configuration parameter called AUTOIQDC. The AUTOIQDC parameter indicates that Communications Server should automatically create, manage, and converge the HSCI with the associated OSA interfaces. Communications Server associates the dynamically generated IQD interface with an OSA interface based on the IQD and OSA CHPIDs that have matching PNetIDs.

Other than the AUTOIQDC TCP/IP parameter there are no other TCP/IP or VTAM definitions that are required to use the HSCI function. However, the associated OSA configuration must be defined with the following:

- VMAC (OSA generated)

The AUTOIQDC setting enables the dynamic creation of the HSCI and the VTAM TRLE when an OSA interface is started. The IQD CHPID I/O device definitions are required in HCD. For each unique IQD CHPID Communications Server creates a single TRLE for IPv4 and a separate (single) TRLE for IPv6. Each HSCI TRLE uses up to 10 devices (eight data devices and two control devices).

Communications Server dynamically determines whether traffic routed to the external LAN over a given OSA CHPID can also use the HSCI; if the traffic can use the HSCI, Communications Server routes the traffic over the high-performance HiperSockets IQD CHPID. If the AUTOIQDC parameter on the GLOBALCONFIG statement in the TCP/IP profile is specified, when the first OSA INTERFACE is started the HSCI, also known as the IQDC interface, and TRLEs are dynamically created.

The naming convention for the dynamically created:

- HSCI is EZAIQCxx (IPv4) and EZ6IQCxx (IPv6), where xx is the IQD CHPID number to which a particular HSCI is associated. The HSCIs are identified by interface type IPAQIQDC for IPv4 and interface type IPAQIQDC6 for IPv6. Traffic for unique VLANs over the same OSA CHPID (multiple VLANs) share the same HSCI.
- HSCI TRLEs is IUTIQCxx (IPv4) and IUTIC6xx (IPv6), where xx is the IQD CHPID number to which a particular HSCI is associated.

Routing, IP security, and packet tracing of the dynamic HSCI is controlled through their associated OSA interfaces; the HSCI is generally not visible to these functions.

- Routing daemons such as OMPROUTE are aware of only the associated OSD interfaces; the stack does not report IQDC interfaces to OMPROUTE, and static routes cannot reference the dynamic IQDC interfaces. z/OS Communications Server decides to direct traffic over an IQDC interface after the associated OSA interface is chosen as the route for the traffic.
- HSCI is not directly visible to IP security. If IP security is enabled, traffic over an HSCI inherits the security class (SECCLASS) from the associated OSA interface. For packets that are sent and received over the HSCI, IPsec filtering applies to the security class of the associated OSA interface.
- Packet tracing of an OSD interface includes traffic that is redirected or received over the HSCI. If you perform a packet trace for data over an HSCI, all outbound packets are traced as if they were sent over OSA. Inbound packet trace has a flag that indicates the packet was received over the HSCI.

You can use Netstat reports to display information about dynamically created IQDC interfaces.

- The Netstat DEvlinks/-d report displays information for each IQDC interface, as it does for any defined interface. The Netstat DEvlinks/-d report for a given OSA interface also displays how much traffic was sent and received over the associated IQDC interface. For more information about the [Netstat DEvlinks/-d report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).
- You can monitor which IP addresses are reachable over the OSA interfaces and over the associated HSCI by using the Netstat ARp/-R and Netstat ND/-n reports. For more information about the [Netstat ARp/-R report](#) and the [Netstat ND/-n report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).
- You can display information about the dynamic HSCI TRLEs and their associated IQD datapath devices by issuing the **D NET,ID=trle** command or the **D NET,TRL,TRLE=trle** command. For more information about the [DISPLAY ID command](#) and the [DISPLAY TRL command](#), see [z/OS Communications Server: SNA Operation](#).

Using the hardware configuration definition (HCD) you can define up to 32 unique IQD channel path IDs (CHPIDs) within each CPC. Each IQD CHPID within a CPC functions as a unique internal isolated network. Each IQD CHPID (network) can optionally support a single unique PNetID. HSCI requires an IQD PNetID to be configured on the IQD CHPID.

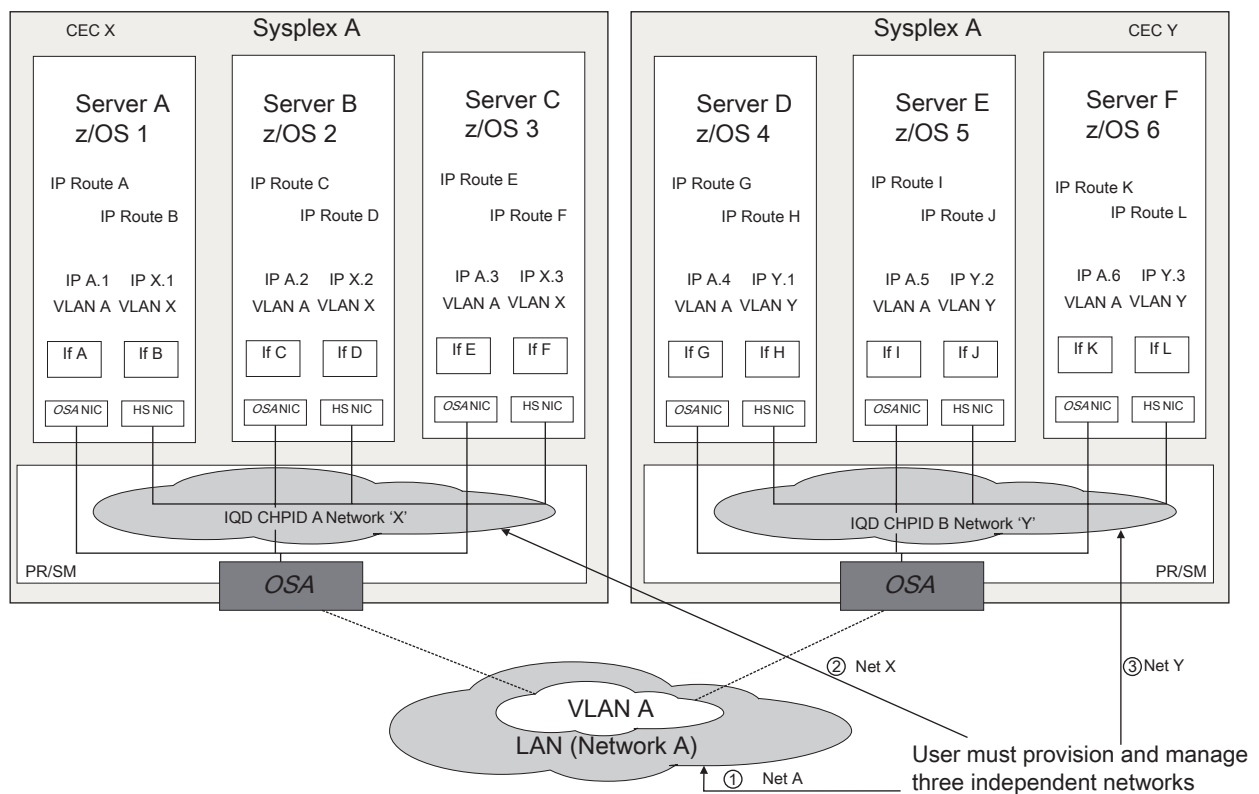

Figure 21. Managing HiperSockets networks without HSCI

Figure 21 on page 113 illustrates two CPCs (CECs X and Y) each with a single IQD network. Both systems also have access to the same external LAN (network A). In this basic (non-sysplex) network example, the administrator must manage three independent networks (Networks X, Y, and A). Networks X, Y, and A also represent (the concepts of) three unique physical L2 networks each having a unique PNetID. Here the term physical means each network (broadcast domain) is physically (logically) isolated from the other two networks. Each physical network could optionally be subdivided into multiple separate L2 networks by defining (multiple) IP subnets each with corresponding VLAN IDs (for example, as in VLAN A). Connecting hosts across multiple unique L2 networks requires a Layer 3 (L3) IP router.

In this configuration, each z/OS instance is shown to have two IP interfaces each having unique IP addresses, VLAN IDs and IP subnets (subnet masks). Each corresponding IP interface also has a unique (static or dynamic) IP route that is defined for directing traffic over each associated interface. The network administrator creates three unique networks requiring that each network and all associated network resources must be independently provisioned and managed. As the number of IP network interfaces increases, the complexity of network administration also increases.

In this example, if an instance of z/OS is to be moved (for example, z/OS 3 moved from CPC X to CPC Y), the HiperSockets interface needs to be reconfigured to access Network Y (in CPC Y) instead of Network X (in CPC X).

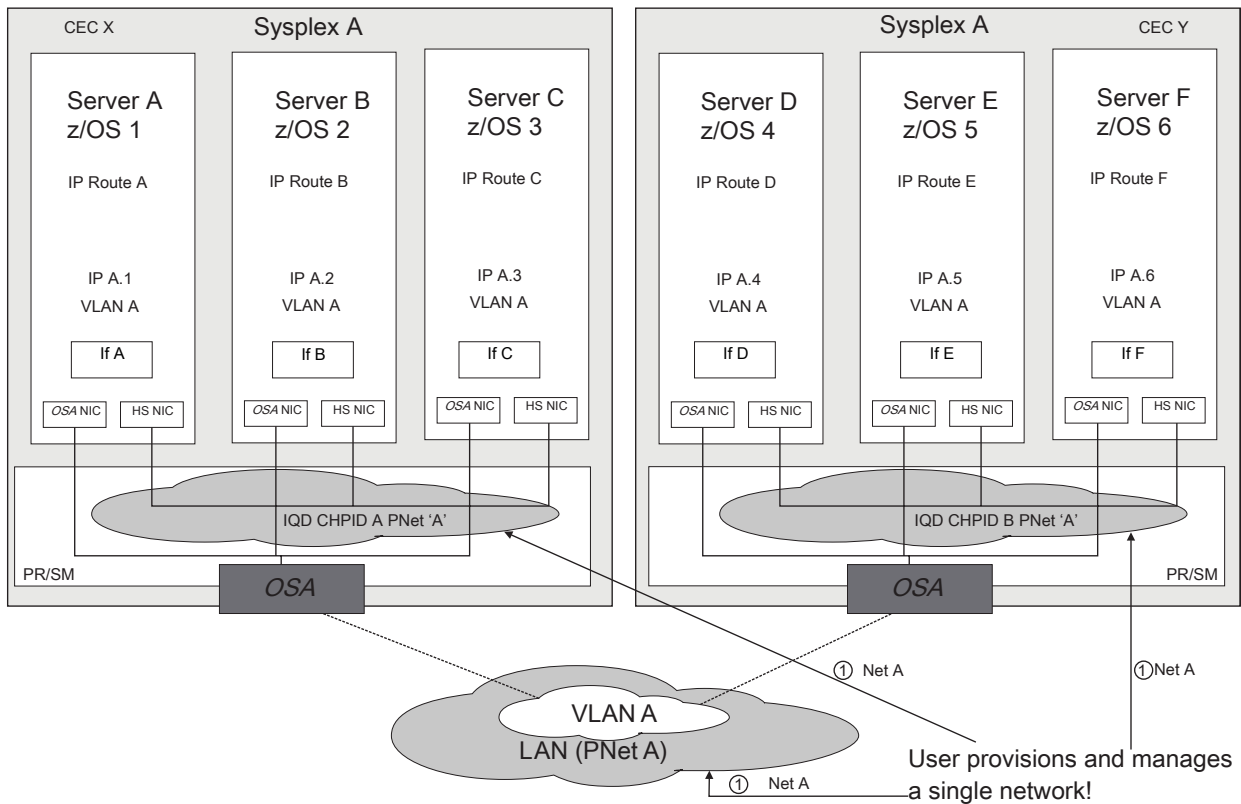

Figure 22. Managing HiperSockets networks with HSCI

When using the HSCI function the HiperSockets interfaces are no longer visible to, configured, or managed by the z/OS administrator. When z/OS is using the HSCI function, it can only communicate with other z/OS instances over HiperSockets that are also using the HSCI function.

When contrasting [Figure 21 on page 113](#) with [Figure 22 on page 114](#), many of the key advantages of HSCI are readily seen and summarized as follows:

- HSCI creates a single internal and external IP network.

Instead of provisioning and managing three unique networks, two internal and a third external network for the two systems, the administrator only provisions and manages a single IP network (network A).

- HSCI eliminates all resources that are related to the HiperSockets networks.

Each z/OS instance has access to a single IP network (network A), defined by the OSA interface thereby eliminating the HiperSockets interface related resources, such as the HiperSockets, IP route, IP address, IP interface, IP subnet, and VLAN.

- z/OS mobility is streamlined.

Therefore, when moving an instance of z/OS (for example, z/OS 3 from CPC X to CPC Y), the HiperSockets interface (HSCI) is not visible to z/OS, HiperSockets no longer must be reconfigured. HSCI automatically and dynamically provides access to HiperSockets on the new CPC.

- The HSCI function uses HiperSockets in L2 mode only.
- Using HSCI with multiple (unique) external LANs.

The z/OS HSCI function supports integration with multiple external LANs. [Figure 22 on page 114](#) illustrates a use case that has a single external LAN (Net A). In cases where a customer has multiple unique external LANs (for example, multiple LANs that require isolation, such as Net A, Net B, Net C) and you want to use the HSCI function for more than one LAN or each unique external LAN, you can provision a unique IQD CHPID for each unique external LAN. In this example, you can provision another IQD CHPID for each unique LAN defining each IQD CHPID with the corresponding PNetID (Net A, Net

B, Net C). The OSA interfaces that are associated with each unique external LAN will require matching PNetIDs to correspond with the IQD PNetIDs. IBM Z supports up to 32 unique IQD CPHIDs per CPC.

- z/OS to z/OS HSCI migration considerations.

When z/OS is using the HSCI function, it can only communicate with other z/OS instances over this same IQD CPHID that are also using the HSCI function. If your z/OS system must communicate with down-level z/OS instances over HiperSockets, you are required to use the L3 HiperSockets support that is provided by:

- Non-sysplex: user-defined HiperSockets interface statements (for z/OS instances that are not within the same sysplex).
- Sysplex: HiperSockets interfaces that are created by DYNXCF (for z/OS instances within the same sysplex).

HSCI in other configurations

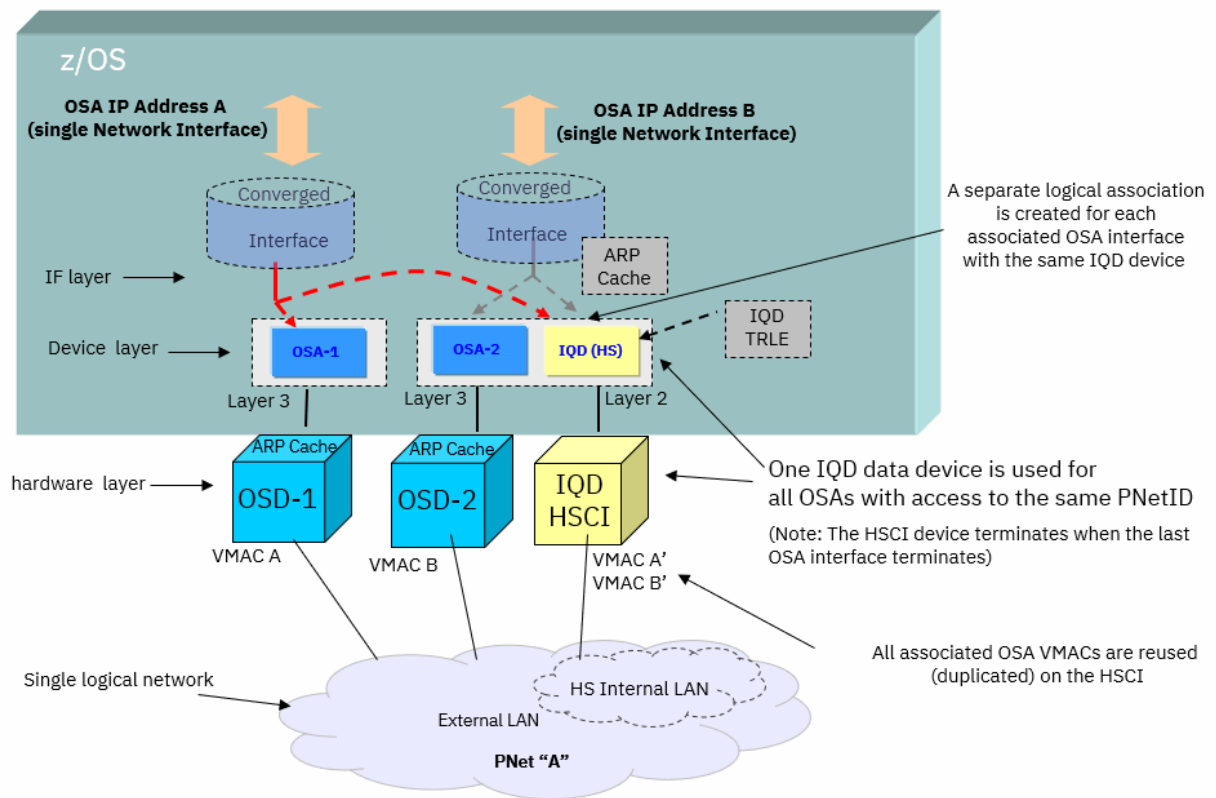

Figure 23. An HSCI sample configuration with two OSA-Express features, two IP interfaces and a single subnet

Figure 23 on page 115 illustrates that when two logical IP (OSA) interfaces share the same PNetID, they will converge with the same HiperSockets (IQDC) data device. No matter how many OSA interfaces share the PNetID, the same HiperSockets data device is used (i.e., the same IQDC interface and the same TRLE are used for all the OSA interfaces with the same PNetID). The first associated OSA activates the IQDC interface and the last OSA that terminates will terminate the IQDC interface.

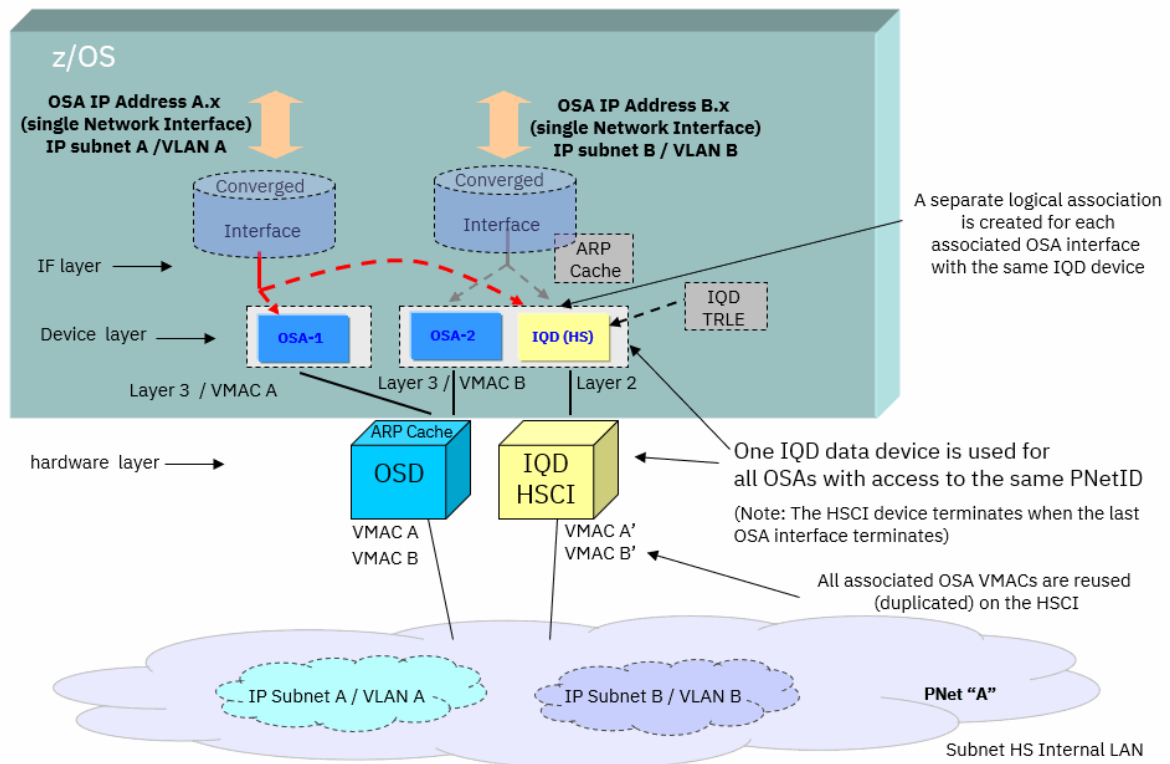

Figure 24. An HSCI sample configuration with a single OSA-Express feature, two IP interfaces and two subnets

Figure 24 on page 116 illustrates that when two logical IP (OSA) interfaces are configured to the same physical OSA feature, they share the same PNetID and converge to the same IQD data device. The IP interfaces in this example are defined with unique VLANs and subnets. No matter how many OSA interfaces are defined for the same physical OSA feature, the same HiperSockets (IQDC) data device is used (i.e., the same IQDC interface and the same TRLE are used for all the OSA interfaces). The first associated OSA interface activates the IQDC interface and the last OSA interface that terminates will terminate the IQDC interface.

Linux and z/VM VSwitch bridge considerations

In addition to the administrative advantages provided by the HiperSockets Converged Interface (HSCI) function for the z/OS environment, the z/OS HSCI function also provides unique advantages for HiperSockets connectivity when connecting to Linux in the z/VM VSwitch bridge environment.

Linux on IBM Z administrators prefer the administrative and operational advantages that are offered by Linux configured with a single IP interface using a (QDIO) Layer 2 (L2) mode. Conversely, managing multi-home (multiple IP interfaces) Linux instances can increase operational complexity. This complexity increases, as the number of Linux guests increase. This (single IP interface) objective is preserved by the z/VM VSwitch bridge support.

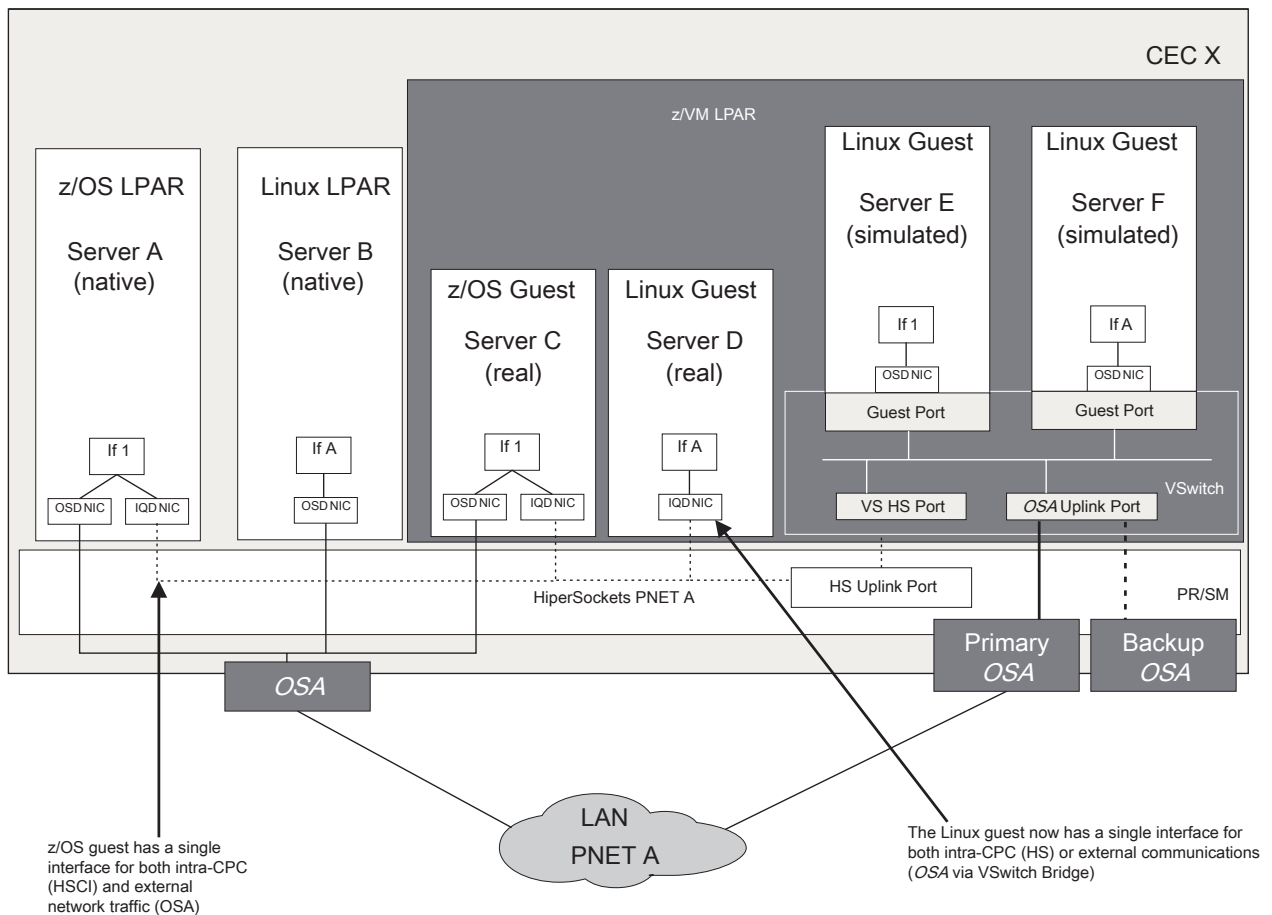

Figure 25. Linux and z/VM VSwitch bridge environment

Figure 25 on page 117 provides an example of the Linux and z/VM VSwitch bridge environment. It illustrates how the VSwitch bridge function allows Linux guests (Server D) to be configured with a single HyperSockets interface that provides both intra-CPC communications (HyperSockets to Servers A and C) and external communications via the VSwitch bridge port through OSA. The Linux usability advantages of the single IP interface are extended by the allowing Linux guests to configure a single IP interface for HyperSockets providing both internal central processor complex (CPC) and external LAN communications.

Linux native LPARs can also (transparently) use the z/VM VSwitch bridge support. Any operating system (running as a z/VM guest or native LPAR) that connects to an Internal Queued Direct I/O (IQD) channel configured with the External Bridge option (in HCD) is automatically bridge eligible by default. z/OS connects to an External Bridge IQD channel only when configured with AUTOIQDC (HSCI). With AUTOIQDC, z/OS uses OSA for external connectivity and the HSCI for internal connectivity. This provides bridge compatibility to communicate with other operating systems on the same IQD channel, but z/OS always "opts out" of the external bridge capability.

Note the following important network configuration concepts that are shown in Figure 25 on page 117:

- The IQD channel path ID (CHPID) and the OSA PCHPID (port) were configured with the same physical network ID (PNetID = NETA), both providing access to the same physical network.
- The IP topology for both interfaces (in every host) is also configured such that both the HyperSockets and the OSA interfaces are attached to the same IP subnet (and VLAN ID when applicable).
- From the z/OS (servers A and C) HSCI perspective, every host that is reachable via the internal HSCI must also be reachable via OSA (packets are transmitted over both interfaces to the same peer hosts, for example to Server D).

This means when connecting to z/OS using the HSCI function to Linux, that Linux instance (guest or native LPAR) must be configured to use the same IQD CHPID with the VSwitch bridge support.

- In z/OS if the HSCI terminates, OSA can still be used to communicate with peer hosts. When the last OSA interface terminates, network connectivity is lost (the HSCI is not usable without the OSA interface).
- The HSCI supports (QDIO) L2 mode only. When the IQD system firmware is operating in L2 mode, the firmware is unaware of the Layer 3 (L3) protocol (IP protocol or version).
- z/OS and z/VM VSwitch bridge compatibility:
 - z/OS HSCI is compatible with the z/VM VSwitch bridge environment (z/OS can communicate with Linux guests or Linux LPARs over HiperSockets that are exploiting the bridge, such as Server D).
 - While z/OS with HSCI is compatible with the bridge environment, z/OS is not bridge capable, which means z/OS does not use the z/VM VSwitch bridge (z/OS network traffic does not traverse the z/VM VSwitch bridge port). With the HSCI function, external network connectivity is provided by the converged OSD instead of the bridge function.

For example, in [Figure 25 on page 117](#), z/OS servers A and C can communicate with servers E and F via external connectivity via OSA only (HiperSockets cannot be used because it does require z/OS being bridge capable).

- Conversely, the z/OS HiperSockets support that is not related to HSCI only supports L3 mode connectivity which is incompatible with Linux in the z/VM VSwitch bridge environment. The z/OS HSCI support resolves this incompatibility by providing compatibility for HS L2 mode for Linux guests or LPARs using HS with the z/VM VSwitch bridge.
- Linux supports IQD connectivity in both L2 and L3 modes. The z/VM VSwitch bridge requires (supports) L2 mode only.

For more information about the z/VM VSwitch bridge support, see *z/VM Planning and Administration*.

- z/OS to Linux HSCI migration considerations:

When z/OS uses the HSCI function, it can only communicate with Linux guests or LPARs using HiperSockets configured to use the z/VM VSwitch bridge. If your z/OS system is to communicate with Linux instances that are not configured to use the z/VM VSwitch bridge, you are required to use the L3 HiperSockets support that is provided by z/OS user-defined HiperSockets INTERFACE statement.

Performance considerations for HiperSockets Converged Interface

For network traffic within a central processor complex (CPC), HiperSockets can provide lower latency when compared to external networks. Lower latency is most likely beneficial for interactive (request and response) workloads where latency (response time) is critical.

However, when large amounts of data are transmitted (typically, streaming or bulk data workloads) as a significant portion of the intra-CPC workload, you might prefer OSA processing because of differences in the OSA processing for large data transmissions (for example, segmentation offload). The savings that are offered by OSA processing for large data transfers vary. HiperSockets transmissions generally use more processor cycles than OSA transmissions, and this difference in processing cycles is magnified as transmission size grows. If you prefer using OSA processing for large transmissions, while still using HSCI, then this variation is also supported.

The HiperSockets Converged Interface (HSCI) function uses the strengths of both the HiperSockets and OSA technologies, by providing a configuration option that transparently controls traffic selection. Specifying NOLARGEDATA on the AUTOIQDC parameter of the GLOBALCONFIG statement transparently directs large data transmissions over OSA for HSCI while directing small data transmissions over Internal Queued Direct I/O Converged (IQDC) interfaces. You can enable this setting to get the lower latency of HiperSockets for small data transmissions, while avoiding the processor cost penalty sometimes incurred with HiperSockets for large data transmissions. If you do not anticipate a significant number of large data transmissions or you always prefer the internal processing of HiperSockets (regardless of processor cycle consumption), you should use the default setting (do not specify NOLARGEDATA on the AUTOIQDC parameter).

Tips:

- IQDMULTIWRITE provides optimization when sending large transmissions or a high volume of traffic over HiperSockets. When IQDMULTIWRITE is enabled on the GLOBALCONFIG statement, the IQDC interface also uses this feature. You can optionally disable IQDMULTIWRITE on the GLOBALCONFIG statement (which disables multiple write for all HiperSockets devices).
- The QDIO Accelerator function provides accelerated forwarding at the DLC layer for inbound packets over HiperSockets (IQDC interfaces) that are forwarded outbound over OSA-Express QDIO. Network Express does not support acceleration over HiperSockets. For more information, see [“QDIO Accelerator”](#) on page 122.

Guidelines:

- When NOLARGEDATA is specified for the AUTOIQDC parameter, Communications Server forces large TCP transmissions to the OSA path. Communications Server defines a large transmission as a TCP socket send of 32 K or larger. All other eligible traffic is transmitted over IQDC interfaces.
- When an OSA adapter is shared among two or more logical partitions (LPARs), the processor savings offered by the OSA adapter are less than the savings offered by configurations that use multiple OSA adapters that are not shared. For example, some OSA assist functions, such as segmentation offload, are not available for the shared OSA configuration.
- When workloads which transmit large data (socket applications issue socket send of 32 K or larger) are a predominant part of the overall network workload and you use HS, you should consider using:
 - The IBM Z Integrated Information Processor (zIIP) function for HiperSockets, which minimizes the general-purpose processor usage that is incurred with HiperSockets.
 - A configured Internal Queued Direct I/O (IQD) maximum frame size of 64 K in hardware configuration definition (HCD).
- When transmitting packets, the HSCI uses the OSA MTU size. Jumbo frames are 9 K (8992) and can be used by TCP connection over the OSA interface. Jumbo frames are too large for the default IQD frame size (16 K supporting an 8 K MTU). To be sure to take full advantage of IQDC for streaming workloads, consider using an IQDC frame size larger than 16 K if you use an MTU size larger than 8192 bytes for OSA. Otherwise, certain streaming workloads are not able to use the HSCI.

SMC and HSCI PNetID considerations

Shared Memory Communications (SMC) and the HiperSockets Converged Interface (HSCI) function are independent functions that can be used independently of or concurrently with each other. The two functions have some subtle overlap that must be considered when configuring the physical network IDs (PNetIDs).

When reviewing the following PNetID concepts and rules, see examples in the previous figures.

The following list provides a summary of the PNetID background concepts and usage rules:

- PNetIDs represent a user-defined logical ID (name) of a physical network. The physical network represents the physical broadcast domain of a given network.
- PNetIDs are defined on a physical port of a physical adapter indicating the ID of the network that this port is associated with (connected to).
- PNetIDs are used by z/OS to associate related adapters with each other. When physical ports have matching PNetIDs, it indicates that the adapters have connectivity to the same physical network and the IDs are used by z/OS as follows:
 - Shared Memory Communications over Remote Direct Memory Access (SMC-R): Associate OSA ports with RoCE ports.
 - Shared Memory Communication - Direct Memory Access (SMC-D): Associate Internal Queued Direct I/O (IQD) channel path IDs (CHPIDs) with Internal Shared Memory (ISM) CHPIDs or OSA ports.

Note: IQD and ISM CHPIDs are virtual adapters (provided by system firmware) that do not have physical ports. Logically (defined by system architecture), each virtual adapter (CHPID) has a single logical port (supporting a single PNetID per CHPID).

- PNetIDs rules without the HSCI function.

Without the HSCI function, OSA and IQD networks cannot have matching PNetIDs since the interfaces to those networks connect to separate and unique isolated networks.

Note: The definition of "without HSCI" means Layer 3 (L3) HiperSockets interfaces that are created by both of the following:

- User-defined HiperSockets interfaces.
- Dynamically defined HiperSockets interfaces that are created by DYNXCF.

The HSCI function logically combines IQD and OSA networks into a single logical network (see examples in [Figure 22 on page 114](#) and [Figure 25 on page 117](#)). The following list describes how the HSCI function impacts the configuration and usage rules of PNetIDs:

- PNetIDs with the HSCI function:
 - The HSCI function is applicable when the following conditions are true:
 - HSCI is enabled for this TCP/IP stack (global configuration).
 - An IQD CHPID is available to this z/OS instance, and the CHPID is configured in HCD with both of the following:
 - The External Bridge parameter.
 - A PNetID that matches an OSA PNetID.
 - When the HSCI function is not used (not applicable):

ISM can be associated (have a matching PNetID) with either IQD or OSA, but not both (IQD and OSA are unique networks and cannot have the same PNetIDs).
 - When the HSCI function is used (applicable):

ISM can be associated (have a matching PNetID) with both IQD and OSA (IQD and OSD are now converged into a single physical network, supporting a single PNetID).

With the HSCI function, OSD, RoCE, IQD, and ISM can all have the same PNetID.

Note: The z/VM VSwitch bridge support also combines (bridges) IQD to OSA networks together forming a single logical network. In the bridge configuration, the PNetIDs can also be equal (forming a single network). z/OS does not directly use the z/VM bridge function (z/OS is not bridge eligible). z/OS is compatible with the bridge function when using the HSCI function. Without the HSCI function, z/OS is not aware of or does not validate PNetIDs for bridge configurations.
- Considerations for dynamic changes in system I/O configuration:
 - HCD definitions (PNetID values and External Bridge parameter) can be changed using dynamic I/O CHPID operations. Changing the IQD CHPID in HCD can alter the PNetID rules (enabling or disabling the HSCI function).
 - z/OS evaluates the PNetID values and applies the PNetID rules when activating an applicable network interface (interfaces that support PNetIDs).
 - During the interface activation process, z/OS applies the PNetID usage rules based on the current state and applicability of the HSCI function.
 - Once an interface is activated, changing the state of the HSCI function has no effect on an already active interface. You must stop an active interface and then restart the interface to pick up any changes in the HSCI function.

Steps for enabling HiperSockets Converged Interface

It is recommended that users begin by reviewing the HiperSockets Converged Interface (HSCI) background information that is provided in this section along with your anticipated IP connectivity and topology requirements. Your use case for the HSCI function can be for a z/OS only environment or a z/OS environment that also includes Linux using the z/VM VSwitch bridge function.

When z/OS is using the HSCI function, the dynamically created HiperSockets interface operates in Layer 2 (L2) mode only. z/OS HSCI can only connect to other z/OS instances over the HSCI when the peer

for the HSCI PNetID (all interfaces that are created for unique physical OSAs and interfaces that are created for multiple VLANs over the same OSA).

3. In HCD define the IQD CHPID to support both of the following:

- External Bridge

Note: The External Bridge setting is a required setting for HSCI. This is a system-wide setting informing all users of this IQD CHPID that special rules apply (this IQD CHPID is L2 only).

This setting does not indicate (require) that the z/VM VSwitch bridge is used.

- Define the IQD PNetID to match your OSAs PNetID.

Note: The OSA PNetIDs must also be configured in HCD for each associated OSA port.

z/OS Communications Server procedure

When the HCD configuration steps are complete for both IQD and OSA CHPIDs, you can enable the HSCI function in z/OS.

1. In your TCP/IP profile GLOBALCONFIG statement, specify AUTOIQDC. Determine whether you want large data to use your HSCI. See [“Performance considerations for HiperSockets Converged Interface” on page 118.](#)

2. Start your OSA interfaces that are associated with your IQD CHPID (OSAs having the same PNetID as the IQD CHPID).

Use Netstat to verify that the HSCI is automatically activated with your OSA interface. As the HSCI is activated in other z/OS instances using this same IQD CHPID use Netstat to verify that your eligible network traffic is using the HSCI.

The first associated OSA interface that activates will dynamically create the HSCI TRLE and activate the HSCI. As other associated OSA interfaces are activated, the existing HSCI is discovered and used. The last associated OSA interface to terminate will dynamically terminate the HSCI. The user can optionally manually stop and restart the HSCI.

QDIO Accelerator

The QDIO Accelerator function extends the HiperSockets Accelerator function. HiperSockets Accelerator provides accelerated forwarding at the DLC layer for the following types of packets:

- Inbound packets over HiperSockets that are forwarded outbound over OSA-Express QDIO
- Inbound packets over OSA-Express QDIO that are forwarded outbound over HiperSockets

For more information about HiperSockets Accelerator, see [“Efficient routing using HiperSockets Accelerator” on page 105.](#)

QDIO Accelerator for Network Express supports acceleration of traffic from and to EQDIO interfaces only. For EQDIO interfaces, no other combinations are supported.

Tip: The QDIO Accelerator function is associated with other keywords and displays. Network Express reuses the same accelerator capability without introducing new keywords or terminology (the terminology “EQDIO Accelerator” does not exist).

QDIO Accelerator for OSA-Express supports acceleration of traffic for all combinations of QDIO and EQDIO interfaces. QDIO acceleration for OSA-Express provides all of the function supported by HiperSockets Accelerator, and also provides accelerated forwarding at the DLC layer for the following types of packets:

- Inbound packets over OSA-Express QDIO that are forwarded outbound over OSA-Express QDIO
- Inbound packets over HiperSockets that are forwarded outbound over HiperSockets
- Sysplex distributor packets that are forwarded to a target stack, when the route involves any of the following inbound and outbound DLC combinations:
 - Inbound over HiperSockets, forwarded outbound over OSA-Express QDIO

- Inbound over OSA-Express QDIO, forwarded outbound over HiperSockets
- Inbound over OSA-Express QDIO, forwarded outbound over OSA-Express QDIO
- Inbound over HiperSockets, forwarded outbound over HiperSockets

QDIO Acceleration is supported with or without the VIPAROUTE statement. When QDIO Accelerator is active, the stack dynamically creates QDIO Accelerator routes as it forwards packets in any of the inbound and outbound DLC combinations previously described. The DLC layer can perform accelerated routing for packets across these routes, bypassing the IP forwarding function in the stack. Similarly, the stack dynamically creates QDIO Accelerator routes for packets that would be forwarded by the sysplex distributor in any of the inbound and outbound DLC combinations. The DLC layer can perform accelerated sysplex distributor routing for such packets.

To configure QDIO Accelerator, specify the QDIOACCELERATOR parameter on the IPCONFIG statement. For more information about the [IPCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

You can display the QDIO Accelerator routing entries that are dynamically created for non-sysplex distributor packets using the Netstat ROUTE/-r report option with the QDIOACCEL modifier. For more information about the [Netstat ROUTE/-r report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

You can use the Netstat VCRT/-V report with the DETAIL modifier to display whether a sysplex distributor connection is eligible for acceleration. For more information about the [Netstat VCRT/-V report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

You can also use VTAM tuning statistics to monitor and measure the accelerated packets. For more information about [Gathering tuning statistics](#), see [z/OS Communications Server: SNA Network Implementation Guide](#).

Restrictions:

- QDIO Accelerator is supported for IPv4 only.
- QDIO Accelerator for Network Express supports acceleration of traffic from and to EQDIO interfaces only. For EQDIO interfaces, no other combinations are supported
- If IP security is enabled on the stack, the stack monitors IP filter rules and defensive filter rules that apply to routed traffic. Depending on your filter configuration, QDIO Accelerator might be restricted to only packets that are forwarded by the sysplex distributor. For more information about QDIO Accelerator and IP security, see [“QDIO Accelerator and IP security” on page 123](#).
- If IP forwarding is disabled on the stack, then QDIO Accelerator applies only to packets that are forwarded by the sysplex distributor.
- Packets from the sysplex distributor to the target are not accelerated with the VIPAROUTE destination when the outbound interface is HiperSockets.

Tip: If packet trace is enabled, then packets that are accelerated by QDIO Accelerator do not appear in the packet trace (either inbound or outbound). If you want function similar to that of the packet trace in conjunction with QDIO Accelerator, you can use the OSA-Express network traffic analyzer (OSAENTA) to trace these packets that are accelerated to or from OSA-Express QDIO. For more details on OSAENTA, see [“OSA-Express network traffic analyzer trace” on page 125](#).

QDIO Accelerator and IP security

When you enable IP security, the TCP/IP stack applies your configured filter policy to IP packets that it receives and sends. Depending on your filter policy, the IP layer might permit packets, deny packets, or protect packets using IPSec. For more information about IP security, see [Chapter 17, “IP security,” on page 911](#).

QDIO Accelerator processes some packets at the DLC layer, bypassing the IP layer. If such packets were allowed to be routed by QDIO Accelerator, this would prevent the IP layer from performing any special processing for these packets that is required by your filter policy.

Note: This topic “QDIO Accelerator and IP security” applies to both Network Express and OSA-Express. Network Express supports acceleration of traffic from and to EQDIO interfaces only.

When IP security is enabled, sysplex distributor packets are always eligible for acceleration using QDIO Accelerator because the packets are subject to IP filtering at the target stack rather than the distributor stack. However, QDIO Accelerator might not be able to forward routed traffic when IP security is enabled if any of your routed traffic is subject to special processing in your filter policy.

QDIO Accelerator forwards routed traffic only if your IP filter policy and defensive filters explicitly permit all routed traffic without logging. If your IP filter policy and defensive filters do not explicitly permit all routed traffic without logging, QDIO Accelerator does not forward routed traffic and one or more of the following messages is displayed on your console:

- EZD2020A

TCP/IP issues message EZD2020A if you are currently using the IP filters defined in your TCP/IP profile and one of the following conditions is true:

- There is no IPSECRULE statement with the ROUTING value Routed or Either to permit routed traffic.
- The first IPSECRULE statement that permits routed traffic does not permit all source addresses, all destination addresses, all protocols, and all security classes.
- The first IPSECRULE statement that permits all routed traffic specifies that logging is enabled, or logging is enabled as the default.

- EZD2021A

TCP/IP issues message EZD2021A if you are currently using the IP filters defined in your policy configuration and one of the following conditions is true:

- There is no IP filter rule that permits routed IPv4 traffic.
- The first IP filter rule that applies to routed IPv4 traffic does not permit all IPv4 source addresses, all IPv4 destination addresses, both directions, all protocols, and all security classes.
- The first IP filter rule that permits all routed IPv4 traffic specifies that logging is enabled, or logging is enabled as the default.

- EZD2022A

TCP/IP issues message EZD2022A if you are using the Defense Manager daemon (DMD) to manage defensive filter rules, and you have a defensive filter installed that applies to routed traffic.

If you have enabled IP security and you want to allow QDIO Accelerator to forward routed traffic, see [“Steps to allow QDIO Accelerator to forward routed traffic when IP security is enabled” on page 124.](#)

Steps to allow QDIO Accelerator to forward routed traffic when IP security is enabled

Before you begin

Discuss all changes to your filter policy and defensive filters with your security administrator. Do not permit all routed traffic without first verifying that your network security policy specifies that all routed traffic is to be permitted.

Procedure

If you enabled IP security and you want to allow QDIO Accelerator to forward routed traffic, perform the following steps:

1. Consult your network security policy to determine how TCP/IP processes routed traffic.

You cannot use QDIO Accelerator for routed traffic when any of the following conditions are true:

- Some routed traffic must be denied in your IP filter policy.
- Some routed traffic must be protected by IPsec in your IP filter policy.

- Some routed traffic must be logged using TRMD.

If any of these conditions are true, QDIO Accelerator forwards only sysplex distributor traffic.

2. If TCP/IP issues message EZD2020A and your network security policy specifies that all routed traffic is permitted, configure your TCP/IP profile to permit all routed traffic without logging:
 - a) Ensure that the first IPv4 IPSECRULE statement with the Routing value Routed or Either permits all IPv4 addresses, all protocols, and all security classes.

Tip: If your rule has the ROUTING value Either, the rule applies to both local and routed traffic. If your security policy does not allow you to permit all local traffic, split this rule into two rules, one with the Routing value Routed and one with the Routing value Local.
 - b) Ensure that the first IPv4 IPSECRULE statement does not specify LOG to enable filter logging.
3. If TCP/IP issues message EZD2021A and your network security policy specifies that all routed traffic is permitted, configure your policy filter rules to permit all routed traffic without logging.
 - a) If you are using the IBM Configuration Assistant for z/OS Communications Server to configure your IPsec policy, use the following settings:
 - i) Ensure that the first connectivity rule that applies to routed IPv4 traffic specifies a topology of filtering only, applies to all IPv4 addresses, and uses a requirement map that maps all IP protocols and all security classes to a Permit security level.

Tip: Your connectivity rule might apply to both local and routed traffic. If your security policy does not allow you to permit all local traffic, split this rule into two rules, one that applies to filtering for routed traffic and one that applies to filtering for local traffic.
 - ii) Ensure that the first connectivity rule specifies that filter matches are not logged.
 - b) If you are manually configuring your IPsec policy, use the following settings:
 - i) Ensure that the associated IpService statement for the first IpFilterRule statement has the Routing value Routed or Either, permits all IPv4 addresses, all protocols, and all security classes, and has the Direction value Bidirectional.

Tip: If your rule has the Routing value Either, the rule applies to both local and routed traffic. If your security policy does not allow you to permit all local traffic, split this filter rule into two filter rules, one with the Routing value Routed and one with the Routing value Local.
 - ii) Ensure that the associated IpGenericFilterAction statement for the first IpFilterRule statement specifies the IpFilterLogging setting No to disable filter logging.
4. If TCP/IP issues message EZD2022A, and your network security policy specifies that all routed traffic is permitted, ensure that your defensive filters permit routed traffic:
 - a) Issue the **ipsec -F display** command to display the defensive filters.
 - b) If any filters are listed that apply to routed traffic, you have the following options:
 - Because defensive filters are temporary filters designed to address temporary conditions, you can wait for these filters to expire. After the filters expire, QDIO Accelerator can resume forwarding routed traffic.
 - If you and your security administrator determine that these defensive filters are no longer needed, your security administrator can issue the **ipsec -F delete** command to delete these filters so that QDIO Accelerator can resume forwarding routed traffic.

For more information about the `ipsec` command, see [z/OS Communications Server: IP System Administrator's Commands](#).

OSA-Express network traffic analyzer trace

When data problems occur in a network with OSA adapters, multiple traces are usually required. A sniffer trace might be required to see the data as it was received from or sent to the network, an OSA hardware trace might be required if the problem is suspected in the OSA, and z/OS Communications Server traces are required to diagnose VTAM or TCP/IP problems.

To help with problem diagnosis, the OSA-Express network traffic analyzer (OSAENTA) function provides a way to trace inbound and outbound frames for an OSA-Express feature.

Restriction: The OSAENTA function is not supported by the Network Express feature

The OSAENTA trace function is controlled and formatted by z/OS Communications Server, but is collected in the OSA at the network port. You can control the OSAENTA trace function by using either the OSAENTA statement in the TCP/IP profile or the VARY TCPIP,,OSAENTA command. The controls that are provided include the ability to filter what data is collected by parameters such as IP address, TCP/UDP port, or frame type, and to specify how much data is to be collected. They also provide the capability to trace frames that are discarded by the OSA-Express feature. You can display current settings for the OSAENTA trace function by using the Netstat DEVLINKS/-d command.

Because the data is collected at the Ethernet frame level, you can use this function to trace the MAC headers for packets, a capability that is not provided by existing packet traces. It also enables the tracing of other types of packets that existing packet traces do not contain, including the following packets:

- ARP packets
- Packets to and from other users sharing the OSA, including other TCP/IP stacks, z/Linux users, and z/VM users
- SNA packets

There are obvious security considerations for this type of trace. Security control is enabled at the Hardware Management Console (HMC) of the OSA-Express feature. To trace packets for stacks or images other than the operating system image where you activate the OSAENTA trace interface, you must use the HMC to configure the OSA to enable this tracing.

The OSAENTA trace function communicates with the OSA-Express feature being traced by using a dynamically defined QDIO interface to the OSA-Express feature. The interface is created when the first VARY TCPIP,,OSAENTA command for that OSA is entered, or the first OSAENTA TCP/IP profile statement is processed. The interface is named EZANTAXXXXXXX, where XXXXXXXX is the port name of the OSA specified on the VARY TCPIP,,OSAENTA command, and must match the PORTNAME parameter on the VTAM TRLE representing the traced OSA-Express feature. This also means that a TRLE must be defined in VTAM for this OSA-Express trace interface, though the same TRLE used for IPAQENET and IPAQENET6 interfaces is used for this dynamically defined trace interface. The EZANTAXXXXXXX interface is used exclusively for receiving trace records from that OSA-Express feature. It is started, stopped, and deleted with the ON, OFF, and DEL parameters of the VARY TCPIP,,OSAENTA command.

When the OSAENTA trace is enabled, the received trace records are collected by Component Trace (CTRACE) using the SYSTCPOT component. The traced records can then be formatted using the IPCS CTRACE command, specifying the component name SYSTCPOT. For information about retrieving the OSA-Express network traffic analyzer data in real time, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

The OSAENTA trace can have a negative impact on performance if sufficient trace filters are not specified before you enable the trace. OSAENTA can reduce the amount of traffic that the OSA-Express feature can process and the amount of traffic that can be accelerated through that OSA-Express feature. Also, host processing to collect the OSAENTA trace records can increase host CPU consumption. Specify sufficient filters to limit the amount of traffic that is traced to only what is necessary for problem diagnosis.

For more information about the [OSAENTA statement](#), see [z/OS Communications Server: IP Configuration Reference](#). For more information about the [VARY TCPIP,,OSAENTA command](#), see [z/OS Communications Server: IP System Administrator's Commands](#). For more information about [TCP/IP services traces and IPCS support](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

Synchronization of OSA-Express diagnostic data

VTAM provides the externals that control the QDIOSYNC trace facility, used to synchronize OSA-Express diagnostic data with host diagnostic data. For information about the use of the [QDIOSYNC facility](#), see [z/OS Communications Server: SNA Diagnosis Vol 1, Techniques and Procedures](#).

Prioritizing outbound OSA data

z/OS Communications Server supports four outbound transmission queues for OSA. The purpose of exploiting multiple transmission queues is to prioritize outbound work across the four OSA queues. The OSA firmware will then service each outbound queue based on priority definitions within the OSA architecture.

This function is referred to as “OSA Outbound Priority Queuing” and is supported by both Network Express and OSA-Express. Four outbound transmission queues are used by both features. The numbering of the outbound queues is slightly different based on each feature (OSA-Express starts with Queue 1 and Network Express starts with Queue 2).

The VTAM D, NET TRLE output displays the activity for the four outbound (write) queues using the term “write number” vs. “queue number” (e.g. Write 1 vs. Queue 1) shown as follows:

- OSA-Express four outbound queues (highest to lowest priority):
 - Write 1 (Queue 1)
 - Write 2 (Queue 2)
 - Write 3 (Queue 3)
 - Write 4 (Queue 4)
- Network Express four outbound queues (highest to lowest priority):
 - Write 2 (Queue 2)
 - Write 3 (Queue 3)
 - Write 4 (Queue 4)
 - Write 5 (Queue 5)

Note: Network Express architecture uses the first two queues, Queues 0 and 1 for control operations.

Tip: The differences in the outbound queue numbering (starting at 1 vs. starting at 2) has no impact on how you configure the outbound priority of your workloads. Prioritizing outbound work is based on defining four outbound priorities (irrespective of queue number).

z/OS Communications Server supports four priority values for OSA outbound traffic, 1 through 4, with 1 being the highest priority. Priorities with lower numbers are given preferential treatment by the OSA device driver and the OSA feature.

There are two methods for configuring the priority of your OSA outbound traffic using:

- WLM PRIORITYQ parameter
- QoS Policy definitions

Using WLM PRIORITYQ Parameter for OSA outbound priority queuing

The z/OS Workload Manager (WLM) provides a priority associated with each unit of work that runs a TCP/IP socket API to send data. The priority provided by WLM is related to the WLM service class associated with the unit of work. The unit of work can derive its priority from the service class associated with the address space in which it is running or from the service class associated with the enclave to which it belongs. The priorities provided by WLM, from highest priority to lowest priority, are as follows:

- System-defined service class (SYSTEM), used for system address spaces
- System-defined service class (SYSSTC), used for high-priority started tasks
- User-defined service classes with importance level 1
- User-defined service classes with importance level 2
- User-defined service classes with importance level 3
- User-defined service classes with importance level 4
- User-defined service classes with importance level 5

- User-defined service classes associated with a discretionary goal

For more information about WLM and the WLM service classes, see [z/OS MVS Planning: Workload Management](#) and [z/OS MVS Programming: Workload Management Services](#).

To influence the OSA outbound traffic priority, use the WLMRIORITYQ parameter on the GLOBALCONFIG profile statement. The WLMRIORITYQ parameter automatically extends the preferential treatment of the most important workloads for a business through the OSA device driver all the way to the LAN. When the WLMRIORITYQ parameter is specified and a packet with a ToS or traffic class value 0 is sent over OSA, Communications Server sets the OSA write priority of the packet based on the priority value provided by the WLM service class. In addition, the WLMRIORITYQ parameter can be used to influence the OSA outbound traffic priority of forwarded packets with a ToS or traffic class value 0.

For more information about the [GLOBALCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Restrictions:

- Prioritization using the WLM service class is effective only when enabled and when the ToS or traffic class value is 0.
- Prioritization using the WLM service class is only applicable to OSA interfaces.
- Prioritization of forwarded packets is ineffective unless DATAGRAMFWD is specified on the IPCONFIG statement, the IPCONFIG6 statement, or both statements.
- The WLMRIORITYQ setting for forwarded packets has no effect on accelerated packets. To set the write priority for accelerated packets:
 - For OSA-Express, use QDIOPRIORITY on the IQDIOROUTING parameter or the QDIOACCELERATOR parameter on the IPCONFIG profile statement.
 - For Network Express, use QDIOACCELERATOR parameter on the IPCONFIG profile statement.

For more information about the [IPCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Using QoS Policy for OSA outbound priority queueing

Another way to influence the OSA outbound traffic priority is to specify the OSA priority value on the SetSubnetPrioToSMask statement in a Quality of Service (QoS) policy. The SetSubnetPrioToSMask statement maps the IPv4 type of service (ToS) byte or IPv6 traffic class to these four OSA traffic priorities. For more information about the Intersubnetwork, see [z/OS Communications Server: IP Configuration Reference](#).

Restriction:

- Prioritization of forwarded packets is ineffective unless DATAGRAMFWD is specified on the IPCONFIG statement, the IPCONFIG6 statement, or both statements.
- The prioritization of forwarded packets has no effect on accelerated packets. To set the write priority for accelerated packets:
 - For OSA-Express, use QDIOPRIORITY on the IQDIOROUTING parameter or the QDIOACCELERATOR parameter on the IPCONFIG profile statement.
 - For Network Express, use QDIOACCELERATOR parameter on the IPCONFIG profile statement.

For more information about the [IPCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Using TEMPIP interfaces

You can configure a TEMPIP interface by configuring the interface with the TEMPIP parameter. The TEMPIP parameter allows the interface to be started with an IP address of 0.0.0.0 instead of a statically defined IP address. The 0.0.0.0 IP address enables TEMPIP interfaces to broadcast and multicast IP

traffic. Unicast traffic cannot use TEMPPIP interfaces. The TEMPPIP parameter can be configured only on the IPv4 IPAQENET OSA-Express and the IPv4 EQENET INTERFACE statements.

About this task

TEMPPIP interfaces are used in a unit test environment to support applications that provide a DHCP client, such as IBM Rational® Developer for System z Unit Test feature (Rdz-UT).

Procedure

To use a TEMPPIP interface, take the following steps:

1. Define an interface with the TEMPPIP parameter instead of the IPADDR parameter.
2. Start the interface.
3. Use UDP broadcasts to communicate with the DHCP server to obtain an IP address, subnet, default router, and DNS servers.
4. Stop the interface.
5. Use the V TCP/IP,,OBEYFILE command to delete the interface.
6. Configure the interface in the TCP/IP profile with the IPADDR parameter and the IP address that is obtained with DHCP. Routing information and DNS server information must be configured in the correct data files. Use the V TCP/IP,,OBEYFILE command to add the new interface.
7. Start the interface.

Guidelines for using TEMPPIP interfaces

Follow these guidelines when you are using TEMPPIP interfaces:

- Do not code the SOURCEVIPINTERFACE parameter because DHCP servers expect a source IP address of 0.0.0.0 on packets from the DHCP client.
- If the VMAC parameter is defined on the INTERFACE statement, you must specify the virtual MAC address. If you delete a device and then add it back, the generated VMAC address of this device is changed.
- You must define the IPBCAST parameter on the INTERFACE statement to allow broadcasts.
- The VLANID parameter is supported for TEMPPIP interfaces, except when multiple interfaces are sharing an OSA feature.

Network Express RoCE Support

The Shared Memory Communications (SMC) protocol requires additional considerations for network connectivity for RoCE and ISM. The SMC connectivity topics are described in detail in [Chapter 10, “Shared Memory Communications,”](#) on page 531.

Network Express provides support for both IP protocols such as TCP/IP functioning as a NIC (Network Interface Card) and the RoCE support used for RDMA protocols such as SMC-R functioning as an RNIC (RDMA capable NIC). Network Express converges the protocols on the same physical port. This capability provides the “hybrid” aspect of Network Express or the Open Systems Adapter for hybrid networks (OSH). With Network Express a separate RoCE Express card is not required. The converged support is illustrated in [Figure 27](#) on page 130.

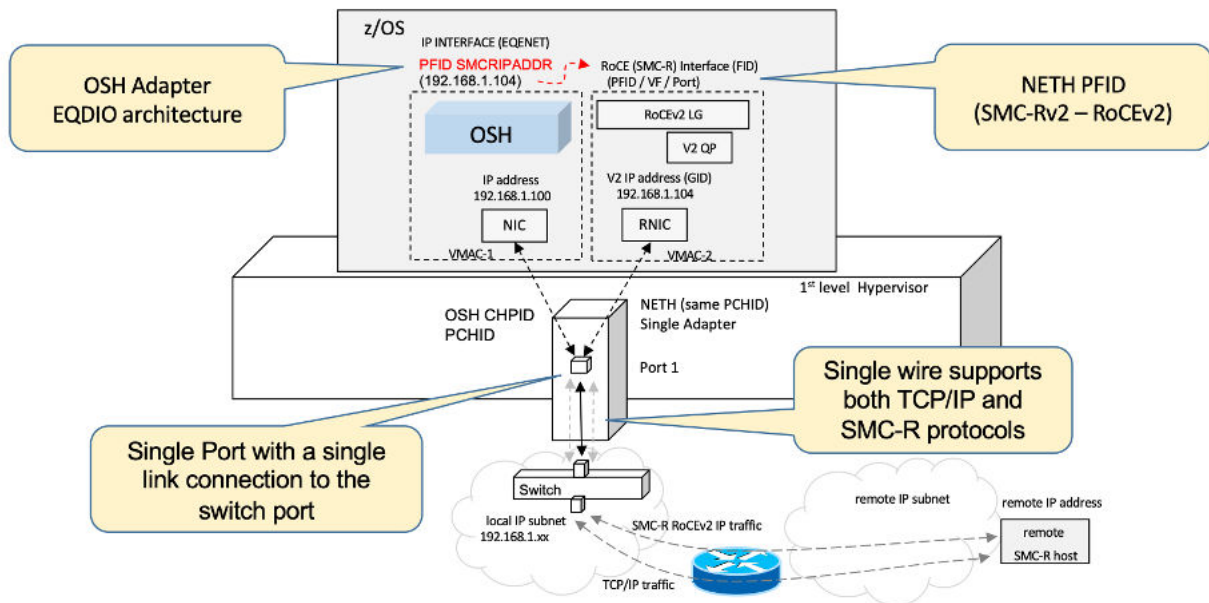

Figure 27. Network Express with Converged RoCE support

Some of the key concepts of the converged support illustrated here are:

- A single physical adapter and port support both protocols
- The OSH CHPID is used for EQENET and NETH is used for the PFID
- The EQENET INTERFACE statement uses parameters PFID and SMCRIPADDR to dynamically create the SMC-R interface
- The PFID parameter must point to the same physical adapter

For additional information about SMC or the converged Network Express support refer to:

- Chapter 10, “Shared Memory Communications,” on page 531

Determining the maximum transmission unit

TCP/IP uses the maximum transmission unit (MTU) value to determine the largest sized frame to send. The MTU value that is in effect for a given outbound send is one of the following two values:

- Path MTU value

TCP/IP automatically enables path MTU discovery for IPv6. If a packet is an IPv6 packet, or if a packet is an IPv4 packet and path MTU discovery is enabled, the path MTU value is used to determine the maximum size of the packet. Path MTU discovery initially sets the path MTU value to the actual route MTU value for the route. If packets require fragmentation to get to the final destination, path MTU discovery determines the path MTU value by repeatedly decreasing the value until it can send packets to the final destination without fragmentation.

Guideline: You can enable path MTU discovery for IPv4 by configuring IPCONFIG PATHMTUDISCOVERY in the TCP/IP profile.

- Actual route MTU value

The actual route MTU value is the lesser of the interface MTU value and the configured route MTU value. If path MTU discovery is not enabled, the actual route MTU value is used.

- Interface MTU value

The interface MTU value is a characteristic of an interface, and is either learned from the device during activation or is hardcoded based on the type of the physical device. For information about the

interface MTU values that TCP/IP uses for the various network interface types supported by TCP/IP, see the summary of `DEVICE` and `LINK` statements and the Summary of `INTERFACE` statements in *z/OS Communications Server: IP Configuration Reference*. For an `IPAQENET`, `IPAQENET6`, `EQENET`, `EQENET6` or `IPAQIDIO` interfaces defined with the `INTERFACE` statement, you can configure a lower interface MTU value using the `MTU` keyword on the `INTERFACE` statement.

Restriction: You cannot modify the interface MTU value for `IPAQIDIO` interfaces defined using the `DEVICE`, `LINK`, and `HOME` statements.

Results:

- The TCP/IP stack sets the interface MTU value to the lesser of the learned MTU value and the MTU value configured on the `INTERFACE` statement.
- For an active link or interface, TCP/IP reports the interface MTU value in the `ActMtu` field of the `Netstat DEVLINKS/-d` report.
- Configured route MTU value

The configured route MTU value is the MTU size that is configured for a route.

- Static route

For a static route, you can specify the configured route MTU value in the TCP/IP profile on a `ROUTE` entry in a `BEGINROUTES` block.

- IPv4 dynamic route

For IPv4 dynamic routes over an interface that are added by `OMPROUTE`, the configured route MTU value is the value of the `MTU` keyword specified on the `RIP_INTERFACE`, `OSPF_INTERFACE` or `INTERFACE` statement in the `OMPROUTE` configuration file for the outgoing interface of the route.

Result: If you do not specify an MTU value for an interface in the `OMPROUTE` configuration file, `OMPROUTE` uses the value 576.

- IPv6 dynamic route

For IPv6 dynamic routes added by `OMPROUTE`, `OMPROUTE` learns the interface MTU value from TCP/IP; you cannot configure a route MTU value in the `OMPROUTE` configuration file.

Result: For IPv6 dynamic routes that are learned by `OMPROUTE`, the configured route MTU size is the same as the interface MTU size.

These factors comprise a general set of rules for how TCP/IP determines the MTU, but there are some exceptions. For example, if an application uses the `IPV6_USE_MIN_MTU` socket option, TCP/IP sends outbound packets using the IPv6 minimum MTU value 1280.

Guidelines:

- Enable path MTU discovery in configurations where traffic originating in the z/OS TCP/IP stack will traverse multiple hops with different MTU sizes.
- OSA-Express supports an interface MTU of 8992 and Network Express supports an interface MTU of 9000. However, not all routers and switches support an MTU value of this size. If you are using this adapter and any routers or switches in your configuration do not support an MTU value of 8992, then either configure a lower MTU value for your routes or specify a lower MTU value on the `INTERFACE` statement in the TCP/IP profile.
- When you are using `OMPROUTE`, specify the `MTU` keyword for each IPv4 interface.
- When you are using `OMPROUTE`, configure all nodes on a LAN to use the same MTU value. Otherwise, you might encounter problems, such as OSPF adjacency errors.

Considerations for multiple servers sharing a TCP port

For a TCP server application to support a large number of client connections on a single system while providing good performance for those connections, it might be necessary to run more than one instance of the server application to service the connection requests. For all instances of the server application

to receive client connection requests without changing the client applications, the servers must all bind to the same server IP address and port. To enable this in the TCP/IP stack, you must add the SHAREPORT or SHAREPORTWLM keyword to the PORT profile statement that reserves the TCP port for the server instances. For more detailed information on the [PORT statement](#) and its keywords, see [z/OS Communications Server: IP Configuration Reference](#).

The set of server instances sharing the same TCP port on the same TCP/IP stack is called a shareport group. As incoming client connections arrive for this port and IP address, TCP/IP distributes them across the servers in the shareport group.

If the SHAREPORT keyword was specified, the connections are distributed across the available servers using a weighted round-robin distribution based on the Servers' accept Efficiency Fractions (SEFs).

If the SHAREPORTWLM keyword was specified, the connections are distributed across the available servers using a weighted round-robin distribution based on the WLM server-specific recommendations, modified by the SEFs.

The SEF is a measure, calculated at intervals of approximately 1 minute, of the efficiency of the server application in accepting new connection requests and managing its backlog queue. You can use the Netstat ALL/-A command to obtain the current SEF value for a server. For more detailed information about the Netstat command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Configuring a shareport group can also be used to improve the availability of key applications. For example, should an application server instance become inactive (encounters a failure or is stopped for planned maintenance), the other applications in the shareport group can continue to process client requests.

Applications that might be good candidates for being placed in a shareport group must also satisfy the following requirements:

- Multiple instances of the application can be started within a single system.
- Each application instance must provide the same functional capabilities. That is, each must be capable of processing any TCP connection requests to the shared port.

In addition, each TCP connection directed to a shareport group must be eligible for load balancing (it cannot have an affinity to a specific server). If specific client affinities exist to a specific server, you should consider using sysplex distributor, which provides for load balancing of connections while maintaining client affinities to a specific server instance over a period of time (Timed Affinity). While the primary focus of the sysplex distributor is on load balancing across servers on multiple target systems, it also supports multiple servers in a shareport group on the target systems. For more information on sysplex distributor configuration, see [Chapter 8, "TCP/IP in a sysplex,"](#) on page 463.

IBM z/OS Container Extensions network overview

IBM z/OS Container Extensions (zCX) provides an execution environment allowing z/OS to host applications based on Linux that are managed with docker containers. Each instance of zCX (unique zCX job) is provisioned within a unique z/OS address space. The zCX address space represents a virtual server which hosts applications managed in docker containers. The virtual server does not require operational tasks from the z/OS environment or the z/OS administrator. From an operational perspective, the virtual server is transparent to the z/OS environment. The zCX environment is configured using z/OSMF. For information about configuring the zCX environment, see [z/OS Container Extensions](#) and *IBM z/OS Management Facility Online Help* for Configuration Workflow.

z/OS Communications Server provides network communications and network related services for the zCX workloads. The Linux virtual server is represented by a unique type of application instance DVIPA called a zCX DVIPA. The VIPARange statement is used with the ZCX keyword to create zCX DVIPAs. Defining zCX DVIPAs is the primary IP configuration task and in many instances it will be the only required configuration task. For additional information about zCX DVIPAs, ["Configuring application-instance DVIPAs for IBM z/OS Container Extensions \(zCX\)"](#) on page 408.

The following figure provides an overview of the z/OS Communications Server support provided for the zCX environment.

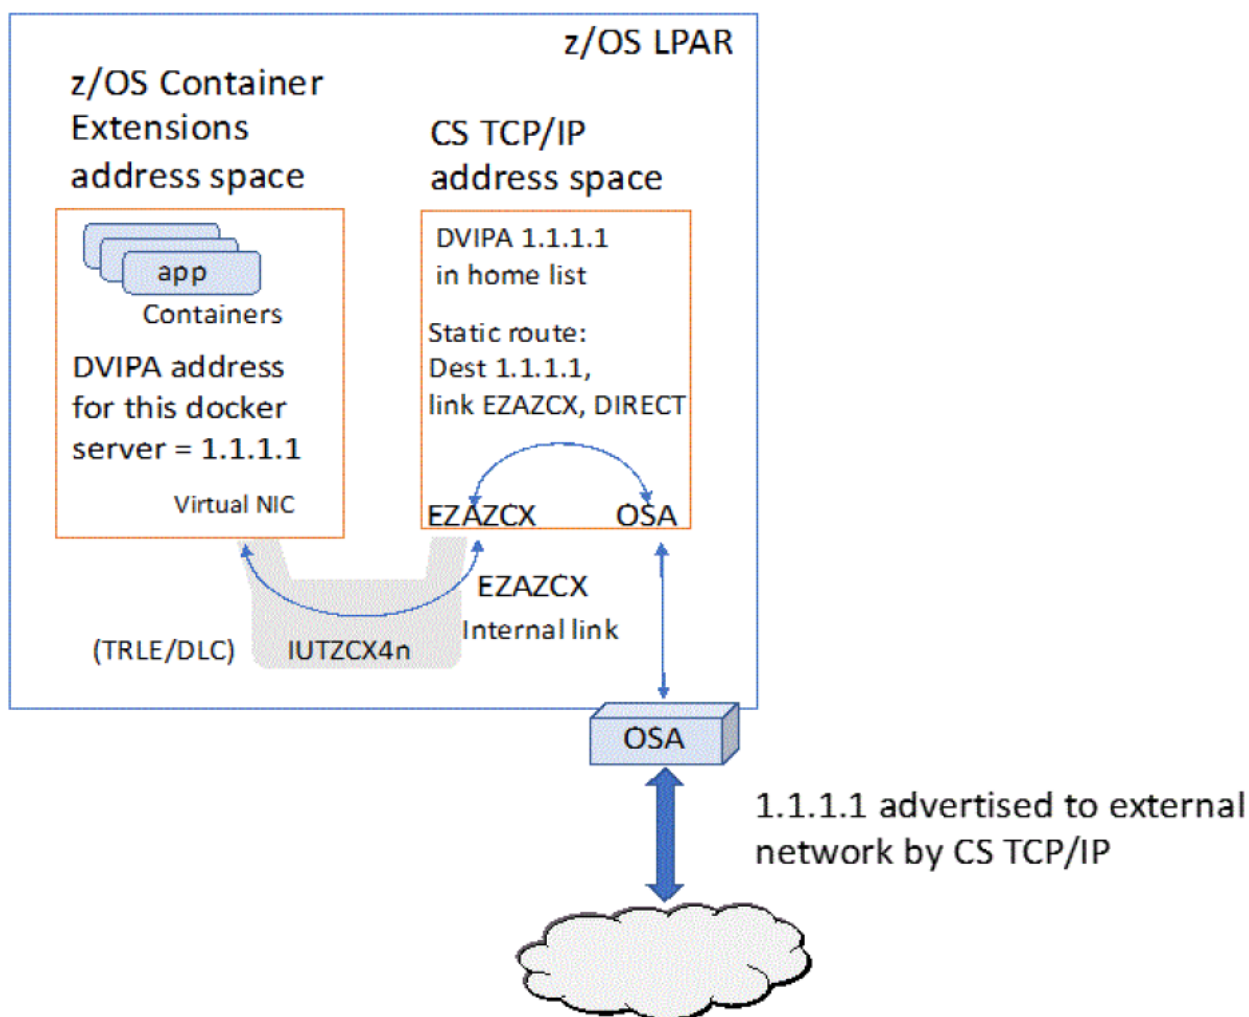

Figure 28. z/OS Communications Server support provided for the z/CX environment

Users define zCX DVIPAs to TCP/IP using VIPARange with the ZCX parameter using Network Configuration Assistant or directly in their TCP/IP profile.

The remaining steps are automatic:

Note: You must have IPCONFIG DYNAMICXCF in your TCP/IP profile in order for these steps to be automatic.

1. EZAZCX interface is automatically created¹ by TCP/IP and connected to a dynamically created internal network represented by a dynamically created TRLE called IUTZCX4n. A unique instance of the IUTZCX4n DLC is created for each TCP/IP stack connecting to zCX servers. The n represents the instance of each IUTZCX4n DLC created.
2. When the zCX job is started by the user:
 - a. this instance of zCX binds to the DVIPA and connects to TCP/IP over EZAZCX
 - b. DVIPA (zCX) is activated / added to the home list
 - c. TCP/IP creates a static route to the zCX DVIPAs for its own internal use. This route is local to and controlled by the stack that owns the zCX and is not advertised using dynamic routing.

¹ The EZAZCX interface is automatically created when the IUTSAMEH interface is created (either by DYNAMICXCF or static DEVICE/LINK/HOME for IUTSAMEH) and at least one VIPARANGE ZCX is configured. The EZAZCX interface transitions to ready when the first zCX DVIPA is activated. The EZAZCX interface is created for zCX instances using an IPv4 DVIPA. If the zCX instance is using an IPv6 DVIPA, the interface created is EZ6ZCX and the TRLE created is IUTZCX6n.

3. When using dynamic routing the zCX DVIPAs are treated by OMPROUTE as application-instance DVIPAs and are advertised accordingly.²
4. CS TCP/IP forwards packets for 1.1.1.1 over the zCX IP route and the EZAZCX Interface.

Note: IP filters can be configured and applied during IP forwarding. IPsec tunnels can be applied to the external IP routes. If you have IP filters defined, updates to your IP filter rules are required. You must ensure that you permit ROUTED and LOCAL (EITHER) traffic for the zCX DVIPAs.

z/OS Container Extensions IPv6 network overview

z/OS supports zCX instances with both IPv4 and IPv6 connectivity. A zCX instance can support just IPv4 or both IPv4 and IPv6 connectivity.

Defining zCX DVIPAs using VIPARange remains as the primary IP configuration task that controls and enables each zCX instance for each specific IP version. When the zCX job is started, the appropriate zCX interfaces will be started.

Configuring and enabling zCX IPv6 requires that your zCX instance is already enabled for IPv4 (see the above IPv4 steps) and then the required IPv6 steps are summarized below for the following two use cases:

- **z/OS TCP/IP users who already have enabled z/OS for IPv6 (key steps):**

1. Define IPv6 zCX DVIPAs using the VIPARange statement.

Note:

- a. A separate IPv6 VIPARange statement should be created for each zCX instance that requires IPv6 connectivity.
- b. For supporting high availability for zCX, your IPv6 VIPARange statements should be configured in all z/OS TCP/IP instances within the sysplex eligible to host this zCX IPv6 instance.
2. Specify the IPv6 DVIPA in the z/OSMF zCX workflows (provisioning or reconfiguration workflows). Optionally specify any other IPv6 addresses or hostnames for any zCX configuration options, such as DNS, Registry, Proxy, or LDAP addresses using the z/OSMF zCX workflows.
3. Common IPv6 configuration steps:

Most existing z/OS IPv6 users will have already completed the following common IPv6 steps, but here are some key steps to consider:

- a. External IPv6 Interfaces:

To enable IPv6 communications with hosts external to this z/OS TCP/IP instance you must enable the associated z/OS IPv6 interfaces, such as OSA or HiperSockets.

- b. IPv6 Dynamic XCF must be enabled.³

- c. If using dynamic routing, define your IPv6 DVIPAs to OMPRoute.

Note: IP filters can be configured and applied during IP forwarding. IPsec tunnels can be applied to the external IPv6 routes. If you have IP filters defined, updates to your IP filter rules are

² When using dynamic routing, you must define the zCX DVIPAs to OMPRoute just like any other application-instance DVIPA. OMPROUTE will then advertise the zCX DVIPA when it activates on the host. When the DVIPA is moved, external hosts will automatically (with dynamic routing updates) find the new location of the DVIPA and the related zCX applications. If OMPROUTE is not being used, you must ensure the zCX DVIPAs can be reached by other hosts by defining static routes on other hosts that need to reach the zCX instance.

³ The EZAZCX interface is automatically created when the IUTSAMEH interface is created (either by IPCONFIG(6) DYNAMICXCF or static DEVICE/LINK/HOME for IUTSAMEH) and at least one VIPARANGE ZCX is configured. The EZAZCX interface transitions to ready when the first zCX DVIPA is activated. The EZAZCX interface is created for zCX instances using an IPv4 DVIPA. If the zCX instance is using an IPv6 DVIPA, the interface created is EZ6ZCX and the TRLE created is IUTZCX6n.

required. You must ensure that you permit ROUTED and LOCAL (EITHER) traffic for the zCX DVIPAs.

- **z/OS TCP/IP users who have not enabled z/OS for IPv6:**

1. This type of user must first complete the z/OS IPv6 migration or enablement. This type of user must start with the [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).
2. Once your z/OS TCP/IP stack is enabled for IPv6, review the first list above for the specific zCX IPv6 steps.

Required steps before starting TCP/IP

This information describes the steps you must complete before starting TCP/IP.

Planning your installation and migration

It will be to your advantage to have thoroughly studied the following documentation prior to the installation and customization of z/OS Communications Server:

- Program Directory for z/OS for CBPDO Installation and ServerPac Reference, Program Number 5650-ZOS
- Preventive Service Planning (PSP) bucket
- [z/OS Communications Server: New Function Summary](#)
- [z/OS UNIX System Services Planning](#)
- OS390CKL, IBM MKTTOOLS information for the z/OS UNIX System Services implementer

It is also recommended that you attend a z/OS UNIX System Services concepts class and a class in using z/OS UNIX System Services prior to migrating to z/OS Communications Server. If this is not possible, then you will want to ensure that the z/OS UNIX System Services implementer and the RACF administrator work together with you during the installation and customization process.

Planning for and installing z/OS Communications Server requires MVS, UNIX, and networking skill. If your background is in traditional MVS programming or system programming, the z/OS UNIX System Services terminology might at first seem to be somewhat confusing. If your background is in the UNIX environment, the terms should be familiar to you.

In the past, MVS TCP/IP system programmers have needed a working knowledge of the MVS or z/OS system. These programmers have been accustomed to working closely with the RACF administrator and z/OS system programmer for authorizations; the IP address administrator for basic name and address assignments; and the administrators of the router network and channel-attached peripherals for connection definition and problem determination.

With the introduction of z/OS Communications Server, the TCP/IP system programmer needs to develop an additional alliance with the z/OS UNIX System Services system programmer. The TSO interfaces that have been traditionally available in the host-based TCP/IP still stand at the system programmer's disposal and additional MVS console commands simplify some TCP/IP operations. However, another user interface provided by the UNIX shell environment, either with the z/OS shell or the ISPF SHELL, is a useful and sometimes necessary tool that the TCP/IP system programmer will need to work with. Additionally, the tight coupling of z/OS Communications Server with z/OS UNIX System Services means that the TCP/IP system programmer needs more than a passing knowledge of UNIX conventions, commands, and hierarchical file system concepts. Even if the system programmer is familiar with other UNIX environments, work with the UNIX shell requires more than basic familiarity.

In the first version of a full TCP/IP stack based on native MVS and on z/OS UNIX System Services, few have all the requisite skills to successfully implement z/OS Communications Server on their own. As more and more system programmers acquire skills in UNIX System Services and in TCP/IP, this will become less and less the case. Working with the z/OS UNIX System Services implementer when implementing z/OS Communications Server provides the most effective solution to establishing a working z/OS Communications Server environment.

If you are migrating to z/OS Communications Server, establish a migration process to move all your existing applications, and after this, consider the use of new and enhanced functions based on [z/OS Communications Server: New Function Summary](#). z/OS Communications Server allows multiple copies of the TCP/IP protocol stack to execute on the same MVS image. However, with all the performance enhancements introduced in z/OS Communications Server, it is probably not necessary to implement a multi-stack system for production purposes unless one is considering building a system programming test stack.

Step 1: Install z/OS Communications Server

Before you begin the installation:

- To help you plan the installation and migration of z/OS Communications Server, see:
 - [z/OS Planning for Installation](#)
 - [z/OS Communications Server: New Function Summary](#)
 - [z/OS Upgrade Workflow](#)
- Be sure you understand the data set naming conventions used in TCP/IP. You can find this information in [“Configuration data set naming conventions”](#) on page 13.
- Consult the *z/OS Program Directory* (Customization considerations for Wave 1D) for current information about the material, procedures, and storage estimates of the MVS image.

Install z/OS Communications Server with other elements of z/OS. If you use the ServerPac method of installation, see *z/OS Installing Your Order*; if you use the CBPDO method of installation, see *z/OS Program Directory*. When appropriate, that information will direct you back to this information to customize the TCP/IP data sets and procedures and verify their configuration.

Verifying the initial installation

Both the *z/OS Program Directory* and *z/OS Installing Your Order* contain step-by-step instructions that can be used to set up and verify a basic TCP/IP configuration with only the loopback address and a few key servers. For more information regarding these instructions, see the information about Wave 1D customizations in the [z/OS Program Directory](#) or the information about verifying your installation in *z/OS Installing Your Order*.

Step 2: Customize z/OS Communications Server

To customize TCP/IP you need to update the cataloged procedures and configuration data sets for the TCP/IP address space, its clients, and servers.

z/OS Communications Server runs as a started task in its own address space. Each of the servers runs in its own address space and is started with its own procedure. The TCP/IP address space requires:

- A procedure in a system or recognized PROCLIB.
- A data set that provides configuration definitions for the TCP/IP address space and includes statements affecting many of the servers. This data set is referred to as PROFILE.TCPIP.
- A data set to provide the parameters that are common across all clients. This data set is referred to as TCPIP.DATA.

Other topics show you how to:

- Configure the TCP/IP address space by updating the samples provided in SEZAINST(SAMPPROF) and SEZAINST(TCPIPROC).
- Configure the universal client parameters provided in SEZAINST(TCPDATA).
- Configure the site table, defined in *hlq*.HOSTS.LOCAL or *hlq*.ETC.IPNODES, to identify the Internet names and addresses of your TCP/IP host.
- Customize the TCP/IP Component Trace parameters by updating the CTRACE parameter in the PARM= field of the EXEC JCL statement in the TCP/IP started procedure.

You can find a description of the MVS Component Trace support in the [z/OS Communications Server: IP Diagnosis Guide](#).

- Specify the ENVAR parameter on the PARM=keyword to override the resolver file. For more information on setting the environment variable RESOLVER_CONFIG using the ENVAR parameter, see [“Considerations for multiple instances of TCP/IP” on page 45](#).
- Configure each of the servers you want to run. This might require:
 - Modifying sample procedures and adding them in your PROCLIB
 - Modifying the configuration data set, PROFILE.TCPIP
 - Adding port numbers to *hlq.ETC.SERVICES*
 - Modifying other data sets containing server-specific parameters

You can find the sample procedures and data sets in SEZAINST. Table 1 on page 15 provides additional reference information you can use as you configure and customize each server.

You can find general information about starting, stopping, and dynamically controlling the servers in [z/OS Communications Server: IP System Administrator's Commands](#).

Many of the servers also require other data sets for their specific functions.

Making SYS1.PARMLIB changes

You need to make certain changes to SYS1.PARMLIB. These changes depend on which of the following installation methods you use:

ServerPac method

After the file system is restored (through the RESTFS job), you will see that ServerPac has changed some of the parmlib members. Follow the instructions to change the BPXPRMxx member of parmlib.

CBPDO method

Change the parmlib members according to the instructions listed in the installation instructions for Wave 1. Tables describing changes to parmlib and changes to the BPXPRMxx member are included.

Note: z/OS Communications Server exploits z/OS UNIX services even for traditional MVS environments and applications. Before using TCP/IP services, the z/OS UNIX environment must be set up in full function mode. For a list of tasks involved in setting up for full function mode, see [z/OS UNIX System Services Planning](#). System Managed Storage (SMS, which is part of the DFSMSdfp element of z/OS) must be configured, and you will need to customize SMS, RACF, and the z/OS UNIX file system.

Additional information about required TCP/IP definitions for the UNIX environment can be found in [“Defining TCP/IP as a UNIX System Services physical file system” on page 40](#) and [“UNIX System Services security considerations” on page 36](#).

Common z/OS UNIX configuration problems

The following list includes some explanations and possible solutions for common problems that you might encounter when you are configuring the z/OS UNIX environment.

- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIP-BPX1SOC,
00000003,FFFFFFFF,00000070,112B00B6
```

These messages usually indicate that both INET and CINET FILESYSTYPE have been specified. Only one should be specified; see the FILESYSTYPE information in [z/OS UNIX System Services Planning](#) for additional information.

- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIP-BPX1SOC,
00000003,FFFFFFFF,0000006F,112B00B0
```

These messages indicate that the requester of the service is not privileged. The service requested requires a privileged user. Check the documentation for the service to understand what privilege is required.

- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR
        FOR TCPIPA-BPX1IOC,8008C981,FFFFFFFF,0000009E,12B2005A

EZZ4204I TCPIP INITIALIZATION FOR TCPIPA FAILED
```

These messages usually indicate that an incorrect jobname was specified in the SUBFILESYSTYPE NAME() definition in the BPXPRMxx member for a common INET environment. In this scenario, the NAME() must match TCPIPA.

- TCP/IP initialization fails with the following messages:

```
IEA8481 DUMP SUPPRESSED - ABDUMP MAY NOT DUMP STORAG FOR KEY 0-7 JOB TCPV34A
IEF4501 TCPIPA TCPIPA - ABEND=SEC6 U0000 REASON=0F01C008
```

These messages are usually an indicator that an OMVS RACF segment has not been defined for the user ID associated with the TCP/IP started procedure. Define an OMVS segment with a UID of 0 for the user ID associated with the TCP/IP started procedure.

- TCP/IP initialization fails with the following messages:

```
IEF4031 TCPIPA - STARTED - TIME=16.01.25
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIPA-BPX110C,
        8008139A,FFFFFFFF,00000079,12D2025E
EZZ4204I TCPIP INITIALIZATION FOR TCPIPA FAILED.

==> The 0079 value is EINVAL - The parameter is incorrect
==> The 025E value is JRSocketCallParmError - A socket syscall
    contains incorrect parameters
```

These messages usually indicate that an incorrect entry point name has been specified in the SUBFILESYSTYPE ENTRYPOINT() definition. The correct value is ENTRYPOINT(EZBPFINI).

- TCP/IP initialization fails with the following messages:

```
EZZ4203I Z/OS UNIX-TCP/IP CONNECTION ERROR FOR TCPIPA-BPX1SOC,
        00000003,FFFFFFFF,0000045A,112B0000
EZZ4204I TCPIP INITIALIZATION FOR TCPIPA FAILED.

==> The 045A value is EAFNOSUPPORT - The address family is not supported
```

These messages indicate that AF_INET was not defined or did not initialize properly. Check for any earlier z/OS UNIX messages and verify that the z/OS UNIX NETWORK DOMAINNAME(AF_INET) statement is in your BPXPRMxx member.

- After issuing a NETSTAT command from TSO, the following message is displayed:

```
netstat
CEE5101C During initialization, the z/OS UNIX callable service
        BPX1MSS failed. The system return code was 0000000156,
        the reason code was 0507014D. The application will be
        terminated.
NETSTAT ENDED DUE TO ERROR+
READY
?
USER ABEND CODE 4093 REASON CODE 00000090
READY

==> The 0156 value is EMVSINITIAL - Process initialization error
==> The 014D value is JRFsFailChdir - The dub failed, due to
    an error with the initial home directory
```

These messages indicate that the user ID issuing the NETSTAT command does not have an OMVS RACF segment defined for it. Define an OMVS segment for this user ID or activate the automatic assignment of unique UNIX identities support. For details, see [“UNIX System Services security considerations” on page 36](#).

- Socket applications using the z/OS Communications Server TCP/IP Services APIs fail with an ERRNO of 156.

ERRNO 156 indicates a z/OS UNIX process initialization failure. This is usually an indication that an appropriate OMVS RACF segment is not defined for the user ID associated with the application. The RACF OMVS segment may not be defined or may contain errors such as an improper HOME() directory specification. If the OMVS segment is not defined, you may also receive the following message:

```
ICH4081 USER(USER8  ) GROUP(SYS1  )  NAME(TSO USERID USER8  )
      CL(PROCESS  )
      OMVS SEGMENT NOT DEFINED
```

In this example, USER8 is the user ID associated with the failing application. To correct this problem, define an appropriate OMVS segment for the user ID associated with the failing application. For details, see [“UNIX System Services security considerations”](#) on page 36.

Step 3: Configure VMCF and TNF

The Pascal socket interface uses the IUCV/VMCF services for a limited set of inter-address space communication flows. As a result, if you are using any applications (provided by IBM or others) that use the Pascal socket API, you must ensure that the Virtual Machine Communication Facility (VMCF) and Termination Notification Facility (TNF) subsystems are active before the applications are started. TCP/IP provides the following applications and commands that use the Pascal socket interface:

- LPD servers
- TSO HOMETEST, LPQ, LPR, LPRM, LPRSET, TELNET, and TESTSITE commands

If you are using any of these applications or commands, you need to set up VMCF and TNF.

You can configure VMCF and TNF in two different ways: as restartable subsystems or as non-restartable subsystems.

If you configure VMCF and TNF as restartable subsystems and you want the VMCF node name to be used as a default host name during TCP/IP initialization (when no other host name can be located), VMCF must be started before TCP/IP.

Tip: The host name value is typically specified on the TCPIP.DATA HOSTNAME statement.

Restartable subsystems

Configuring VMCF and TNF as restartable subsystems has the following advantages:

- Error detection is provided when the subsystems do not seem to be initializing properly.
- You can change the system name on the restart.
- Commands are available to remove users from internal tables, display current users and to terminate the subsystem.

In summary, a restartable VMCF and TNF configuration provides better availability and is therefore recommended.

If you choose to use restartable VMCF and TNF, follow these steps:

1. Update your IEFSSNxx member in SYS1.PARMLIB with the TNF and VMCF subsystem statements required by TCP/IP. The specification can be in either the IBM recommended keyword parameter form or the positional parameter form of IEFSSNxx. For example:

```
* The keyword parameter form is:
SUBSYS SUBNAME(TNF)
SUBSYS SUBNAME(VMCF)

* The positional parameter form is:
TNF
VMCF
```

2. Add procedure EZAZSSI to your system PROCLIB. A sample of this procedure is located in the SEZAINST library.

```
//EZAZSSI PROC P=&SYSNAME.  
//STARTVT EXEC PGM=EZAZSSI,PARM=&P,TIME=1440
```

3. Start VMCF and TNF using the procedure EZAZSSI before starting TCP/IP. If your node name is the same as the MVS system symbolic &SYSNAME, then you can start VMCF and TNF with the following command:

```
S EZAZSSI
```

If your node name is different than the MVS system symbolic &SYSNAME, start VMCF and TNF with the following command:

```
S EZAZSSI,P=nodename
```

Replace *nodename* with the system name of your MVS system.

Non-restartable subsystems

If you will not be using restartable VMCF and TNF, you should update your IEFSSNxx member in SYS1.PARMLIB with the following subsystem statements required by TCP/IP. The specification can be in either the IBM suggested keyword parameter form or the positional parameter form of IEFSSNxx.

Restriction: If you are using the keyword parameter form and your IEFSSNxx member contains the BEGINPARALLEL statement, the TNF and VMCF statements must precede the BEGINPARALLEL statement, so that TNF and VMCF are initialized serially instead of in parallel. VMCF requires that TNF is initialized first.

The keyword parameter form is:

```
SUBSYS SUBNAME(TNF) INITRTN(MVPTSSI)  
SUBSYS SUBNAME(VMCF) INITRTN(MVPXSSI) INITPARM(nodename)
```

The positional parameter form is:

```
TNF,MVPTSSI  
VMCF,MVPXSSI,nodename
```

Replace *nodename* on the VMCF line with the system name of your MVS system.

VMCF commands

If you will be using restartable VMCF, the following VMCF commands let you display the names of the current users of VMCF and TNF, and if necessary, remove names from the name lists.

Note: Removing names from the name lists and stopping either subsystem can have unwanted results, if done hastily. Use the REMOVE and stop (P) commands carefully and only as a last resort.

If you remove a user, the application is not canceled, nor is the connection severed. In other words, the removed application may remain active in the system, and may subsequently abend 0D6/0D4/0C4, or cause TCP/IP to hang. A user that is removed from VMCF may still be a user of TNF and even TCP/IP, and vice versa.

To terminate users and stop VMCF or TNF properly, follow these steps:

1. Display the current users of the subsystems by using one of the following commands:

```
F VMCF,DISPLAY,NAME=*
```

```
F TNF,DISPLAY,NAME=*
```

2. Terminate those users. If termination fails, use the REMOVE command as a last resort to force them from the name list.
3. Stop the subsystem, using one of the following commands:

```
P VMCF
```

```
P TNF
```

If the P command fails, use one of the following commands:

```
FORCE VMCF,ARM
```

```
FORCE TNF,ARM
```

The following list describes the commands:

F TNF,DISPLAY,NAME=[name | *]

Displays the named user [or all (*) users] of TNF, sorted by ASID.

F TNF,REMOVE,NAME=[name | *]

Removes either the named user [or all (*) users] from the TNF internal tables.

P TNF

Requests TNF to terminate.

F VMCF,DISPLAY,NAME=[name | *]

Displays the named user [or all (*) users] of VMCF, sorted by name.

F VMCF,REMOVE,NAME=[name | *]

Removes either the named user [or all (*) users] from the VMCF internal tables.

P VMCF

Requests VMCF to terminate

Sample commands:

```
F TNF,DISPLAY,NAME=TCPV3
F VMCF,DISPLAY,NAME=*
F TNF,REMOVE,NAME=FTPSERV
F VMCF,REMOVE,NAME=*
P TNF
```

Common VMCF problems

The following problems are some common VMCF problems:

- VMCF or TNF fail to initialize with an OC4 abend.

This is probably an installation problem; check the program properties table (PPT) entries for errors. Some levels of MVS do not flag PPT syntax errors properly.

- Abends 0D5 and 0D6 after REMOVEing a user.

This is probably because the application is still running and using VMCF. It is not recommended that users be removed from VMCF or TNF without first terminating the affected user.

- VMCF or TNF do not respond to commands.

This is probably because one or both of the non-restartable versions of VMCF or TNF are still active. To get them to respond to commands, stop all VMCF/TNF users, FORCE ARM VMCF and TNF, then use EZAZSSI to restart.

- VMCF or TNF cannot be stopped.

This is probably because users still exist in the VMCF and TNF lists. Use the F VMCF,DISPLAY,NAME=* and F TNF,DISPLAY,NAME=* commands to identify those users who are still active. Then either cancel those users or remove them from the lists using the F VMCF,REMOVE and F TNF,REMOVE commands.

- Address Space Identifiers (ASIDs) become nonreusable when VMCF and TNF address spaces are stopped or restarted.

Because VMCF and TNF address spaces provide PC-entered services that must be accessible to all address spaces, they each obtain a system LX. This causes the ASIDs associated with these address spaces to be nonreusable when these address spaces are terminated. If VMCF and TNF are terminated enough times all available ASIDs could be exhausted, preventing the creation of new address spaces on the system. In this case, an IPL will be required. For more information on tuning parameters for the maximum number of ASIDs in a system, see the MAXUSER parameter in [z/OS MVS Initialization and Tuning Reference](#).

IUCV/VMCF considerations

The IUCV/VMCF inter-address space communication API enables applications running in the same MVS image to communicate with each other without requiring the services of the TCP/IP protocol stack. The VMCF/TNF subsystems provide these services, which are still available in z/OS Communications Server. Several components of TCP/IP in z/OS Communications Server continue to make some use of these services for the purpose of inter-address space communications. These include:

- The AF_IUCV domain sockets for the TCP/IP C socket interface. The AF_IUCV domain enables applications executing in the same z/OS image and using the TCP/IP C socket interface to communicate with each other using a socket API, but without requiring the services of the TCP/IP protocol stack, as no network flows result in these communications. This is quite different from the more common AF_INET domain that enables socket communication over an IP network. AF_IUCV sockets continue to be supported in z/OS Communications Server.

An example of a TCP/IP-provided application that exploits AF_IUCV sockets is the SNMP Query Engine component (SQSERVE). The z/OS UNIX socket library provides a similar functionality to the AF_IUCV domain sockets with its AF_UNIX domain. Users creating new applications should consider using AF_UNIX domain sockets.

- The Pascal socket interface also makes use of the IUCV/VMCF services for a limited set of inter-address space communication flows. As a result, any applications (provided by IBM or others) that use the Pascal socket API also still have a requirement for the VMCF/TNF subsystems. TCP/IP provides several applications and commands that use these interfaces, such as the LPD servers, and the TSO TELNET, HOMETEST, TESTSITE, and LPR commands. IUCV/VMCF services require the usage of an address space name of SYSTEM. This means a TSO user cannot have the user ID name of SYSTEM.

Therefore, in z/OS Communications Server you must continue to configure and start the VMCF and TNF subsystems as you did in TCP/IP V3R2. However, because the VMCF/TNF subsystems are no longer used to communicate directly with the TCP/IP protocol stack in z/OS Communications Server, the amount of CPU they will consume will be significantly lower than in the TCP/IP V3R2 environment.

Step 4: Update the VTAM application definitions

You must update the VTAM definitions for the TN3270E Telnet server. See [“Steps for customizing the VTAM configuration data set for Telnet”](#) on page 597 for an example of the VTAM definitions.

SEZAINST(VTAMLST) contains a sample of the VTAM definitions for TN3270E Telnet server applications. You should copy this member, update it, and add it to the ATCCONxx member of VTAMLST. This ensures that the TN3270E Telnet server applications are activated when VTAM is started.

Because the TCP/IP LU code cannot handle multiple concurrent sessions, you must code SESSLIM=YES for each TN3270E Telnet server LU defined to VTAM. Otherwise, if SESSLIM=NO, menu or session manager applications that use return session processing might cause session termination.

Step 5: Verify that the required address spaces are active

TCP/IP uses services from other address spaces in its processing. While TCP/IP waits for availability of those services, it is recommended that you verify that the OMVS, resolver, and VTAM address spaces have completed initialization before starting TCP/IP. If using automation to start TCP/IP, have it look for the BPXI004I, EZZ9291I, and IST020I messages, respectively, before issuing the START command.

For information on how the resolver can be started, see [“Starting the resolver” on page 761](#). You can use the resolver's MODIFY DISPLAY command to check that the resolver is active and what resolver setup statements are being used. For the syntax and usage of the command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Step 6: Start the TCP/IP address space

Enter the MVS START command from the operator's console to start TCP/IP, specifying the member name of your cataloged procedure. This will start the TCP/IP address space and any of the servers you have defined in the AUTOLOG statement in PROFILE.TCPIP. For example, if the procedure to start the TCP/IP address space was called TCP1 in your PROCLIB, you would enter the following:

```
START TCP1
```

There are two optional parameters that can be added after the procedure name. These are ASCBV31=YES and REUSASID=YES. These options help to maximize storage usage. ASCBV31 specifies that the address space attempts to use a 31-bit ASCB. REUSASID specifies that the address space attempts to use an ASID from the reusable address space pool.

```
START TCP1, REUSASID=YES, ASCBV31=YES
```

For information on updating the TCP/IP cataloged procedure or configuration statements used to configure the TCPIP address space, see [z/OS Communications Server: IP Configuration Reference](#).

Step 7: Set up cataloged procedures and configuration data sets

At this point in the configuration process, you can choose to either set up procedures or you can do each one individually when you set up the appropriate application, function, or server.

See the appropriate topics for more information about setting up a particular application, function, or server.

Chapter 3. Security

The z/OS Communications Server, along with other elements of z/OS, provide numerous enterprise-strength security services to protect your mission-critical data. This topic provides an overview of these technologies and how they can be used for a safe and secure z/OS TCP/IP deployment.

Figure 29. Elements of a secure TCP/IP deployment

Tip: Many of the tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.

The Communications Server protects data and other resources on the system. Communications Server applications use RACF services to ensure that users requesting application access are identified and authenticated, and to protect data and other system resources from unauthorized access. The Communications Server safeguards the availability of the system by protecting against denial of service attacks from the network.

The Communications Server protects data in the network by supporting a variety of cryptographic-based network security protocols such as IPSec and TLS/SSL. z/OS also supports the SSH protocol. These security protocols ensure the identity of the communication partners (partner authentication), that data received is originated by the claimed sender (data origin authentication), that contents were unchanged in transit (message integrity), and that sensitive data is concealed using encryption (data privacy).

The Communications Server provides security event reporting to record potential security violations. These services may help you identify potential sources of subsequent attacks, respond more quickly to network attacks, and manage system resources during periods of high network traffic for key applications.

Note: Some of the security features described in this information have not yet been implemented for IPv6. To determine which functions are supported for IPv6, see the [IPv6 support tables in z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

Application security

The Communications Server protects data and other system resources accessed by applications included in the Communications Server element. This protection requires verification of the identity of the user requesting access. This process is called identification and authentication. In addition, access to resources must be limited to those users with permission. This process is called access control.

Communications Server applications use RACF for identification and authentication, and access control decisions. Authenticated users are granted access to RACF resources only for which they have permission

Some applications allow anonymous access. Applications that allow anonymous access include anonymous FTP and Remote Execution. The Communications Server ensures that all anonymous access can be controlled by the installation. If anonymous access is allowed, the resources accessed can be limited in several ways:

- The application can be configured to limit resources for which access will be attempted.
- The application can be configured to use a RACF user ID to represent the anonymous user. In this case, access is allowed for those resources specifically permitted for the anonymous RACF user ID and for those resources that are universally accessible.

Most Communications Server applications must be configured specifically to allow anonymous access.

Table 10 on page 146 depicts a representative set of Communications Server applications, whether user identification is required, and the security credentials under which resource access is made. For more information on specific application considerations, see the topic about each application.

<i>Table 10. User identification, authentication, and access control for z/OS Communications Server applications</i>		
Server	End-user identification	Resource access
FTP	Optional ¹	End-user ID or configured anonymous user ID ²
LPD	Optional ¹	Server ID or end-user ID
MVS REXECD	Required	End-user ID
MVS RSHD	Required (password optional) ¹	Surrogate user ID or end-user ID
NSSD [network security services (NSS) server]	Required	NSS client user ID
Policy Agent server	Required	Policy client user ID
UNIX REXECD	Required	End-user ID
UNIX RSHD	Required (password optional) ¹	End-user ID or Server user ID (exit routine to verify request)
UNIX shell (Telnet/rlogin)	Required	End-user ID
<p>1. All items listed as optional are installation controlled and can all be configured to require full end-user identification.</p> <p>2. Accessible files can be configured on a server basis to limit access.</p>		

TCP/IP resource protection

The Communications Server uses the System Authorization Facility (SAF) to protect TCP/IP resources from unauthorized access. These resources are represented by resource profiles defined in the SERVAUTH class. When describing resource profile names, the following conventions are used:

- *sysname* is the MVS system name. Substitute your system name.
- *tcpname* is the TCP/IP job name. Substitute your job name.
- *ftpdadmonname* is the job name of the FTP daemon. Substitute your FTPD job name. If your FTPD job name contains fewer than 8 characters, substitute the job name of the process that is started by FTPD, which is usually the original job name with the number 1 appended.

- *rpcbindname* is the job name of rpcbind. Substitute your rpcbind job name. If your rpcbind job name contains fewer than 8 characters, substitute the job name of the process that is started by rpcbind, which is usually the original job name with the number 1 appended.

The use of SERVAUTH is optional. The installation can choose to use any combination of the protections provided by SERVAUTH.

In addition to the use of SERVAUTH protection, further resource protection is provided through such functions as intrusion detection services (IDS), syslogd isolation, and IP filtering, or through controlling access to the VARY TCPIP command.

Local user access control to TCP/IP resources using SAF

You can use System Authorization Facility (SAF) to control which z/OS users can access specific TCP/IP resources, which protects against unauthorized user access to these resources.

You define SAF resource profiles in the SERVAUTH class to control access to the TCP/IP resources. After you define a SAF resource profile, a local user can access the associated TCP/IP resource if their user ID has at least READ access to the resource.

z/OS Communication Server programs call SAF to determine which users have access to protected resources. The user's credentials, a resource name, and a requested level of access (READ, UPDATE, and so on) are provided to SAF. SAF has three defined return codes:

- 0**
Permit
- 4**
No decision
- 8**
Deny

The following situations can result in a no-decision return code from SAF:

- The security server is not available.
- The resource class is not active.
- The named resource does not have a profile defined in the class.

When SAF returns a no-decision return code, the resource manager decides whether to allow access. The No SAF decision column in [Table 11 on page 147](#) indicates the action that the resource manager takes for each resource.

[Table 11 on page 147](#) summarizes the SERVAUTH resource names that are used by TCP/IP.

Table 11. SERVAUTH resource names used by TCP/IP			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
Broadcast access control	Provides ability to control whether an application is permitted to set the SO_BROADCAST socket option needed to send broadcast datagrams	Permit	EZB.SOCKOPT.sysname.tcpname.SO_BROADCAST
			TCPIP SOCKOPT ACCESS CHECK

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
DCAS server access control	Controls ability to access DCAS server based on SAF user ID associated with TLS-authenticated X.509 client certificate	Permit	EZA.DCAS.cvtsysname
			DCAS SAFCERT CHECK FOR USER certuser or TCPIP EZACDRAU AUTH CHECK FOR EZA.DCAS.cvtsysname
Fast Response Cache Accelerator (FRCA) Access Control	Provides ability of user to create FRCA cache (FRCA used by web servers for caching static web pages in the stack)	Deny, see result 1	EZB.FRCAACCESS.sysname.tcpname
			TCPIP FRCA ACCESS CHECK
FTP server access control	Controls ability to access FTP server based on SAF user ID used to log in	Permit	EZB.FTP.sysname.ftpdamonname.PORTxx xxx
			(none)
FTP SITE command control	Provides ability to restrict usage of SITE DUMP and DEBUG commands (commands generate large amount of output)	Permit	EZB.FTP.sysname.ftpdamonname.SITE.D UMP
			EZB.FTP.sysname.ftpdamonname.SITE.D EBUG
FTP z/OS UNIX file system access control	Provides ability to generally restrict FTP user access to the z/OS UNIX file system	Permit	(none)
			EZB.FTP.sysname.ftpdamonname.ACCESS S.HFS
FTP server JES access control	Controls ability to use FILETYPE JES mode based on SAF user ID used to log in	Permit	(none)
			EZB.FTP.sysname.ftpdamonname.ACCESS S.JES
ipsec command access control	Provides ability to control ipsec command usage	Deny	EZB.IPSECCMD.sysname.tcpname.comma nd_type
			EZB.IPSECCMD.sysname.DMD_GLOBAL.co mmand_type
			TCPIP EZACDRAU AUTH CHECK FOR EZB.IPSECCMD.sysname.tcpname.comma nd_type
			or TCPIP EZACDRAU AUTH CHECK FOR EZB.IPSECCMD.sysname.DMD_GLOBAL.co mmand_type

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
IPSec network management interface (NMI) access control for control requests (local)	Controls whether a user can issue NMI control requests to the local IKE daemon to manage IP filtering and IPSec function (for example, activate and deactivate requests) pertaining to a local TCP/IP stack	Deny	EZB.NETMGMT.sysname.tcpname.IPSEC.CONTROL
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NETMGMT.sysname.tcpname.IPSEC.CONTROL
IPSec NMI access control for display requests (local)	Controls whether a user can issue NMI monitoring requests to the local IKE daemon to retrieve IP filtering and IPSec monitoring data pertaining to a local TCP/IP stack	Deny	EZB.NETMGMT.sysname.tcpname.IPSEC.DISPLAY
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NETMGMT.sysname.tcpname.IPSEC.DISPLAY
IPSec NMI and ipsec command access control	Controls whether a user can issue: <ul style="list-style-type: none"> NMI requests to display IKE daemon NSS client information The ipsec command with the -w option to display IKE daemon NSS IPSec client information 	Deny	EZB.NETMGMT.sysname.sysname.IKED.DISPLAY
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NETMGMT.sysname.sysname.IKED.DISPLAY

Table 11. *SERVAUTH* resource names used by TCP/IP (continued)

Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
IPSec NMI and ipsec command access control for control requests (remote)	Controls whether a user can issue: <ul style="list-style-type: none"> NMI management requests to the NSS server that pertain to an NSS client (for example, activate and deactivate requests) The ipsec command with the -z option to perform a management action to an NSS IPSec client (for example, to activate and deactivate options) 	Deny	EZB.NETMGMT.sysname.clientname.IPSEC.CONTROL
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NETMGMT.sysname.clientname.IPSEC.CONTROL
IPSec NMI and ipsec command access control for display requests (remote)	Controls whether a user can issue: <ul style="list-style-type: none"> NMI monitoring requests to the NSS server that pertain to an NSS client (that is, get requests) The ipsec command with the -z option to display options for an NSS IPSec client 	Deny	EZB.NETMGMT.sysname.clientname.IPSEC.DISPLAY
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NETMGMT.sysname.clientname.IPSEC.DISPLAY

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
IPv6 Advanced Socket API access control	Provides ability to control whether an application is permitted to set IPv6 advanced socket API options: IPv6_NEXTHOP IPv6_TCLASS IPv6_RTHDR IPv6_HOPOPTS IPv6_DSPOPTS IPv6_RTHDRDSTOPT IPv6_PKTINFO IPv6_HOPLIMIT	Deny, see result 2	EZB.SOCKOPT.sysname.tcpname.IPV6_NEXTHOP EZB.SOCKOPT.sysname.tcpname.IPV6_TCLASS EZB.SOCKOPT.sysname.tcpname.IPV6_RTHDR EZB.SOCKOPT.sysname.tcpname.IPV6_HOPOPTS EZB.SOCKOPT.sysname.tcpname.IPV6_DSPOPTS EZB.SOCKOPT.sysname.tcpname.IPV6_RTHDRDSTOPT EZB.SOCKOPT.sysname.tcpname.IPV6_PKTINFO EZB.SOCKOPT.sysname.tcpname.IPV6_HOPLIMIT
			TCPIP SOCKOPT ACCESS CHECK
Netstat command access control	Provides ability to restrict Netstat usage	Permit, see result 3	EZB.NETSTAT.sysname.tcpname.netstat_option
			TCPIP EZACDNET AUTH CHECK FOR EZB.NETSTAT.sysname.tcpname.netstat_option
Network security services (NSS) NMI and command access control	Controls whether a user can issue: • NMI requests to display connections to the NSS server • The ipsec command with the -x option to display NSS IPsec client connections to the NSS server • The nssctl command to display NSS client connections to the NSS server.	Deny	EZB.NETMGMT.sysname.sysname.NSS.DISPLAY
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NETMGMT.sysname.sysname.NSS.DISPLAY

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
NSS server access control	Controls whether an NSS IPsec client can register with the NSS server for the NSS IPsec certificate service	Deny	EZB.NSS.sysname.clientname.IPSEC.CERT
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSS.sysname.clientname.IPSEC.CERT
NSS server access control	Controls whether an NSS IPsec client can register with the NSS server for the NSS IPsec remote management service	Deny	EZB.NSS.sysname.clientname.IPSEC.NETM GMT
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSS.sysname.clientname.IPSEC.NETM GMT
NSS server access control	Controls whether an NSS XMLAppliance client can register with the NSS server for the XMLAppliance SAFAccess service.	Deny	EZB.NSS.sysname.clientname.XMLAPPLIANCE.SAFACCESS
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSS.sysname.clientname.XMLAPPLIANCE.SAFACCESS
NSS server access control	Controls whether an NSS XMLAppliance client can register with the NSS server for the XMLAppliance certificate service.	Deny	EZB.NSS.sysname.clientname.XMLAPPLIANCE.CERT
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSS.sysname.clientname.XMLAPPLIANCE.CERT
NSS server access control	Controls whether an NSS XMLAppliance client can register with the NSS server for the XMLAppliance private key service.	Deny	EZB.NSS.sysname.clientname.XMLAPPLIANCE.PRIVKEY
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSS.sysname.clientname.XMLAPPLIANCE.PRIVKEY
NSS server certificate access control	Controls whether an NSS client can access a CERTAUTH certificate on the key ring of the NSS server	Deny	EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
NSS server certificate access control	Controls whether an NSS client can access a PERSONAL or SITE certificate on the key ring of the NSS server	Deny	EZB.NSSCERT.sysname.mappedlabelname.HOST
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSSCERT.sysname.mappedlabelname.HOST
NSS server private key access control	Controls whether an NSS XMLAppliance client can access the private key for a certificate on the key ring of the NSS server	Deny	EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY
			TCPIP EZACDRAU AUTH CHECK FOR EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY
OSM access control	Controls ability to access the intranode management network using OSM interfaces	Deny	EZB.OSM.sysname.tcpname
			TCPIP OSM ACCESS CHECK
Partner information ioctl access control	Controls whether an application can use the SIOCGPARTNERINFO ioctl to obtain partner security credentials within a sysplex or subplex over a trusted TCP connection	Deny	EZB.IOCTL.sysname.tcpprocname.PARTNERINFO
			SIOCGPARTNERINFO
Policy Agent command control	Provides ability to restrict pasearch command, IKE daemon, policy clients, and nslapm2 usage by type	Deny	EZB.PAGENT.sysname.image.ptype
			TCPIP EZACDRAU AUTH CHECK FOR EZB.PAGENT.sysname.image.ptype
Real-time application-controlled TCP/IP trace NMI access control - Open request	Controls whether an application can invoke the NMI to open a trace; intended for network management applications	Deny	EZB.TRCCTL.sysname.tcpname.OPEN
			TCPIP NETWORK MANAGEMENT

Table 11. SERVAUTH resource names used by TCP/IP (continued)

Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
Real-time application-controlled TCP/IP trace NMI access control - Set filters	Controls whether an application can invoke the NMI to set filters for packet trace; intended for network management applications	Deny	EZB.TRCCTL.sysname.tcpname.PKTTRACE
			TCPIP NETWORK MANAGEMENT
Real-time application-controlled TCP/IP trace NMI access control - Set filters	Controls whether an application can request IPsec cleartext data on a packet trace filter	Deny	EZB.TRCSEC.sysname.tcpname.IPSEC
			TCPIP NETWORK MANAGEMENT
Real-time application-controlled TCP/IP trace NMI access control - Set filters	Controls whether an application can invoke the NMI to set filters for data trace; intended for network management applications	Deny	EZB.TRCCTL.sysname.tcpname.DATTRACE
			TCPIP NETWORK MANAGEMENT
Real-time application-controlled TCP/IP trace NMI access control - Set filters	Controls whether an application can request AT-TLS cleartext data on a data trace filter	Deny	EZB.TRCSEC.sysname.tcpname.ATTLS
			TCPIP NETWORK MANAGEMENT
Real-time OSAENTA information service access control	Provides ability to restrict access to select real-time OSAENTA packet trace records accessible using the OSAENTA information service; intended for network management applications	Deny, see result 4	EZB.NETMGMT.sysname.tcpname.SYSTCPO
			TCPIP NETWORK MANAGEMENT

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
Real-time SMF information service access control	Provides ability to restrict access to select real-time SMF records accessible using the SMF information service; intended for network management applications	Deny, see result 4	EZB.NETMGMT.sysname.tcpname.SYSTCP SM
			TCPIP NETWORK MANAGEMENT
Real-time TCP connection information service access control	Provides ability to restrict access to the TCP connection information using TCP connection information service; intended for network management applications	Deny, see result 4	EZB.NETMGMT.sysname.tcpname.SYSTCP CN
			TCPIP NETWORK MANAGEMENT
Real-time TCP/IP packet trace service access control	Provides ability to restrict access to select real-time packet trace records accessible using the TCP/IP packet trace service; intended for network management applications	Deny, see result 4	EZB.NETMGMT.sysname.tcpname.SYSTCP DA
			TCPIP NETWORK MANAGEMENT
Real-time zERT connection detail service access control	Provides ability to restrict access to z/OS Encryption Readiness Technology information using the zERT connection detail service; intended for network management applications	Deny, see result 4	EZB.NETMGMT.sysname.tcpname.SYSTCP ER
			TCPIP NETWORK MANAGEMENT

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
Real-time zERT summary service access control	Provides ability to restrict access to z/OS Encryption Readiness Technology information using the zERT summary service; intended for network management applications	Deny, see result 4	EZB.NETMGMT.sysname.tcpname.SYSTCPES
			TCPIP NETWORK MANAGEMENT
rpcbind access control	Provides ability to control whether an applications is permitted to register and unregister its port with rpcbind.	Deny	EZB.RPCBIND.sysname.rpcbindname.REGISTRY
			(none)
SNMP agent control	Provides control over usage of SNMP subagents that connect to the SNMP agent by using a TCP connection	Permit	EZB.SNMPAGENT.sysname.tcpname
			TCPIP EZACDRAU AUTH CHECK FOR EZB.SNMPAGENT.sysname.tcpname
TCP/IP local port access control	Controls user ability to bind to a non-ephemeral TCP or UDP port	Deny	EZB.PORTACCESS.sysname.tcpname.port_safname
			TCPIP PORT ACCESS CHECK PORT portnum
TCP/IP netaccess access control	Controls local user inbound and outbound access to network resources, and local user access to local IP address when explicitly binding to local interface (or using job-specific or destination-specific source IP addresses)	Deny	EZB.NETACCESS.sysname.tcpname.zonename
			TCPIP NETWORK ACCESS CHECK ipaddress
TCP/IP stack access control	Controls user ability to open a socket and get host name or host ID	Permit	EZB.STACKACCESS.sysname.tcpname
			TCPIP STACK ACCESS CHECK

Table 11. <i>SERVAUTH</i> resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
TCP/IP stack initialization access control	Controls ability of applications to open a socket before AT-TLS policy is loaded into the TCP/IP stack	Deny	EZB.INITSTACK.sysname.tcpname
			TCPIP INIT STACK ACCESS CHECK
TN3270E Telnet server access control	Controls ability to access TN3270E Telnet server based on SAF user ID associated with TLS-authenticated X.509 client certificate	Deny	EZB.TN3270.sysname.tn3270name.PORTxxxx
			TN3270 SAFCERT CHECK FOR USER userid PORT portnum ON tn3270name
VIPARANGE access control for any VIPA range (bind)	Controls whether an application can create a DVIPA by binding to a DVIPA that is specified by any VIPARANGE statement	Permit	EZB.BINDDVIPARANGE.sysname.tcpname
			TCPIP BINDDVIPA ACCESS CHECK
VIPARANGE access control for any VIPA range (MODDVIPA and ioctl)	Provides access control for all VIPARANGE statements, and controls whether a user or application can perform the following tasks: <ul style="list-style-type: none"> • Create a dynamic VIPA (DVIPA) that is specified by any VIPARANGE statement, using the SIOCSVIPA ioctl call, the SIOCSVIPA6 ioctl call, or the MODDVIPA utility • Delete a DVIPA that was created using this profile and the SIOCSVIPA ioctl call, the SIOCSVIPA6 ioctl call, or the MODDVIPA utility 	Deny, see result 5	EZB.MODDVIPA.sysname.tcpname
			TCPIP MODDVIPA or SIOCSVIPA(6) ACCESS CHECK

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
VIPARANGE access control for a specific VIPA range (bind)	Controls whether an application can create an application-specific DVIPA, by binding to a DVIPA that is specified by a VIPARANGE statement that includes the SAF parameter with the same value for <i>resname</i> .	Deny	EZB.BINDDVIPARANGE.sysname.tcpname.resname
			TCPIP BINDDVIPA SAF ACCESS CHECK
VIPARANGE access control for a specific VIPA range (MODDVIPA and ioctl)	Provides access control for a specific VIPARANGE statement that includes the SAF parameter with the same value for <i>resname</i> , and controls whether a user or application can perform the following tasks: <ul style="list-style-type: none"> • Create an application-specific DVIPA that is specified by a specific VIPARANGE statement, using the SIOCSVIPA ioctl call, the SIOCSVIPA6 ioctl call, or the MODDVIPA utility • Delete a DVIPA that was created using this profile and the SIOCSVIPA ioctl call, the SIOCSVIPA6 ioctl call, or the MODDVIPA utility 	Deny	EZB.MODDVIPA.sysname.tcpname.resname
			TCPIP MODDVIPA or SIOCSVIPA(6) SAF ACCESS CHECK

Table 11. SERVAUTH resource names used by TCP/IP (continued)			
Function	Description	No SAF decision	SERVAUTH resource name
			LOGSTR in any SAF logging (SMF type 80 records for RACF)
Results:			
1. Deny, unless the user ID is a WLM user or is a UNIX System Services superuser.			
2. Deny, unless the user ID is APF authorized or is a UNIX System Services superuser.			
3. Permit, except for the DROP option, when access is denied.			
4. Deny, unless the user ID is a UNIX System Services superuser or has READ access to BPX.SUPERUSER.			
5. Deny, unless the user ID is APF authorized and is a UNIX System Services superuser.			

Stack access control

You can create a SAF resource profile to control access to a TCP/IP stack. There are no new TCP definitions required. The resource profile controls whether users or groups of users have access to the TCP/IP stack by controlling their ability to open an AF_INET or AF_INET6 socket and to obtain the host ID or host name. Create the EZB.STACKACCESS.*sysname.tcpname* resource profile in the SERVAUTH class for the TCP/IP stack to be protected. After you define this resource profile, permit users to the profile and grant them READ access to the resource. If a user does not have READ access to the resource for a stack, the user cannot access the stack. If you do not define a resource profile for a stack, all users have access to that stack.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the stack access resource profile and permit users to it whenever the SERVAUTH class is active.

Figure 30 on page 159 provides an overview of stack access control. *sysname* refers to the MVS system variable *sysname*. *tcpname* refers to the TCP/IP job name. User Tom has permission to access both Stack1 and Stack2, Joe does not have permission to access any stack, and Bob has permission to access Stack2 but not Stack1.

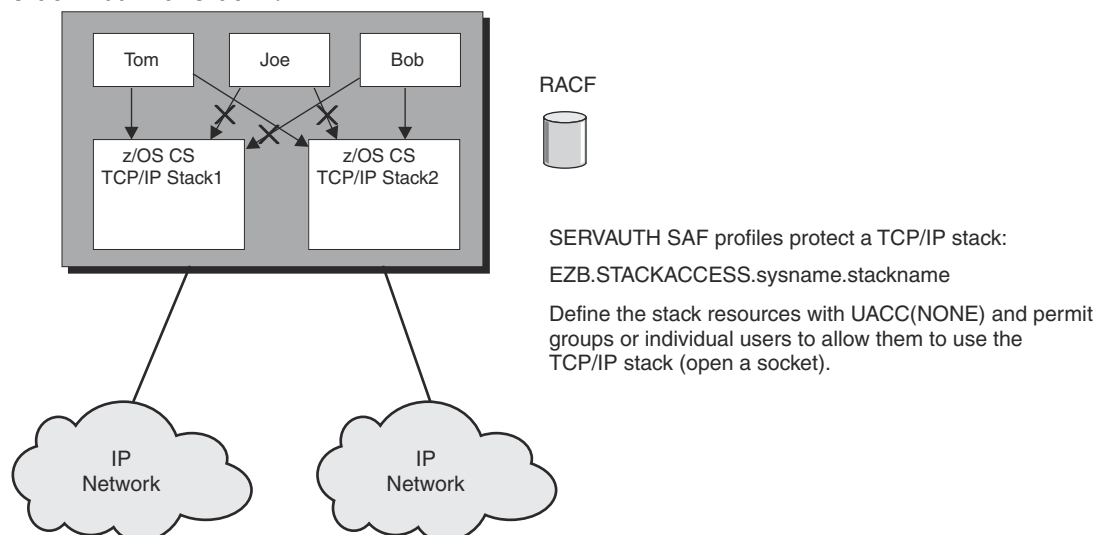

Figure 30. Stack access control overview

Port access control

You can use port access control to protect against unauthorized use of ports. You can control an application's ability to explicitly bind to, or listen on, specific TCP and UDP ports or port ranges by either reserving particular ports or by controlling access to unreserved ports.

Controlling access to particular ports

You can control access to particular ports by port number, by reserving the port using the PORT or PORTRANGE profile statements. Use the PORT and PORTRANGE statements to reserve well-known or configured ports for the applications that need to bind to them. You can use the optional SAF parameter to provide additional access control.

You can reserve an individual port or range of ports with a job name, a wildcard job name (*), a partial wildcard job name (1 - 8 characters with one or more wildcard characters), or the special job name of RESERVED. The asterisk wildcard character can be used to indicate zero or more unspecified characters. The question mark wildcard character can be used to indicate a single unspecified character. If you specify a job name, the port is reserved for an application that has the specified job name. If you specify a partial wildcard job name, the port is reserved for any application that matches the partial wildcard job name. If you specify a wildcard job name, the port is reserved for any application with any job name. The RESERVED job name shuts down the use of a port or range of ports for any application.

If you specify the SAF keyword on the PORT or PORTRANGE statement, it can provide additional access control by verifying that the user ID associated with an application at the time of a bind to the port is authorized to access the port. The SAF keyword value specifies a portion of the resource name that represents the port. Define the EZB.PORTACCESS.sysname.stackname.port_safname resource profile in the SERVAUTH class to control access to the port, where *port_safname* is the same value that you specify on the SAF keyword of the PORT or PORTRANGE statement. The user ID that is associated with the application at the time of the bind request must have READ access to this resource for the application to be able to bind to the port.

Figure 31 on page 160 provides an overview of port access control. In this example, z/OS user WEBSERV (web server) is permitted to bind to port 80. User Bob is not permitted to bind to port 80.

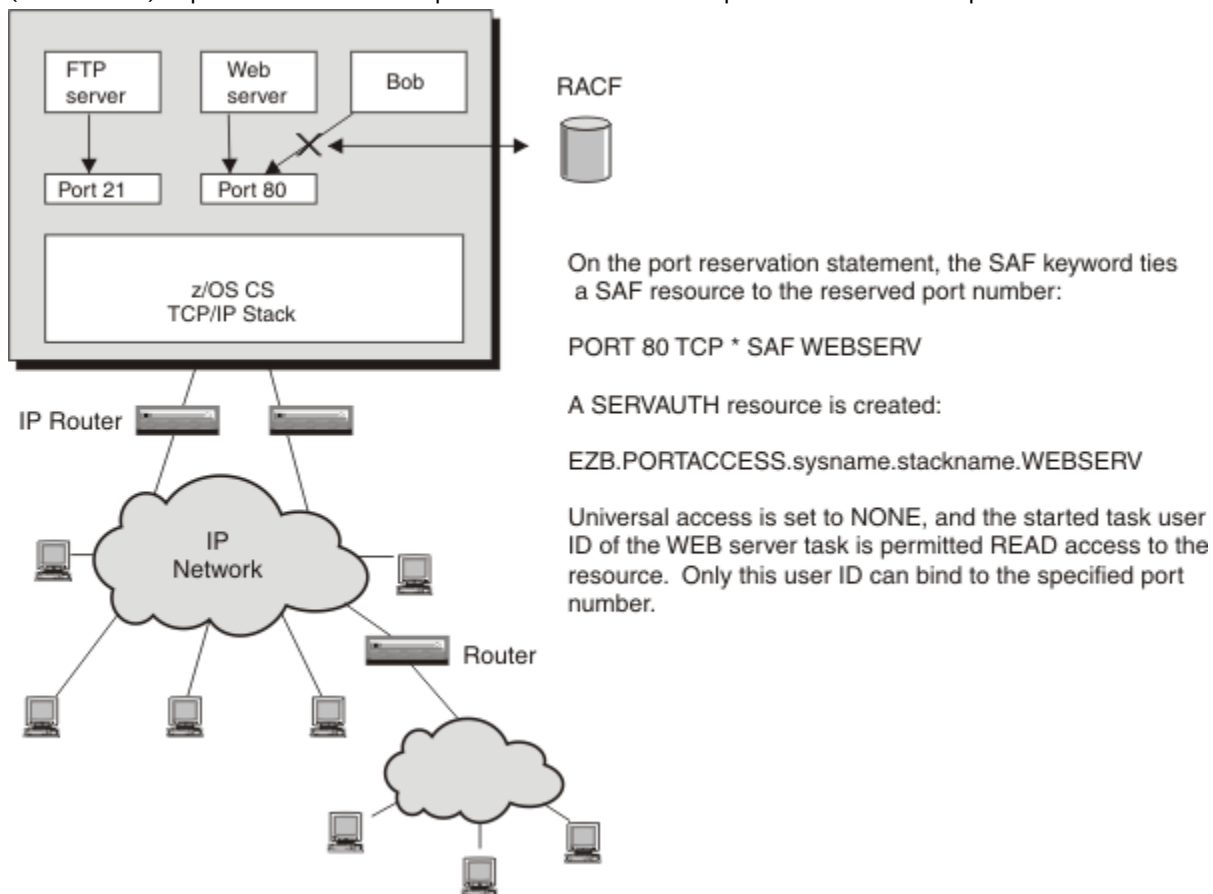

Figure 31. Port access control overview

Controlling access to unreserved ports

You can control which applications are allowed to access ports that have not been reserved by a PORT or PORTRANGE statement. You can use the PORT statement with the UNRSV keyword, or the RESTRICTLOWPORTS parameter on the UDPCONFIG or TCPCONFIG statements.

Using the PORT statement to control access to all unreserved ports

In addition to reserving particular ports, you can also use the PORT statement to control application access to user-specified ports that have not been reserved. Access control is applied when an application issues an explicit bind or a TCP listen.

You can use job names or SAF resources, or a combination of both, to control access to user-specified unreserved ports, or you can unconditionally deny access to user-specified unreserved ports. You do this by configuring one or more PORT statements in which the port number is replaced by the keyword UNRSV.

Result: PORT UNRSV statements control access to nonzero, unreserved ports specified on explicit binds. Access to unreserved ports that are assigned by the stack is not affected.

If you want to use PORT UNRSV access control, see the following considerations:

- Using the parameters on the PORT UNRSV statement

To use only job names to control unreserved port access, configure one or more PORT UNRSV statements using the JOBNAME keyword with specific job names or partial wildcard job names (1 - 8 characters with one or more wildcard characters). If you specify the wildcard job name (*), the PORT UNRSV statement applies to all job names. If an application's job name matches more than one PORT UNRSV statement, the statement with the closest matching specified job name is used to control access to unreserved ports.

To use a SAF resource instead of job names to control unreserved port access, configure a PORT UNRSV statement specifying the wildcard job name (*) and the SAF keyword and resource name. Because you can have only one PORT UNRSV statement with the wildcard job name per protocol, this method allows the use of only one SAF resource per protocol.

To use a combination of job names and a SAF resource to control access, specify the SAF keyword and resource name on one or more PORT UNRSV statements with different job names. You can specify a different SAF resource on each of these PORT UNRSV statements.

If you do not configure any PORT UNRSV statements for a protocol, all applications are allowed to use unreserved ports. This is the default behavior. To change this behavior and unconditionally deny access to user-specified unreserved ports, configure a PORT UNRSV statement, specifying the wildcard job name (*) and the keyword DENY.

For the UDP protocol, access is always controlled when an explicit bind is issued (WHENBIND). For UDP applications, there is no distinction between client or server roles because there is no explicit socket API that indicates that the application is a UDP server. All UDP applications that bind their socket to a specific local unreserved port do need to pass any configured UDP port access control checks.

For the TCP protocol, you can control access to user-specified unreserved ports when the explicit bind is issued (WHENBIND) or when a listen is issued on that port (WHENLISTEN). WHENLISTEN access control is targeted to TCP applications acting as servers (that is, applications able to accept incoming client TCP connections) and is the default for TCP. If the default is used or WHENLISTEN is specified, and no listen is issued for the unreserved port, no access control check is made. WHENBIND access control can affect TCP client applications that bind to a specific local port for outbound TCP connections. Every PORT UNRSV statement for the TCP protocol must specify the same access control. You cannot specify WHENLISTEN on some statements and WHENBIND on other statements. If you do, the conflicting configuration statement will fail.

- Implementing PORT UNRSV access control in stages

Using PORT UNRSV access control can have unexpected consequences. Consider implementing this function in the following stages:

1. Determine the necessary port reservations statements for your applications.

For example, you might begin with 'PORT UNRSV TCP * SAF xyz WHENBIND', where the SERVAUTH profile has UACC(READ) and auditing of successes is enabled. This would give you an indication of how many applications currently bind to unreserved ports. Verify the applications reported, and if deemed valid, reserve their ports using the PORT or PORTRANGE statements.

2. Enable access control enforcement by specifying DENY or a SAF resource with UACC(NONE) and monitor failures.

As failures are identified, configure appropriate PORT reservation statements to allow authorized application access to those ports.

- Enforcing PORT UNRSV access control

If you configure one or more PORT UNRSV statements for a protocol, access is unconditionally denied to any application that explicitly binds to an unreserved port and does not match the protocol and job name on any of the configured PORT UNRSV statements. Applications that explicitly bind to an unreserved port and that do match the protocol and job name on a PORT UNRSV statement are allowed to access the unreserved port, unless the access is restricted by the SAF or DENY keywords. If the SAF keyword is specified, the user ID associated with the application that attempts to access the port must be permitted to the specified SAF resource. If the DENY keyword is specified, access is unconditionally denied.

Rules: If you configure PORT UNRSV statements for UDP or for TCP with the WHENBIND option, the following rules apply:

- Every application using that protocol that explicitly binds to a user-specified local unreserved port is subject to an authorization check. If the application does not have authority to access an unreserved port, the bind will fail.
- For TCP, every client connection that first performs an explicit bind and explicitly specifies a local unreserved port is subject to an authorization check for access to unreserved ports.
- Because client programs might run under many different user IDs, all address spaces in which the client program can run must be authorized (by job name, SAF resource, or both) to access an unreserved port.

Alternatively, you can use the WHEN(PROGRAM) type of RDEFINE statements to authorize specific programs to a particular port, regardless of the address space in which they run. However, in this case these programs must be program-controlled resources.

If you do not configure a PORT UNRSV statement for a protocol, then access to unreserved ports using that protocol is not controlled. If you do configure PORT UNRSV statements for a protocol, access is determined by the PORT UNRSV statement with the job name that most closely matches the application's job name; if the application's job name does not match any of the PORT UNRSV statements, then access to unreserved ports is denied for that protocol.

Using the RESTRICTLOWPORTS parameter to control access to unreserved ports below port 1024

When the RESTRICTLOWPORTS parameter is specified on the UDPCONFIG or TCPCONFIG profile statements, an application cannot obtain a port in the range 1 - 1023 that has not been reserved by a PORT or PORTRANGE statement, unless the application is APF-authorized or has OMVS superuser [UID(0)] authority. z/OS Communications Server client applications that need to bind to a low port are provided as APF-authorized.

Tip: When you configure the RESTRICTLOWPORTS parameter on the TCPCONFIG or UDPCONFIG profile statements, PORT UNRSV statements for the corresponding protocol control access only to unreserved ports above port 1023.

Network access control

Network access control gives system administrators the ability to assign permission for z/OS users to access certain networks and hosts. With this function, the ability of users to send or receive data between z/OS and certain networks can be controlled through z/OS. Network access control provides an additional

layer of security to any authentication and authorization security that is used in the network or at the peer system by disallowing the unauthorized user to communicate with the peer network resource.

Essential elements of this function are as follows:

- The IP network is considered the resource to be protected.
- Use of the IBM zEnterprise® System (zEnterprise) intranode management network is protected by OSM access control and is exempt from network access control. For more information, see [“OSM access control” on page 165](#).
- IP addresses are classified into *security zones*, in which each zone has a certain level of security sensitivity. A default security zone exists for interfaces that are not explicitly associated with a specific security zone. Security zones consist of one or more, perhaps discontinuous, IP address ranges that have the same security sensitivity and are identified by a specific zone name.
- SAF is used to check whether users or groups of users have READ access to a security zone.
- You define a SAF resource profile for each security zone and provide READ access to these resources to the users or groups of users that you want to have access to particular security zones. A security zone is represented by the EZB.NETACCESS.sysname.tcpname.zonename resource name in the SERVAUTH class.
- TCP/IP keeps a mapping of network resources by IP address to security zones. This mapping is consulted on certain inbound and outbound operations to determine the corresponding resource zone name for the most specific network defined. Then the current user's access to that resource is queried using SAF, and the operation is allowed or denied completion accordingly. This mapping is also consulted when the security ioctl is issued to extract the port of entry zone name of a socket's current peer.
- Network access control is used to control z/OS user access to a peer address in an IP network through a sockets application. Resource access checks occur at connection setup or acceptance time for TCP, peer identification time for UDP and RAW, and on the first and potentially subsequent sends or receives (TCP, UDP, or RAW) to a particular destination in a socket's lifetime.
- Network access control is used to control z/OS user access to local addresses when a socket is bound to a local address. Resource access checks occur when an application explicitly binds a socket to a local address, including the IPv4 address INADDR_ANY (0.0.0.0/32) or the IPv6 unspecified address, in6addr_any (::/128). Job-specific or destination-specific source IP addresses (designated by the SRCIP profile statement) are handled as if the application did an explicit bind to the configured address.
- Network access control security checks are made at the transport layer (TCP, UDP, and RAW). Other IP-specific packets generated by the stack are not covered under this function (such as ICMP echo replies, for example). Additionally, there is no user concept when dealing with packets that are being forwarded through the stack, and hence no checks are made.
- Network access control for outbound and inbound can be individually enabled or disabled.
- TCP/IP caches security information following network access control checks. Access is automatically rechecked on the next use of the cache whenever the RACF commands SETROPTS RACLIST, SETROPTS RACLIST REFRESH, or SETROPTS NORACLIST are issued for the SERVAUTH class. If you are using a security product other than RACF, the NetAccess zone table in the TCP/IP profile must be rebuilt to cause TCP/IP to recognize changes to the SERVAUTH class profiles for existing sockets.

You can control the level of caching that is performed by using the CACHEALL, CACHEPERMIT, or CACHESAME parameter on the NETACCESS configuration statement in the TCP/IP profile. These parameters determine which network access control checks are resolved using the cache, without making a new call to SAF, and thus determine which checks can be audited by the security server product. For more information about these parameters and the [NETACCESS statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

- The socket calls bind, connect, and those that send data will fail with errno EACCES if the specified IP address is not permitted to be used by the application user. Inbound UDP and RAW datagrams that are not permitted under the current network access control policy are normally filtered out before they get to socket calls that receive data. It is possible for a datagram to arrive under a network access control policy that would allow it to be read, but then be received after a policy change that does not allow it. If

the application (or common INET) has issued a select or poll on the socket, the receive call returns an EACCES errno to avoid blocking the application. Inbound TCP connections that are not permitted under the current network access control policy are also normally reset and discarded before they get to the socket backlog. In those cases where the only available new connections are not allowed and a select has been issued, accept processing returns a new socket and the next attempt to send or receive data returns an ECONNRESET error.

- NetAccess inbound filtering needs to predict whether a future receive or accept will succeed. When there are multiple processes or threads operating on the same socket, to achieve consistent results you must ensure that certain calls are done under the same identity, or identities with equivalent network access control policies. For UDP and RAW sockets, the select, receive, and send calls must be done under equivalent policies. For TCP listening sockets, the select and accept calls must be done under equivalent policies.
- TCP/IP keeps a mapping of network resources by IP address to security zones. This mapping is consulted on certain inbound and outbound operations to determine the corresponding resource zone name for the most specific network defined. Then the current user's access to that resource is queried using SAF, and the operation is allowed or denied completion accordingly. This mapping is also consulted when SIOCGSOCKPOEATTRS ioctl is issued to extract the port of entry zone name of a socket's current peer.

Figure 32 on page 164 provides an overview of network access control. z/OS user Bob is permitted access to Security Zone A but not Security Zone B. An outbound connect from Bob is permitted to Security Zone A, but not Security Zone B. Bob is permitted to accept connections from Security Zone A but not Security Zone B.

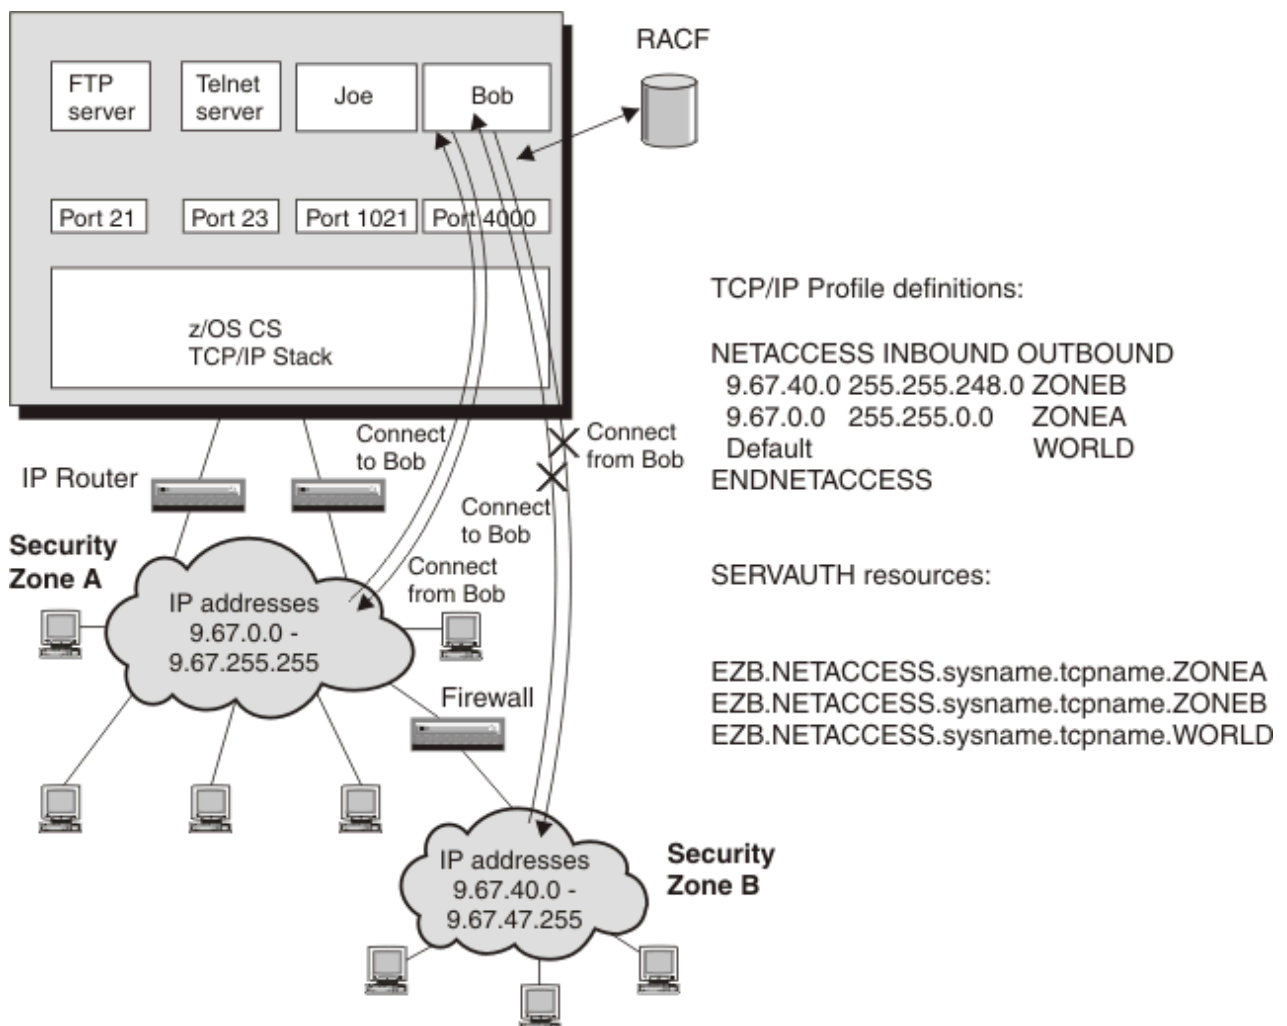

Figure 32. Network access control example

OSM access control

The intranode management network is intended for only authorized applications, such as those performing platform performance management functions. For more information about these applications, see *IBM z Systems® Ensemble Planning Guide*.

The intranode management network can be accessed only through OSM interfaces. To use IOCTL calls to retrieve information about an OSM interface or to send or receive data over OSM interfaces on this network, an application must have READ authorization to the EZB.OSM.sysname.tcpname resource. If you start one of these authorized applications on a z/OS image, authorize the application user ID to this SAF resource. In addition, authorize to this resource any user IDs that might issue diagnostic commands, such as Ping and Traceroute, over OSM interfaces to verify connectivity. Traffic over OSM interfaces is exempt from network access control.

For more information about the intranode management network, see [Chapter 9, “TCP/IP in an ensemble,” on page 521](#).

Socket option access control

Socket option access control gives system administrators the ability to assign permission for z/OS users to set selected socket options using a SAF-compliant security server. Access control is provided for the SOL_SOCKET level, SO_BROADCAST option, and the IPv6 advanced socket API options.

SO_BROADCAST socket option

IPv4 IP addresses are divided into a network portion, an optional subnetwork portion, and a host portion. Normally, UDP and RAW datagrams are delivered to the single peer system identified by the destination IP address. However, when the destination address is a subnetwork or network base address (host portion is all zeros), or a subnetwork or network broadcast address (host portion is all ones), the datagram is delivered to every peer system in that subnetwork or network. Socket semantics require that an application set the SO_BROADCAST option on before attempting to send a datagram to a base or broadcast address. This protects the application from accidentally sending a datagram to many systems. Network access control does not check to see if there are other security zones defined within the scope of a destination subnetwork or network address or whether the user is permitted to send a datagram to all of these security zones.

Control over setting this socket option allows the system administrator to restrict use of subnetwork or network addresses to those users or programs that require them. This support is enforced at the PFS layer and applies to all z/OS Communications Server socket APIs.

TCP/IP programs known to set the SO_BROADCAST socket option include:

- OMROUTE
- sntpd, when invoked with the -b option

Additionally, any programs that use the clnt_broadcast() service in the SUN RPC libraries, or the send_pkt(sock, pkt, addr, broadcast) service in the NCS RPC library with the broadcast parameter set, require permission to the SO_BROADCAST socket option. The following TCP/IP programs use RPC services that require permission to broadcast:

- rpcinfo, when invoked with the -b option
- orpcinfo, when invoked with the -b option

The socket option to be protected is represented by the resource name EZB.SOCKOPT.sysname.tcpname.SO_BROADCAST. When this profile is defined, users of any program setting this option require READ permission. Access to the option is also allowed if the security server indicates there is no profile covering this resource. Conditional access lists, such as PERMIT WHEN(PROGRAM(...)), are supported for profiles covering socket option access control resources. There are no new TCP definitions required.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the socket option resource profile and permit users to it whenever the SERVAUTH class is active.

The following example shows the definitions:

```
RDEFINE SERVAUTH EZB.SOCKOPT.*.*.SO_BROADCAST UACC(NONE)
PERMIT EZB.SOCKOPT.*.*.SO_BROADCAST CLASS(SERVAUTH) ACCESS(READ) ID(OMPROUT)
PERMIT EZB.SOCKOPT.*.*.SO_BROADCAST CLASS(SERVAUTH) ACCESS(READ) ID(*)
WHEN(PROGRAM(ORPCINFO))
```

The program name listed in the conditional access list must be the name the program is invoked by. Most TCP/IP applications are invoked by an alias name rather than the module name. [Table 12 on page 166](#) lists TCP/IP applications that send broadcast datagrams:

Table 12. TCP/IP application load module and alias names	
Load module	Alias
EZAORRTE	OMPROUTE
EZASNTPD	SNTPD
EZARPCIN	RPCINFO
EZARORNP	ORPCINFO

Tip: In the UNIX System Services environment, both /bin/rpcinfo and /bin/orpcinfo are externally linked to ORPCINFO. Either command executes the EZARORNP program.

To use program names in conditional access lists, the program must be loaded into a controlled environment from a program controlled data set. TCP/IP applications are distributed in the SEZALOAD load library. To program control this data set, you must add it to the ** profile in the PROGRAM class as follows:

```
RALTER PROGRAM ** ADDMEMBER('TCPIP.SEZALOAD'//NOPADCHK)
```

For more information on program control, see [z/OS Security Server RACF Security Administrator's Guide](#).

IPv6 advanced socket API options

You can control access for the IPv6 advanced socket API options that influence outbound packets.

For the IPV6_NEXTHOP, IPV6_TCLASS, IPV6_RTHDR, IPV6_HOPOPTS, IPV6_DSTOPTS, IPV6_RTHDRDSTOPTS, and IPV6_PKTINFO socket options, to set the socket option on setsockopt() or to use the corresponding ancillary data item on sendmsg(), an application must meet one of the following criteria:

- Be APF authorized.
- Have superuser authority.
- The corresponding SERVAUTH resource name in [Table 13 on page 166](#) is defined, and the application has at least READ access to the resource.

Table 13. Socket option resource names	
Socket option/Ancillary data item	Resource name
IPV6_NEXTHOP	EZB.SOCKOPT.sysname.tcpname.IPV6_NEXTHOP
IPV6_TCLASS	EZB.SOCKOPT.sysname.tcpname.IPV6_TCLASS
IPV6_RTHDR	EZB.SOCKOPT.sysname.tcpname.IPV6_RTHDR
IPV6_HOPOPTS	EZB.SOCKOPT.sysname.tcpname.IPV6_HOPOPTS

Table 13. Socket option resource names (continued)	
Socket option/Ancillary data item	Resource name
IPV6_DSTOPTS	EZB.SOCKOPT.sysname.tcpname.IPV6_DSTOPTS
IPV6_RTHDRDSTOPTS	EZB.SOCKOPT.sysname.tcpname.IPV6_RTHDRDSTOPTS
IPV6_PKTINFO	EZB.SOCKOPT.sysname.tcpname.IPV6_PKTINFO
IPV6_HOPLIMIT	EZB.SOCKOPT.sysname.tcpname.IPV6_HOPLIMIT

For the IPV6_HOPLIMIT socket option, to set a hop limit greater than the default using either the IPV6_UNICAST_HOPS or IPV6_MULTICAST_HOPS socket option on setsockopt() or the IPV6_HOPLIMIT ancillary data item on sendmsg(), an application must meet one of the following criteria:

- Be APF authorized.
- Have superuser authority.
- EZB.SOCKOPT.sysname.tcpname.IPV6_HOPLIMIT is defined, and the application has at least READ access to this resource.

TCP/IP applications that set IPv6 advanced socket API options

Table 14 on page 167 lists the TCP/IP applications that set IPv6 advanced socket API options. In a multilevel secure environment, APF and superuser authority are not sufficient; the security product resource name for the socket options appearing in Table 14 on page 167 must be defined for every stack. Usage must be explicitly permitted by user ID, or conditional access lists, such as PERMIT WHEN(PROGRAM(...)) must be defined for the load module and alias names listed in the table. For more information about applications in a multilevel secure environment, see [“Required configuration in a multilevel secure environment”](#) on page 217.

Table 14. TCP/IP applications that set IPv6 advanced socket API options		
Load module	Alias	Socket options set
EZACDOPN	z/OS UNIX ping	IPV6_PKTINFO, IPV6_DONTFRAG
EZACDTPN	TSO PING	IPV6_PKTINFO, IPV6_DONTFRAG
EZACDTRT	z/OS UNIX traceroute	IPV6_HOPLIMIT, IPV6_PKTINFO
EZACDTTR	TSO TRACERTE	IPV6_HOPLIMIT, IPV6_PKTINFO
EZADNSVR	NAMED	IPV6_PKTINFO
EZAORRTE	OMPROUTE	IPV6_HOPLIMIT, IPV6_PKTINFO
EZASNTPD	SNTPD	IPV6_PKTINFO

For more details on these IPv6 advanced socket API options, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

For examples of the security product definitions, see the EZARACF sample in data set SEZAINST.

Netstat access control

You can control access to Netstat command output from the TSO or UNIX System Services shell environments using the System Authorization Facility (SAF). There are no new TCP definitions required. The Netstat command output is considered the resource to be protected, and you protect it by defining EZB.NETSTAT.sysname.tcpname.netstat_option resource profiles in the SERVAUTH class. A user ID has access to the Netstat output for a particular option if a security profile is defined in the SERVAUTH class

for that option, and that user ID has READ access to the associated resource. Access is also given if there is no resource profile defined for a resource.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the Netstat resource profiles and permit users to them whenever the SERVAUTH class is active.

An installation can implement a security policy that indicates which users have authorization to selected Netstat options. The level of granularity for this security policy can be either by individual or all Netstat options.

Even though the Netstat RESCache/-q command returns system-wide resolver cache data, at least one TCP/IP stack must be active to ensure that the correct Netstat access controls are enforced for the command. The same EZB.NETSTAT.sysname.tcpname.netstat_option naming convention applies to this Netstat command as it does for any other Netstat command.

Fast Response Cache Accelerator access control

Fast Response Cache Accelerator access control allows control of application access to Fast Response Cache Accelerator (FRCA) services. For more information on FRCA, see [“Considerations for Fast Response Cache Accelerator”](#) on page 57.

You can control application access to FRCA services by defining the EZB.FRCAACCESS.sysname.tcpname resource profile in the SERVAUTH class. Access to FRCA services is allowed if the web server user has READ access to this resource, or if the resource profile is not defined. There are no new TCP definitions required. This function is enabled if the SERVAUTH class is active and the FRCA resource profile is defined. If this resource profile is not defined, the check is not made.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. If your product does not make this distinction, you must define the FRCA resource profile and permit users to it whenever the SERVAUTH class is active.

TCP/IP stack initialization access control

You can control whether an application can access a TCP/IP stack before the required policies have been installed, during the period of time after the stack is active but before Application Transparent Transport Layer Security (AT-TLS) has been initiated from policy. Access checking is performed only if you have configured AT-TLS in the initial PROFILE.TCPIP configuration data set. If AT-TLS is configured, you can control whether an application can access the TCP/IP stack before the required policies have been installed by defining the EZB.INITSTACK.sysname.tcpname resource profile in the SERVAUTH class. During the period of time after the stack is active and before AT-TLS has been initiated from policy, all socket requests are blocked if this resource profile is not defined. If this resource profile is defined, access to the stack is permitted only to user IDs that have READ access to the resource. Checking ceases the first time that the Policy Agent processing of the AT-TLS policy is completed, or when a profile change deactivates AT-TLS.

Guideline: Some security products do not distinguish between a resource profile that is not defined and a user that is not permitted to that resource profile. However, if AT-TLS is enabled, a profile that is not defined has the same result as a user that is not permitted, regardless of the security product you are using. If AT-TLS is enabled, you must activate the SERVAUTH class, and define the INITSTACK resource profile and permit users to it.

TCP/IP packet trace service access control

The TCP/IP packet trace service provides an interface for network management applications to obtain packet trace data. The information provided through the service is considered the resource to be protected. Access to this information can be controlled through an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.sysname.tcpname.SYSTCPDA.

Access to the information is allowed if the user ID associated with the network management application is permitted (read access) to this resource profile. In addition, to use this service, it should be enabled

on the stack using the NETMONITOR PKTTRCService statement in PROFILE.TCPIP. For details, see [z/OS Communications Server: IP Configuration Reference](#).

If the resource profile is not defined, the service allows access to the packet trace information only to superusers, or those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

TCP connection information service access control

The TCP connection information service allows network management applications to obtain information about TCP connection activity. Access to this information can be controlled by an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.sysname.tcpname.SYSTCPCN.

Access to the TCP connection information is allowed if the user ID associated with the network management application is permitted (read access) to this resource profile. In addition, to use this service, it should be enabled on the stack using the NETMONITOR TCPCONNService statement in PROFILE.TCPIP. For details, see [z/OS Communications Server: IP Configuration Reference](#).

If the resource profile is not defined, the service allows access to the TCP connection information only to superusers, or those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

zERT information service access control

The z/OS encryption readiness technology (zERT) information service allows network management applications to obtain information about the cryptographic protection state of TCP and Enterprise Extender connections. Access to this information can be controlled by an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.sysname.tcpname.SYSTCPCN.

Access to the zERT information is allowed if the user ID associated with the network management application is permitted (read access) to this resource profile. In addition, to use this service, the ZERTService, ZERTServiceByPolicy, or both parameters must be specified on the NETMONITOR statement in the TCP/IP profile data set. For details, see [z/OS Communications Server: IP Configuration Reference](#).

If the resource profile is not defined, the service allows access to the zERT information only to superusers, or those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

Real-time SMF information service access control

The SMF information service allows network management applications to obtain selected TCP/IP SMF records, such as SMF records supported by FTP and Telnet, in a real-time fashion. Access to this information can be controlled through an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.sysname.tcpname.SYSTCPSM.

Access to these SMF records is allowed if the user ID associated with the network management application is permitted (read access) to this resource profile. In addition, to use this service, it should be enabled on the stack using the NETMONITOR SMFService statement in PROFILE.TCPIP. For details, see [z/OS Communications Server: IP Configuration Reference](#).

If the resource profile is not defined, the service allows access to the SMF data only to superusers, or those permitted to become superusers (that is, those with read access to BPX.SUPERUSER).

TCP/IP OSAENTA trace service access control

The TCP/IP OSAENTA trace service is an interface that enables network management applications to obtain packet trace data. You should protect the information that is provided by this service. You can control access to this information through an external security manager product, such as RACF, by defining the SERVAUTH profile name EZB.NETMGMT.sysname.tcpname.SYSTCPCN.

Access to this information is allowed if the user ID associated with the network management application is permitted to (has read access to) to this resource profile. To use this service, ensure that it has been enabled on the stack using the `NTATRCService` parameter on the `NETMONITOR` statement in `PROFILE.TCPIP`. For details about the [NETMONITOR statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

If you do not define this resource profile, the service allows access to the packet trace information only to a superuser, or to those permitted to become a superuser (those with read access to `BPX.SUPERUSER`).

IPSec network management interface access control

The IPSec network management interface (NMI) enables network management applications to obtain detailed information for and exercise control over IP filtering and IPSec security associations. Access to this interface can be controlled through an external security manager product, such as RACF, by defining the `SERVAUTH` profile names `EZB.NETMGMT.sysname.tcpname.IPSEC.DISPLAY` and `EZB.NETMGMT.sysname.tcpname.IPSEC.CONTROL` for display requests and control requests respectively.

Applications can access this interface if the user ID associated with the network management application is permitted (has read access) to the appropriate resource profile.

If the resource profile is not defined, the service allows access to the IPSec NMI only to superusers, or to those permitted to become superusers (that is, those with read access to `BPX.SUPERUSER`).

For more information about the [IPSec NMI](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Real-time application-controlled TCP/IP trace NMI access control

The real-time application-controlled TCP/IP trace NMI provides real-time trace and event information to network management applications. For applications to use some of the functions of this NMI, you must define the following resource profiles and give the application user ID read access to the associated resources. If profiles that protect these resources are not defined, no applications are authorized to use the associated resources.

- If you want to permit network management applications to open a trace instance, define a profile for the following resource:

```
EZB.TRCCTL.sysname.tcpname.OPEN
```

- If you want to permit network management applications to set packet trace filters and options, define a profile for the following resource:

```
EZB.TRCCTL.sysname.tcpname.PKTTRACE
```

- If you want to permit network management applications to obtain packet trace IPSec cleartext data, define a profile for the following resource:

```
EZB.TRCSEC.sysname.tcpname.IPSEC
```

- If you want to permit network management applications to set data trace filters and options, define a profile for the following resource:

```
EZB.TRCCTL.sysname.tcpname.DATTRACE
```

- If you want to permit network management applications to obtain data trace AT-TLS cleartext data, define a profile for the following resource:

```
EZB.TRCSEC.sysname.tcpname.ATTLS
```

For more information about the [Real-time application-controlled TCP/IP trace NMI](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Syslogd isolation

Syslogd isolation provides a capability for the installation to control which user IDs and job names can write syslogd records to specified syslogd facilities. This function enables the installation to separate system and application syslogd records, and to separate syslogd records from different applications. This function prevents an application level process from flooding a syslogd facility intended for system use, possibly causing system syslogd records to be lost. This function is enabled when user ID and/or job name are specified as additional criteria along with existing facility and priority criteria to select a syslogd repository.

In addition, the user ID and job name associated with the syslogd record writer can optionally be stored in a syslogd record based on a syslogd command-line parameter. This capability is useful when syslogd records for multiple jobs or users are recording in the same syslogd facility. This function enables positive identification of the creator of the syslogd records and ensures that the syslogd record, if spoofed, can be identified.

Syslogd isolation also provides a capability to disable reception of syslogd messages from other hosts in the network. This capability is provided by a syslogd command-line parameter. This parameter disables reception of syslogd messages from all hosts. If an installation wants to allow certain hosts in the network access to syslogd, IP Filtering can be used instead to specify which hosts are permitted to access the syslogd TCP and UDP ports.

IP filtering

The IP security function can configure the Communications Server to perform packet filtering at the IP layer for IPv4 and IPv6.

IP filters are rules defined to either discard or permit packets. IP filtering matches a filter rule to data traffic based on any combination of IP source or destination address (or masked address), protocol, source or destination port, direction of flow, or time. IP filtering can control traffic being routed, or control access at the host that has the communication endpoint. Even when an external firewall is providing filtering protection for the host, Communications Server IP filtering can provide a secondary line of defense.

Figure 33. IP filtering at the z/OS communication endpoint

For more information about IP filtering, see [Chapter 17, “IP security,”](#) on page 911.

Security considerations for the VARY command

You can restrict access to the VARY TCPIP command by defining RACF profiles under the OPERCMDS class and specifying the list of users that are authorized to issue the VARY TCPIP command. You can decide on the level of control that is appropriate for your installation. For example, you might want to allow a user to be able to start or stop a TCP/IP device using the VARY TCPIP command, but you do not want the user to be able to modify the TCP/IP configuration. For further information on restricting access to the VARY TCPIP command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Multilevel security

Multilevel security is an enhanced security environment that can be configured on a z/OS system. In this environment, the security server and trusted resource managers enforce mandatory access control policies in addition to the usual discretionary access control policies. To participate in a multilevel-secure environment, the user IDs associated with tasks trying to access z/OS CS resources and those resource profiles in the SERVAUTH class need to have security labels defined. For more information on the multilevel-secure environment and configuring z/OS CS in that environment, see [Chapter 4, “Preparing for IP networking in a multilevel secure environment,”](#) on page 213.

Configuration data set security

The z/OS Communications Server configuration data sets can be encrypted by using z/OS data set encryption. You can specify key labels to identify encryption keys that are in the Cryptographic Key Data Set (CKDS). When an encrypted data set is created, the key label is stored as an attribute of the data set in the catalog. Authorization to view the contents of a data set is based on access to the key label that is associated with the data set. The encryption key that is associated with that key label is used by DFSMS to encrypt and decrypt the data as it is written or read. See *IBM Redbook: Getting Started with z/OS Data Set Encryption* for more information.

Note: You should consider very carefully when enabling data set encryption for resolver data sets accessed by applications issuing resolver calls and FTP client data sets accessed by z/OS FTP clients. In many cases, most users may require access to these data sets due to the wide use of the functions. In order to allow any applications that issue resolver calls and z/OS FTP clients to access these configuration data sets with data set encryption enabled, it is necessary to give UACC(READ) to the key label associated with the resolver and FTP client data sets. See details in the following table.

Table 15. Configuration data sets	
Configuration data set names	Description
ETC.IPNODES	One of the local host data sets used for IPv6 name query, or IPv4 and IPv6 name query when COMMONSEARCH is specified in the resolver setup file. See “Resolver configuration files” on page 796 for more information.
ETC.PROTO	Used to map types of protocol to integer values to determine the availability of the specified protocol. See “Resolver configuration files” on page 796 for more information.
ETC.SERVICES	Establishes port numbers for servers using TCP and UDP. See “Resolver configuration files” on page 796 for more information.
HOSTS.LOCAL	Input data set to MAKESITE for generation of HOSTS.ADDRINFO and HOSTS.SITEINFO. See “Resolver configuration files” on page 796 for more information.
HOSTS.SITEINFO and HOSTS.ADDRINFO	Local host data sets used for IPv4 name query when NOCOMMONSEARCH is specified in the resolver setup file. See “Resolver configuration files” on page 796 for more information.

Table 15. Configuration data sets (continued)

Configuration data set names	Description
FTP.DATA	Overrides default FTP client and server parameters for the FTP server. For more information, see File Transfer Protocol .
SOCKSCONFIGFILE	The FTP client uses this SOCKS server configuration data set to determine which FTP servers require SOCKS protocols. See File Transfer Protocol for more information.
TCPIP.DATA	Provides parameters for TCP/IP client programs. See TCPIP.DATA configuration statements for more information.
TCPXLBIN	The translate tables (EBCDIC-to-ASCII and ASCII-to-EBCDIC) are referenced to determine the translate data sets to be used.

Network security principles

This topic describes network security principles that you can use to protect data in your network.

Cryptography: The foundation of good security

The foundation of good security methods begins with cryptography. Cryptography keeps your data and communications secure using techniques such as encryption, authentication, and data integrity. Encryption services protect sensitive data from being read by other than the intended receiver. Cryptographic authentication and data integrity services allow communicating hosts to detect if data is altered in transit. Public key cryptography can identify and authenticate hosts or users. Public key cryptography can also be used in the secure creation of symmetric session keys for both security endpoints. After a secure session is created, successful data authentication and decryption occur only if both hosts have the correct session keys.

Cryptographic standards and FIPS 140

The National Institute of Standards and Technologies (NIST) publishes Federal Information Processing Standards publication 140 (FIPS 140). This publication specifies security requirements for cryptographic modules for both hardware and software components of computer systems. FIPS 140 places some restrictions on the use of cryptographic algorithms and modules. Some examples of the restrictions are:

- Cryptographic algorithms and keys must be contained within a cryptographic module and accessed through a well defined cryptographic boundary.
- Use of weaker cryptographic algorithms (for example, DES and MD5) is not allowed.
- Use of weaker asymmetric key lengths (for example, RSA digital signature operations using key lengths less than 1024 bits) is not allowed.
- Use of Diffie-Hellman groups with weaker key lengths (key lengths less than 2048 bits) is not allowed. This restriction applies to groups 1, 2, and 5.

See the National Institute of Standards and Technology (NIST) website at <http://csrc.nist.gov/publications/PubsFIPS.html> for the most recent FIPS 140 publication, and other related publications.

On z/OS systems, Integrated Cryptographic Services Facility (ICSF) and System SSL provide cryptographic services. z/OS Communications Server uses ICSF and System SSL in addition to its own cryptographic algorithms in some of its networking security functions, such as AT-TLS and IP security. You can configure ICSF, System SSL, and the z/OS Communications Server networking security functions in FIPS 140 mode, in which case they enforce FIPS 140 restrictions. Enabling FIPS 140 mode might require additional setup and configuration, and it might result in a reduction in performance.

See the following references for information about configuring z/OS functions in FIPS 140 mode:

- [“FIPS 140 mode and IP security” on page 917](#)

- Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149

- [z/OS Cryptographic Services ICSF Overview](#)
- [z/OS Cryptographic Services ICSF Administrator's Guide](#)
- [Operating in compliance with FIPS 140-2 in z/OS Cryptographic Services ICSF Writing PKCS #11 Applications](#)

End to end security

Cryptographic security solutions can be applied to a portion of the data path or end to end, whichever is appropriate for your security policy. Generally, the greatest degree of security is provided when cryptographic methods are used end to end. However, if only portions of the data path are considered untrusted by an enterprise (such as the Internet) it may be adequate to protect only the untrusted portion with cryptography. z/OS offers security protocols that can be configured to protect portions of the data path or the entire data path.

Workload-based security deployment

In making a security protocol selection, an important consideration is the application workload to be protected. In order to illustrate this concept, it is helpful to understand where various protocols are implemented from a protocol layering perspective.

Figure 34. Security protocols from a protocol layering perspective

Existing workload

The network layer is the lowest layer in the protocol stack where end to end security over multiple hops can be applied. Network layer security protocols provide blanket protection for upper-layer application data without requiring modification to the application. IPSec is implemented at the network layer and provides authentication, integrity, and data privacy between any two IP entities. IPSec can protect a segment of the data path (e.g., between two routers), or it can secure the data path end to end. Because IPSec is applied at the IP layer, it is a connectionless security protocol and is applied on a per packet basis.

Transport Layer Security (TLS), which evolved from secure Sockets Layer (SSL), is another popular security protocol implemented above the transport layer at the application interface layer. TCP applications can be modified to use TLS. Many existing socket applications might be able to use Application Transparent Transport Layer Security (AT-TLS) services provided within the TCP/IP TCP layer.

For details, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149.

TLS requires a reliable transport layer and is therefore not used for UDP applications. TLS provides authentication, integrity, and data privacy. TLS is a connection-oriented security protocol and protects all data on a connection or session.

The Communications Server has a TLS-enabled TN3270E Telnet server, which provides secure access to existing SNA applications being accessed over an IP network. Serving as a protocol gateway between the IP network and the SNA network, the TLS-enabled TN3270E Telnet server protects the data path in the IP network from the Telnet client all the way to the z/OS TN3270E Telnet server. If the TN3270E Telnet server is on a different host from the target SNA application, IPsec can be used to secure Enterprise Extender links in the SNA portion of the data path. Enterprise Extender application data can be protected without modification to the SNA applications.

New workload

For new applications, security can be built-in. One method of building security into the application on z/OS is to use z/OS System SSL and Kerberos. Another method is to use the Communication Server's policy-driven Application Transparent Transport Layer Security (AT-TLS), which requires no change to the application unless the application must control certain portions of the AT-TLS support.

Tip: Using AT-TLS is highly recommended over the direct use of System SSL.

Newer versions of network services, such as SNMPv3 that are supported by the Communications Server, have security built into the application protocol using standards-based specifications for secure interoperability.

Network security protocols

This topic describes network security protocols that you can use to protect data in your network.

IPSec and VPNs

IPSec is defined by the IPSec Working Group of the IETF. It provides authentication, integrity, and data privacy between any two IP entities. Management of cryptographic keys and security associations can be done manually or dynamically using an IETF-defined key management protocol called Internet Key Exchange (IKE).

There are two versions of the IKE protocol:

- IKE version 1.0 (IKEv1) is defined by RFC 2409, *The Internet Key Exchange (IKE)*, and related RFCs. This is the version that has been supported by z/OS Communications Server for a number of years.
- IKE version 2.0 (IKEv2) is defined by RFC 5996, *Internet Key Exchange Protocol: IKEv2*, and related RFCs. Support for IKEv2 is introduced with z/OS V1R12.

With IPSec, you can create virtual private networks (VPN). A VPN enables an enterprise to extend its private network across a public network, such as the Internet, through a secure tunnel called a security association. IPSec VPNs enable the secure transfer of data over the public Internet for same-business and business-to-business communications, and protect sensitive data within the enterprise's internal network.

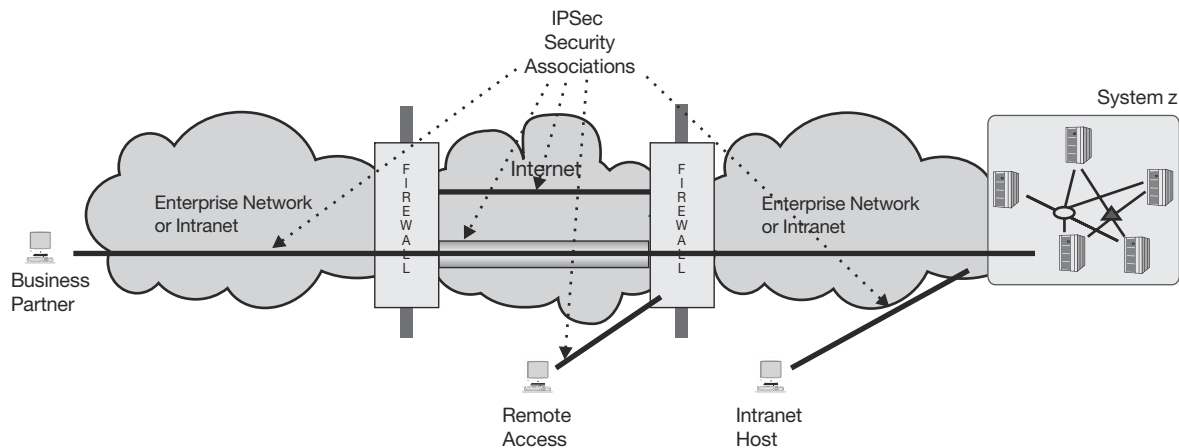

Figure 35. e-business scenarios with virtual private networks

z/OS provides support for IKE and IPSec VPNs, including the following options:

- AH and ESP protocols
- Triple DES
- AES with several choices of mode or key length
- IPSec transport and tunnel mode encapsulation
- IKEv1 and IKEv2 negotiations with support for both aggressive and main mode in IKEv1
- Pre-shared key and digital signature methods of authentication
- NAT traversal (IPv4 only)

For more information about configuring IPSec and VPNs, see [Chapter 17, “IP security,” on page 911](#).

For more information on using IPSec with Dynamic VIPAs, see [“Sysplex-Wide Security Associations” on page 424](#).

Hardware features for encryption, decryption and hashing

IBM CP Assist for Cryptographic Functions (CPACF), where available, or a cryptographic coprocessor provide support for IPSec encryption, decryption, and hashing functions. Where such hardware features are not available, IPSec's encryption, decryption, and hashing functions are performed in software.

Additional IPSec assist using System z Integrated Information Processor (zIIP IP security)

On a System z9® or later server, an additional assist for IPSec protocol traffic is available with the System z Integrated Information Processor (zIIP). To enable zIIP IP security in Communications Server, specify ZIIP IPSECURITY on the GLOBALCONFIG statement. With zIIP IP security enabled, traffic using the AH and ESP protocols can be processed on available zIIPs. When enabled on a z9 or later z/OS image that includes zIIPs, the zIIP IP security function can reduce the IPSec processing load on general purpose central processors, beyond what is achievable using just CPACF or the Cryptographic Coprocessor.

When zIIP IP security is enabled, you might have to modify some Workload Manager (WLM) definitions. The IPSec traffic that can be processed on available zIIP processors is assigned to an independent WLM enclave. The WLM independent enclave encapsulates the IPSec workload as execution units that are separately classified and managed in a WLM service class. See the following considerations:

- All WLM independent enclaves that are not classified are assigned WLM service class SYSOTHER (with a goal of discretionary). In many cases, enclave workload using this service class can result in performance degradation if the workload is left unclassified in the service definition. Also, service that is accumulating in the SYSOTHER service class is an indication that you have unclassified workload in your system.

- Examine the IIPHONORPRIORITY parameter located in the IEAOPTxx member of SYS1.PARMLIB. When this parameter is specified as NO, general purpose central processors do not process zIIP-eligible workload when zIIPs are online. Omitting the IIPHONORPRIORITY parameter or specifying IIPHONORPRIORITY=YES allows zIIPs to request help from general-purpose central processors when the zIIPs can not complete all zIIP-eligible workload within a reasonable period of time (see ZIIPAWT in *z/OS MVS Initialization and Tuning Reference*).
- If there are any other workloads that are eligible to run on your zIIPs, analyze your current WLM workload goals and make any necessary adjustments. For example, if you are operating a workload that is more latency-sensitive than the typically longer running IPsec workloads, such as Db2® Distributed Relational Database Architecture (DRDA) workload, consider classifying the IPsec workload to make it less preferable than the workload that is more latency-sensitive.

Guideline: Make these two performance goal settings for the IPsec independent enclave:

- Set the WLM service class associated with the IPsec independent enclave to a lower execution velocity goal than that which is being assigned to the more latency-sensitive workload (such as Db2 DRDA). The lower execution velocity goal is chosen because the IPsec independent enclave has no associated transactions.
- Set the WLM service class associated with the IPsec independent enclave to a greater importance level value (importance is defined in five levels, 1 to 5, with 1 indicating highest importance) than that which is being assigned to the more latency-sensitive workload (such as Db2 DRDA). Each WLM service class is associated with an importance level that specifies how important it is to your business that this workload is meeting its goal. The importance level defines how work is treated by the system. Achieving the velocity goal for IPsec traffic that can be processed on available zIIP processors is less important than the more latency-sensitive workload.

Because an independent enclave enables WLM to manage the priority of all workload in the enclave, you should classify the workload for IPsec traffic. To classify the independent enclave used for IPsec workload, make the following WLM service definitions using the WLM ISPF panels:

1. Create a workload for the IPsec traffic that will be operating on the independent enclave.

From the primary WLM ISPF panel, select option 2 **Workloads**.

2. Create a service class that contains an appropriate performance goal for the IPsec independent enclave.

On the primary WLM ISPF panel, select option 4 **Service Classes**. From this panel, define your new service class and associate it with the workload you previously defined. When you define the **BASE GOAL** information for your single defined period, choose the goal type **Execution velocity**. After this is selected, define a velocity and importance for the service class that you are defining. Set a value that takes into account other traffic that might be competing for zIIP or general central processor resources. (General central processors become a factor when you have set the IIPHONORPRIORITY parameter to the value YES in the IEAOPTxx member of SYS1.PARMLIB.)

3. Create a WLM subsystem type for TCP/IP.

You must specify the subsystem type name as TCP; define it by using the WLM ISPF application. On the primary WLM ISPF panel, select option 6 **Classification Rules**; the **Subsystem Type Selection List for Rules** panel is displayed. Move your cursor to the field **Subsystem-Type** and press the Enter key. When you are prompted for the type of operation that you want to perform, select option 1 **Create**, because you want to create a new subsystem type. On the **Create Rules for the Subsystem Type** panel, specify the subsystem type TCP and a description for this new subsystem type.

4. Create a classification rule for the subsystem type TCP on the **Create Rules for the Subsystem Type** panel of the WLM ISPF application.

Define a classification rule for the subsystem type. This rule determines what workload is associated with a service class for this subsystem type. You can use the following workload qualifiers for the new independent enclave for IPsec workload:

- Subsystem Instance (SI) will be set to the job name of the TCP/IP stack

- Transaction Name will be set to a value of TCPENC01

To verify that the new independent enclave is being used with an appropriate WLM service class, use the System Display and Search Facility (SDSF) ENC command or view the RMF Monitor III ENCLAVE report (or use any other method to interactively view RMF data).

For a more detailed description of defining Workload Manager (WLM) service definitions (workloads, service classifications, classification rules, subsystem type, and so on) and WLM in general, see *System Programmer's Guide to: Workload Manager* (IBM Redbooks) and *z/OS MVS Planning: Workload Management*. For information about configuring the IIPHONORPRIORITY parameter in the IEAOPTxx member of SYS1.PARMLIB, see *z/OS MVS Initialization and Tuning Reference*. For more information about viewing enclaves using SDSF, see *z/OS SDSF Operation and Customization*. For additional information about the RMF workload activity report, see *z/OS Resource Measurement Facility Report Analysis*.

On system models with no zIIPs (z990, or a z9 or later with no zIIPs configured), you can enable zIIP IP security so that you can project the percentage of existing IPsec workload (running on central processors) that would be eligible to run on zIIPs, if zIIPs were available on the z/OS image. To perform projection analysis, specify ZIIP IPSECURITY on the GLOBALCONFIG statement, and specify PROJECTCPU=YES in the IEAOPTxx member of SYS1.PARMLIB. Run your IPsec workload, and SMF provides accounting information regarding workload that is eligible to run on zIIPs. For information about configuring the PROJECTCPU parameter in the IEAOPTxx member of SYS1.PARMLIB, see *z/OS MVS Initialization and Tuning Reference*. For information about accounting for zIIP eligibility in SMF record types 30 and 7x, see *z/OS MVS System Management Facilities (SMF)*. For information about zIIP-related reporting updates, see *z/OS Resource Measurement Facility Report Analysis*.

Guidelines:

- Because cryptographic hardware performance differs significantly between z9 or later processors and processors that preceded the z990, you should not use zIIP IP security for projection purposes on processors preceding the z990.
- TCP/IP consumes slightly more central processing resources when no zIIPs are online and you have coded GLOBALCONFIG ZIIP IPSECURITY. Remove GLOBALCONFIG ZIIP IPSECURITY from your TCP/IP profile after you have completed your zIIP performance projection runs.

TLS and SSL

The Transport Layer Security (TLS) protocol provides data encryption, data origin authentication, and message integrity. It also provides server and client authentication using X.509 certificates. TLS begins with a handshake during which the server is authenticated to the client using X.509 certificates. Optionally, the client can also be authenticated to the server using X.509 certificates. During the handshake, the TLS protocol version and security session parameters, including suites of cryptographic algorithms called cipher suites, are negotiated and session keys are created. After the handshake, the data is protected during transmission with data origin authentication, integrity and encryption using the session keys.

The cryptographic algorithms that are used for the TLS session are based on the cipher suite that the server and client negotiate. During the TLS handshake, the client and server exchange a list of cipher suites. The suite that is selected is based on the best match between the client list and the server list. You can limit the selectable algorithms by configuring a subset of allowable algorithms at the server. TLS supports cipher suites that include AES-based encryption and a variety of other encryption algorithms. Cryptographic hardware features like CPACF and Crypto Express adapters, if available, are used to accelerate certain cryptographic operations.

TLS typically requires a server X.509 certificate and associated private key, which are stored in a keystore such as a SAF key ring, a gskkyman key database, or a Java™ keystore. The certificate is used as part of the TLS handshake server authentication process. The client validates the server certificate. TLS optionally uses a client X.509 certificate that is used as part of the TLS handshake client authentication process. In order to use client authentication, the client must have a client X.509 certificate and associated private key. Successful client authentication requires that the Certificate Authority (CA) that signed the client certificate be considered trusted by the server. To be considered trusted, the certificate of the CA must be in the key store of the server.

See “Transport Layer Security” on page 622 for detailed information on obtaining certificates.

TLS is based on the Secure Sockets Layer (SSL) protocol and is defined by the Internet Engineering Task Force (IETF) in RFCs 2246 (TLSv1.0), 4346 (TLSv1.1), and 5246 (TLSv1.2) and 8446 (TLSv1.3). SSL was originally defined as a proprietary protocol, not by the IETF. Since TLS evolved from SSL, the two terms are used interchangeably throughout this book. When a specific TLS or SSL protocol version is intended, it will be specifically noted.

On z/OS there are two different TLS implementations. System SSL, a component of the Cryptographic Services element, provides a full set of TLS APIs for C and C++ programs. For Java programs, z/OS provides a full function Java Secure Sockets Extension (JSSE) provider. z/OS Communications Server's AT-TLS support uses System SSL for its TLS protocol processing.

TN3270E Telnet server security

The Communications Server provides z/OS TN3270E Telnet server (Telnet), that is enabled for AT-TLS; the data path in the IP network to Telnet is protected using the TLS protocol. IBM Host On Demand and Personal Communications provide a Telnet client that is enabled for TLS.

Figure 36. TN3270E Telnet server security overview

The Communications Server Telnet TLS support provides several extensions for RACF-based access control to Telnet. These extensions prevent a client from seeing the USSMSG (log on screen) unless the client is authorized. To use this support, define the client certificate to RACF using RACF digital certificate services. The first level of authorization checking verifies that the RACF user ID represented by the client certificate is defined to RACF. The next level of authorization requires that this RACF user ID be permitted to access the Telnet port. The Telnet port is represented as a RACF resource using the SERVAUTH class.

Multiple port support

You can use Telnet multiple port support to enable a combination of secure and non-secure traffic. To use multiple port support, you define separate ports; one port is dedicated to non-secure traffic and another port is dedicated to secure traffic. As an example, assume a scenario where Intranet client connections are not required to be secure, but Internet client connections are so required. In this case, Intranet clients connect to the BASIC port (port 23 in Figure 37 on page 180). Since all clients connecting from the Internet require secure connections, these clients use the TTLSPORT (port 1023 in Figure 37 on page 180). Packet filtering is used at the firewall that separates the intranet and the Internet to control access to the Telnet ports. To prevent Internet access to the BASIC port, port 23 is blocked at the firewall. The TTLSPORT, port 1023, is permitted at the firewall. In this scenario, the best security is achieved when TLS client authentication with the Telnet RACF extensions is used. This support ensures that the client has the authority to attempt to log on to SNA applications through Telnet. Regardless of the method of

authentication used, the SNA application should identify and authenticate the user using RACF before any application access is granted. If you are using TLS encryption services, the user ID and password are encrypted.

Figure 37. Using multiple Telnet ports to separate secure and non-secure traffic

Figure 38 on page 180 shows how you can combine IPSec and Telnet security to provide more secure remote access from the Internet to SNA applications than is depicted in Figure 37 on page 180. In this scenario, IPSec AH protocol is used for authentication between the user's PC and the firewall. The firewall is open for port 1023 for traffic that is authenticated with only IPSec. The firewall discards traffic for port 1023 that cannot be authenticated by IPSec. The additional security provided by IPSec protects the z/OS server from unauthorized access attempts and denial-of-service attacks by hosts outside the VPN.

Figure 38. Combining Telnet security with IPSec client-to-firewall authentication

Secure and non-secure connections using a single Telnet port

A single port can be used to support a mix of secure and non-secure traffic. The port has the designation TTLSPORT. To support the configuration of various security policies for a single port, the TTLSPORT designation indicates that the port can use TLS, but the port does not have to use TLS.

Telnet supports both negotiated and non-negotiated TLS. Negotiated TLS is an IETF-defined extension to the TN3270 protocol. With negotiated TLS, the decision to use TLS for a connection is based on the outcome of a negotiation between the Telnet client and server using TN3270 protocols. This negotiation is performed after the Telnet connection is established, and if TLS is negotiated, the TLS handshake is performed. With non-negotiated TLS, a TLS handshake is required immediately after the connection is established. A single port can concurrently use both negotiated and non-negotiated TLS connections.

Figure 39 on page 181 shows a single Telnet port that allows a mix of secure and non-secure traffic. Intranet clients are not required to be secure. All clients connecting from the Internet are required to use TLS. Both intranet and Internet clients connect to the port designated as TTLSPORT (port 1023 in this example). In this scenario, IPSec AH protocol is used for authentication between the user's PC and the firewall. The firewall is open for port 23 for traffic that is authenticated with only IPSec. The firewall discards traffic for port 23 that IPSec cannot authenticate. In this scenario, packet filtering without IPSec cannot be used at the firewall that separates the intranet and the Internet to control access on the basis

of port, because only one port is used. Without IPsec AH, all access control checks are deferred to Telnet. The additional security provided by IPsec at the firewall protects the z/OS server from unauthorized access attempts and denial-of-service attacks by hosts outside the VPN.

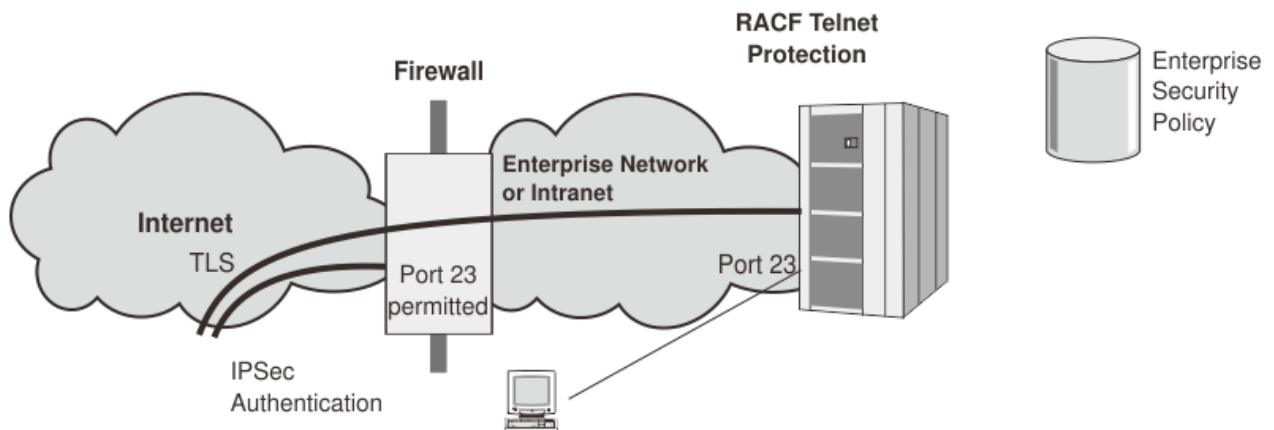

Figure 39. Secure and non-secure traffic using a single Telnet port

Express Logon Feature

With emulator products, the traditional method of authenticating the user is through user ID and password which is kept in sync with the host access control facility (RACF, ACF/2, AS/400 user management, etc.). The Express Logon Feature (ELF) simplifies user ID and password administration for users signing on to SNA applications using Telnet. ELF allows a user to use a TLS-authenticated X.509 certificate for authentication to the SNA application instead of using a user ID and password. ELF requires IBM Host Integration software. The Host Integration requirements depend on the configuration.

There are two network designs available; a two-tier or a three-tier approach. Both are discussed in [Appendix C, “Express Logon Feature,”](#) on page 1365.

TLS-enabled FTP

The Communications Server FTP server and client support Transport Layer Security (TLS). This support enables secure file transfer by providing data privacy, message authentication, and message integrity services for data sent and received using the FTP control and data connections.

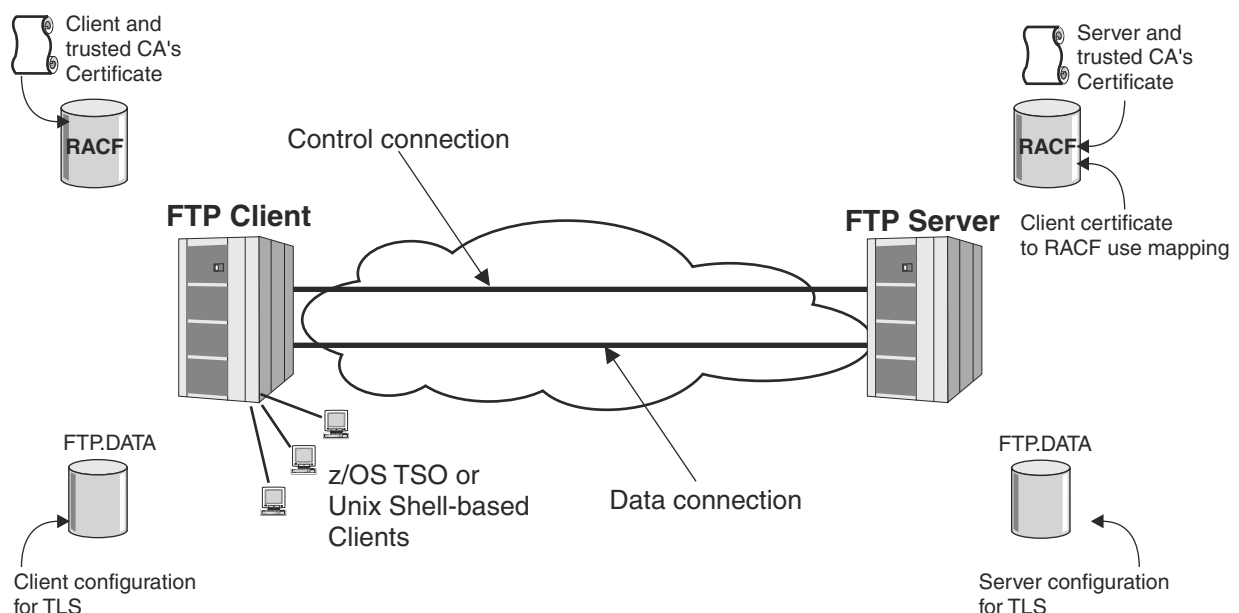

Figure 40. FTP client and server TLS overview

The TLS-enabled FTP server can be configured to run in two modes. Conditional mode allows an installation to use a single port for both TLS and non-TLS FTP control connections. In conditional mode, the FTP client and server negotiate the use of TLS based on a subset of the FTP security negotiation functions documented in RFC 2228. After the use of TLS is negotiated, the TLS handshake is performed which establishes the TLS session and negotiates security parameters and session keys. Unconditional mode allows an installation to use a separate port for all TLS traffic. The port specified by the TLS`PORT` statement in FTP`.DATA` (port 990 by default) is the port designated for control connections for unconditional TLS mode. With unconditional mode, it is assumed that TLS is required, and after the FTP control connection is made, the TLS handshake is performed.

TLS secures the control connection and optionally the data connection. TLS for the data connection requires a TLS session for the control connection. FTP server configuration controls whether the FTP server requires TLS for the control and data connections. This TLS protection by connection type is negotiated during the FTP RFC 2228 negotiation that precedes the TLS handshake. During the lifetime of the control connection, the use of TLS or no TLS for the data connection can be requested by the FTP client using the FTP RFC 2228 commands.

FTP TLS optionally authenticates the client during the TLS handshake using a client X.509 certificate. FTP server configuration specifies whether TLS client authentication is required and what type of validation of the certificate is required. For example, the FTP server can be configured to map the client certificate to a RACF user ID and then verify that the user ID associated with the certificate matches the user ID entered by the user.

FTP TLS optionally simplifies the TLS handshake by resuming a previous TLS session instead of negotiating new security parameters and session keys. The FTP client and server configuration specifies whether reuse of a previous TLS session is required. For example, you can configure the FTP client to require session reuse of a previous TLS session and configure the FTP server to allow but not require session reuse.

The FTP client and server are enabled for AT-TLS with configuration provided through AT-TLS policies. The FTP client also implements minimal TLS support with configuration stored in the FTP`.DATA` data set. AT-TLS support is recommended.

Configuration to control TLS capabilities and options for both FTP client and server TLS are stored in the FTP`.DATA` data set.

Application Transparent Transport Layer Security

Communications Server provides for invocation of System SSL in the TCP transport layer of the stack on behalf of the TCP/IP application or middleware. Application Transparent Transport Layer Security (AT-TLS) support is controlled by the TTLS or NOTTLS parameter on the TCP`CONFIG` statement in the TCP/IP profile. When AT-TLS is enabled, AT-TLS policy statements processed by the Policy Agent define the security attributes for connections that match AT-TLS rules. This policy-driven support can be deployed transparently underneath many existing sockets, leaving the application unaware of the encryption and decryption being done on its behalf. Support is also provided for applications that need to negotiate TLS or need to participate in client authentication. These applications must be aware of AT-TLS support and use `ioctl` support provided by AT-TLS. AT-TLS supports the TLS, SSLv3, and SSLv2 protocols. For more details, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149.

Kerberos

Kerberos is a network authentication protocol that is designed to provide strong authentication for client/server applications using secret-key cryptography. The Kerberos network authentication protocol assumes that services and workstations communicate over an insecure network. It allows clients and servers to do either one way, or two way (mutual) authentication. It allows for data encryption and prevents passwords from having to be retyped to access networked services and also prevents their transmission in plain text over the network. This feature can help reduce the need to manage multiple passwords.

z/OS Integrated Security Services ships Kerberos version 5. You should write new applications to Kerberos version 5 and use z/OS Integrated Security Services.

The following Communications Server IP applications include support for the Kerberos version 5 security protocol:

- The UNIX System Services Telnet server allows clients supporting Kerberos version 5 (as described in RFC 1416) to log in to the shell environment using Kerberos as the authentication protocol.
- The FTP client and server support connections to or from other clients and servers supporting Kerberos version 5 authentication for the FTP protocol (as described in RFC 2228).
- The UNIX System Services RSH server can be configured to support client authentication using Kerberos from RSH clients supporting Kerberos version 5.

Secure Shell (SSH)

Secure Shell, or SSH is a client/server protocol that provides cryptographically secure remote login to a z/OS Unix shell, file transfers with sftp, and other capabilities over TCP connections.

z/OS OpenSSH, a port of open-source software OpenSSH, is a base element of z/OS.

OSPF authentication

Communications Server OSPF (Open Shortest Path First) dynamic routing protocol supports message authentication and message integrity of OSPF routing messages through the use of the OSPF MD5 Authentication security protocol as defined by RFC 2328. OSPF MD5 Authentication ensures that an unauthorized IP resource cannot inject OSPF routing messages into the network without detection, thus ensuring the integrity of the routing tables in the OSPF routing network.

OMPROUTE computes a secure MAC for the routing message using the MD5 algorithm. This MAC is sent with the routing message so that the message can be authenticated by the receiver.

SNMPv3

z/OS Communications Server SNMP supports SNMPv3. The legacy community-based protocols SNMPv1 and SNMPv2 are also supported. SNMPv3, defined in RFCs 3410 through 3415 is the standards-based solution for SNMP security. It is categorized as a User-based Security Model (USM) which provides different levels of security based on the user accessing the managed information. To support this security level, the SNMPv3 framework defines several security functions, such as USM for authentication and privacy, and view-based access control model (VACM) which provides the ability to limit access to different MIB objects on a per-user basis, and the use of authentication and data encryption for privacy. However, SNMP is not just enhanced security. It defines an architecture for SNMP management frameworks, with the intent that pieces of the architecture can advance over time without requiring the entire structure to be rewritten. For that reason, three major subsystems are defined:

- Message processing subsystem
- Security subsystem
- Access control subsystem

The framework is structured so that multiple models can be supported concurrently and replaced over time. For example, although there is a new message format for SNMPv3, messages created with the SNMPv1 and SNMPv2 formats can still be supported. Similarly, the user-based security model can be supported concurrently with the community-based security models previously used. For more information on SNMPv3 and configuring SNMPv3 support, see [Chapter 23, “Simple Network Management Protocol,” on page 1267](#). For information about accessing RFCs, see [Appendix G, “Related protocol specifications,” on page 1439](#).

Monitoring cryptographic network protection: z/OS encryption readiness technology (zERT)

z/OS Encryption Readiness Technology (zERT) is a Communications Server feature that provides information about the cryptographic network protection state of TCP and Enterprise Extender connections terminating on a z/OS system. zERT helps you answer the following questions:

- *What* TCP and Enterprise Extender traffic is being protected (and which is not)?
- *How* is that traffic being protected? For instance, what protocols are being used, which cryptographic algorithms are being used, and what key lengths?
- *Who* on my z/OS system is consuming or producing the network traffic, whether it is protected or not?
- *Where* is the remote endpoint for that traffic?

With zERT policy-based enforcement, you can write rules to enforce real-time compliance monitoring that can generate audit events and even take defensive actions based on the observed cryptographic protection attributes of each TCP connection.

z/OS Encryption Readiness Technology (zERT) Concepts

With the increasing number of corporate, industry, and government regulations regarding cryptographic protection of data in flight, as well as discoveries of weaknesses in existing cryptographic protocols and algorithms, it is important for z/OS administrators and auditors to be able to assess the quality of the cryptographic network protection being applied to their key z/OS workloads.

The landscape of cryptographic network protection on z/OS is varied and can be complex. Because of this, performing such an assessment can be very difficult. Consider the following:

- IBM provides two TLS/SSL protocol implementations on z/OS:
 - z/OS Cryptographic Services System SSL, which is available to software written in C or C++.
 - Java Secure Sockets Extension (JSSE), which is available to Java software (and is written in Java itself).

In addition, users have been known to port third party TLS implementations like OpenSSL onto z/OS. Programs and middleware that use System SSL directly or that use third party implementations usually have their own unique configuration methods to control the details of TLS/SSL protection. Programs and middleware that use JSSE often require a set of JSSE-specific environment variable or parameters to configure their TLS/SSL protection.

- z/OS Communications Server provides AT-TLS, which invokes System SSL on behalf of applications and middleware based on policies that you create. AT-TLS can protect traffic from any program that uses z/OS Unix System Services TCP sockets APIs, regardless of the programming language.
- z/OS Communications Server provides a full IPsec implementation, also configured through policies that you create.
- z/OS also supports the Secure Shell (SSH) protocol, although Communications Server does not directly use it. For more information of Secure Shell (SSH) protocol, see *z/OS OpenSSH* in *z/OS Introduction and Release Guide*.
- Each of these protocols allow the local and remote endpoints to negotiate the exact protection methods to be used for any given security session. This means understanding the z/OS configuration for a given application's cryptographic protection only tells you which attributes (protocol versions, algorithms, key lengths, and so on.) are possible - it usually does not tell you the exact set of protection attributes that were agreed upon for any specific security session that is established between the z/OS application and a remote endpoint.

With such variety of protocols, configuration methods, and audit and log records, it can be difficult to clearly understand the overall state of cryptographic network protection for your z/OS system.

zERT positions the z/OS TCP/IP stack as a central collection and reporting point for the cryptographic protection attributes for TLS, SSL, SSH, and IPsec security sessions that are protecting TCP and

Enterprise Extender connections that terminate on the local stack. This collection and reporting function is called zERT discovery.

A second reporting function called zERT aggregation summarizes the repeated use of security sessions over a period of time (the system's SMF interval or the specified zERT aggregation INTVAL setting). By focusing more on the security session than on individual TCP or EE connections, zERT aggregation provides the same level of cryptographic detail as zERT discovery, but with significantly fewer SMF records. The zERT aggregation function requires the use of zERT discovery to collect the individual TCP and EE connection information that is then summarized by zERT aggregation.

IBM zERT Network Analyzer is a z/OS Management Facility (z/OSMF) task that provides a GUI-based tool for analyzing cryptographic protection characteristics of TCP and Enterprise Extender (EE) connections on your system, using SMF records generated by the zERT aggregation function.

With zERT policy-based enforcement (or simply "zERT enforcement"), the TCP/IP stack uses the cryptographic protection attributes observed by zERT discovery to enforce policy rules that you create based on your local network security requirements. zERT enforcement compares each TCP connection's observed cryptographic attributes to rules installed through the Policy Agent to take appropriate action when a connection's protection attributes match those defined in a zERT enforcement rule. zERT enforcement rules and their associated actions are defined through the IBM Configuration Assistant for z/OS Communications Server in z/OSMF. For acceptable protection, the default action is to silently allow the connection. For questionable or unacceptable protection, actions such as notification through messages, auditing through SMF records, and even dropping the connection can be configured.

What does zERT discovery manage and collect?

In order to understand zERT discovery processing and the information that zERT collects and records, it is important to understand the distinction between application connections and security sessions:

- An **application connection** is a TCP connection or Enterprise Extender (EE) connection (over UDP) over which two application programs communicate with each other.
- A **security session** is an instance of a secure path between two endpoints as defined by a cryptographic security protocol. Examples are TLS/SSL sessions, SSH sessions, and IPsec tunnels (as they apply to a given application connection).

Note: An application connection may have zero or more security sessions at any given time. Since "no protection" is a valid cryptographic protection state, zERT even reports on connections that do not have any recognized cryptographic protection. Likewise, a connection may be simultaneously protected by multiple security sessions, such as a TLS session and an IPsec tunnel. zERT collects and reports information for all of these scenarios.

How does zERT discovery collect the information?

zERT collects cryptographic protection attributes through two different mechanisms.

- For TCP and Enterprise Extender traffic, zERT can be notified of the attributes directly by **cryptographic protocol providers (CPPs)** that are specifically enabled for zERT. Such CPPs notify the TCP/IP stack when a significant event occurs regarding the security sessions they manage. z/OS IPsec, System SSL, IBM z/OS OpenSSH are all zERT-enabled CPPs.

zERT-enabled CPPs generate these notifications when a security session is created, terminated, or renegotiated in a way that significantly changes the cryptographic protection attributes. In addition, IPsec generates a notification when an existing IPsec security association is assigned to protect a TCP or Enterprise Extender connection.

- For TCP traffic, zERT can learn the attributes through **observational discovery**, which is the direct observation of the TCP stream as it passes through the TCP/IP stack for TLS, SSL and SSH handshake messages. This stream observation is performed only at very specific points in the life of the TCP connection for a very limited amount of time in order to avoid any negative impact to performance. The amount of observable information is limited. For detailed limitations of zERT discovery, see [What are the limitations for zERT discovery?](#) Despite its limitations, observational discovery can still provide basic

information regarding cryptographic protection attributes for many TLS, SSL and SSH sessions that are managed by protocol providers that are not enabled for zERT.

How does zERT discovery provide the information?

As cryptographic protection attributes for TCP and Enterprise Extender connections are discovered and collected, you can direct zERT to write those attributes, along with relevant connection information, to the z/OS System Management Facility, to a network management application using the real-time NMI for zERT information, or to both. Regardless of the destination, the information is recorded using SMF 119 subtype 11 (zERT connection detail) records.

zERT connection detail records have the following general format:

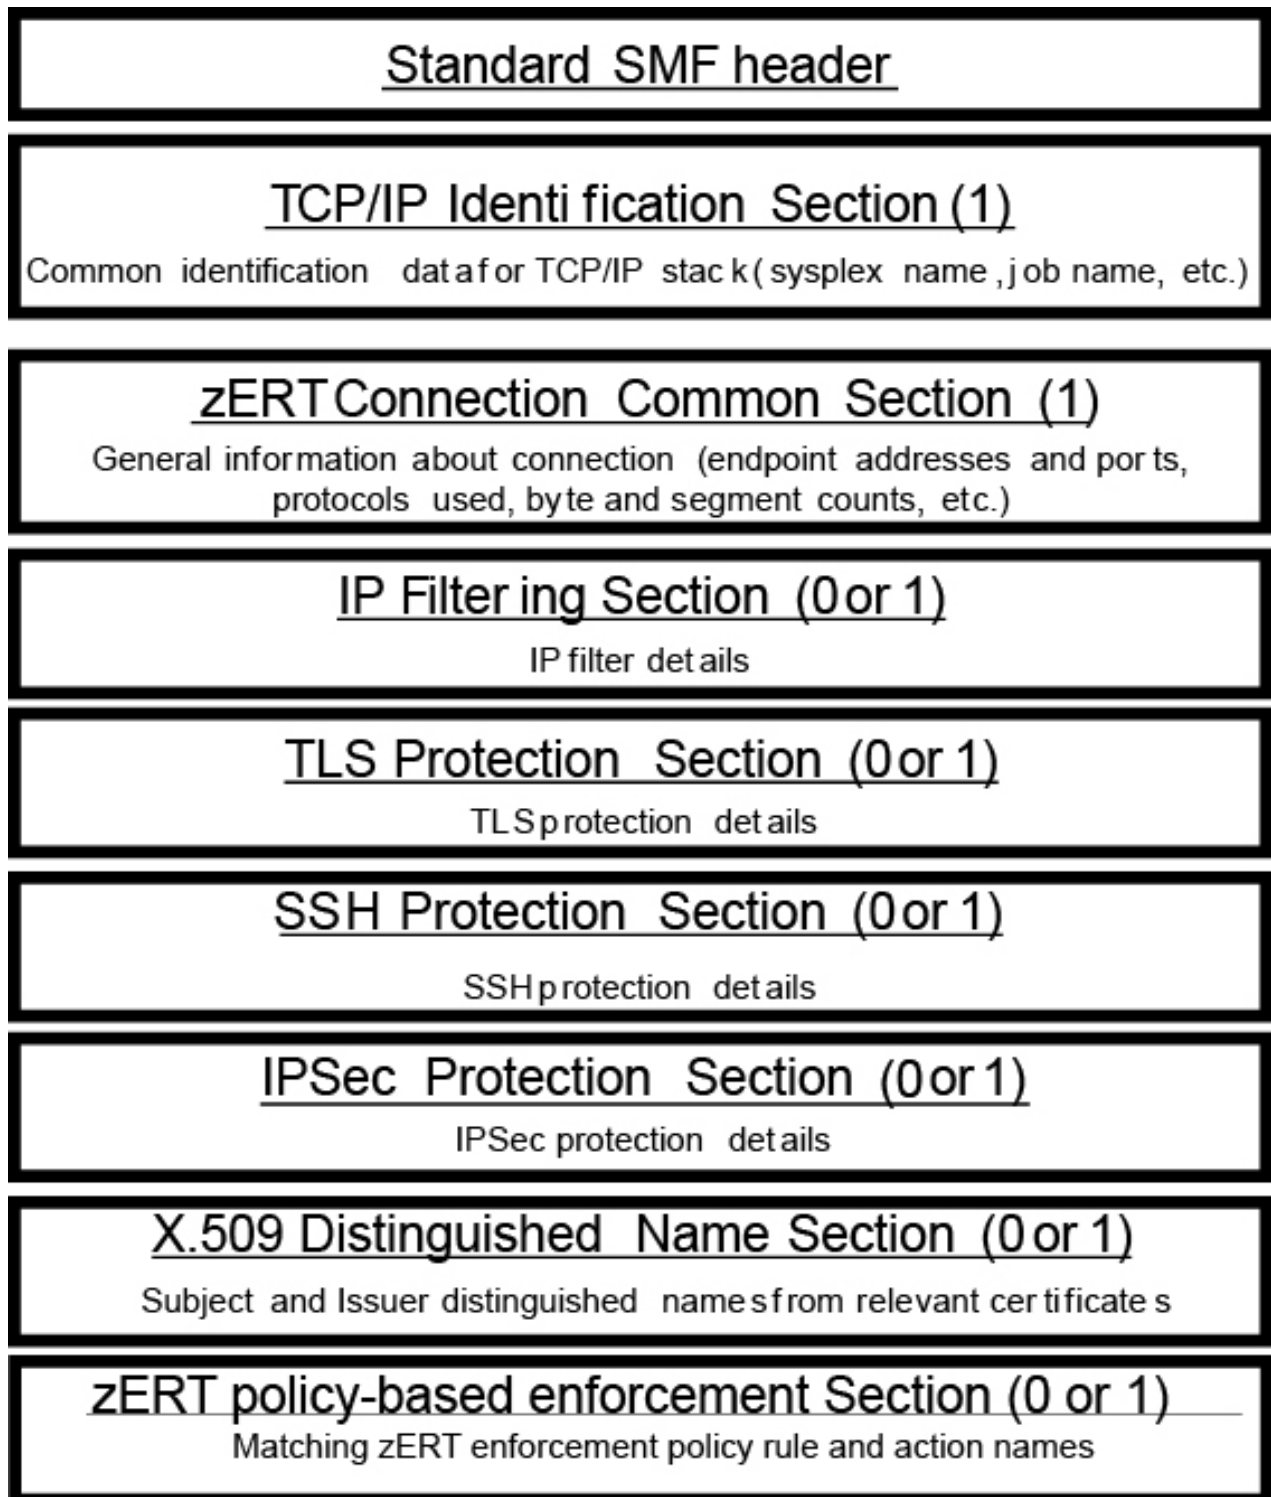

Figure 41. zERT connection detail (SMF 119 subtype 11) record layout

One or more zERT connection detail records are generated for each TCP and Enterprise Extender connection. The zERT Connection Common Section contains an event type field that indicates the reason each subtype 11 record is generated. The number of subtype 11 records written for a given connection depends on a couple of different factors:

- For TCP connections, the length of time that the connection exists can influence the number of records written.

- TCP connections that last 10 seconds or longer will generate an SMF 119 subtype 11 record after the connection has existed for 10 seconds, and this is called a Connection Initiation event; when the TCP connection terminates, it will generate another record, and this is called a Connection Termination event.
- TCP connections that last less than 10 seconds and do not experience a significant change in cryptographic protection during that time generate a single subtype 11 record when the TCP connection terminates. This is called a Short Connection Termination event.
- For EE connections, both a Connection Initiation and a Connection Termination event are generated.
- Any time there is a significant change in the cryptographic protection state after the initial cryptographic state is established, a subtype 11 record will be written to record the new state. This is called a Protection State Change event.
- If a TCP connection matches a zERT enforcement rule that requested an audit record, a subtype 11 record will be written. This is called a zERT Enforcement event.

Restriction: zERT enforcement policy rules are not supported for EE connections.

Each connection-specific subtype 11 record contains information about the connection itself in the zERT Connection Common Section. This includes information like the local and remote connection endpoints, the attributes of the owner of the local socket such as userid and jobname, and information about which cryptographic protocols, if any, are being used to protect the connection.

For connections that have recognized TLS, SSL, SSH or IPSec attributes, the record contains a protocol-specific section that contains important cryptographic attributes of the security session that is protecting the connection. This includes the following attributes:

- Peer authentication method
- Cryptographic algorithms and key lengths in use for encryption, message authentication and key exchange
- Additional useful information like security session lifetime and X.509 certificate serial numbers

For connections where a TLS, SSL, or SSH handshake was attempted but failed, the record contains a protocol-specific section with an indicator that the handshake failed and all cryptographic attributes indicating unknown. This allows a failed handshake to be distinguished from an unprotected connection where no cryptographic protection was attempted.

For connections protected by a security protocol that is using X.509 certificates for peer authentication, an X.509 Distinguished Name (DN) section is included with subject and issuer DNs from the end-entity certificates used for the connections.

Note: zERT does not store or record the values of secret keys, initialization vectors, or any other secret values that are negotiated or derived during cryptographic protocol handshakes.

For TCP connections that map to at least one zERT enforcement rule, the subtype 11 record contains a zERT policy-based enforcement section with the rules to which it was mapped.

Finally, if the connection is subject to an IP filter rule, the subtype 11 record also contains information about the inbound and outbound rules that are controlling the flow of traffic over the connection.

Tip:

1. Since Enterprise Extender (EE) traffic flows over UDP, the only cryptographic protocol that is capable of protecting this traffic is IPSec. As such you may see subtype 11 records for EE connections that have no recognized cryptographic protection, or that are protected by IPSec. In the IPSec case, each subtype 11 record will contain an IP filtering section and an IPSec section. In the case of no recognized protection, the subtype 11 records will have no protocol-specific section and may or may not have an IP filtering section, depending on the local IP filtering policy.
2. Since TCP traffic may be protected by not only IPSec, but also by TLS/SSL and SSH, subtype 11 records may have zero or more protocol-specific sections as described above. They may also have IP filtering sections in the same manner as Enterprise Extender traffic.

Subtype 11 records are also written in two special cases: when zERT discovery is enabled or disabled through the GLOBALCONFIG parameter.

For more information on the SMF 119 zERT connection detail (subtype 11) records, see [zERT connection detail record \(subtype 11\)](#) in [z/OS Communications Server: IP Programmer's Guide and Reference](#).

What are the limitations for zERT discovery?

zERT discovery has the following limitations:

- zERT only monitors TCP and Enterprise Extender (EE) traffic. zERT does not monitor non-EE UDP traffic or any other IP protocol.
- zERT only monitors local traffic, meaning traffic that terminates at the local TCP/IP stack. zERT does not monitor traffic that is being routed through the local TCP/IP stack (this includes traffic that is generated within z/OS Container Extensions).
- zERT monitors for TLS, SSL, SSH and IPsec protection. No other cryptographic security protocols are supported.
- zERT recognition of TLSv1.3 protocols is only available on z/OS V2R4 or later.

The following z/OS cryptographic protocol providers are fully enabled for zERT:

- z/OS Communications Server IPsec
- z/OS Cryptographic Services System SSL (which also covers AT-TLS)
- z/OS OpenSSH
- IBM z/OS JSSE with the ZERTJSSE provider

Other TLS, SSL and SSH implementations running on z/OS are monitored using observational discovery, which provides a more limited set of security attributes. Specifically for the following situations:

- Only initial handshakes are observed. zERT has no visibility to early termination of TLS, SSL or SSH session or changes in security attributes made after the initial handshake is complete since the traffic on the connection is encrypted.
- The number of security attributes observed during the initial handshake is limited. Some attributes are not visible due to the use of encryption during cryptographic protocol negotiations, while others such as distinguished names and serial numbers from X.509 certificates are not observed in order to minimize stream observation's impact on performance.
- Significant portions of TLSv1.3 handshakes are encrypted, meaning zERT has no visibility to those handshake messages. This also means zERT can only infer if the handshake completed successfully.

There are a small number of cases where zERT is unable to monitor System SSL security sessions. These are cases where an application that calls System SSL directly begins a TLS/SSL handshakes in the middle of the application data stream instead of the very beginning of the stream. An API is provided for such applications to notify zERT that the handshake is about to occur. If the application uses that interface, then zERT will have visibility to the System SSL sessions. Otherwise, zERT will not have visibility to such sessions and will report them as having no recognized TLS/SSL protection. For more information about the API for notifying zERT, see [SIOCSHSNOTIFY IOCTL](#) in [z/OS Communications Server: IP Programmer's Guide and Reference](#).

It is important to keep in mind that the number of SMF 119 subtype 11 records generated by the zERT discovery function could be very large, depending on the number of connections supported by your z/OS system as well as the frequency with which those connections are created and deleted. Here are some guidelines for understanding the possible volume of records:

- For TCP connections, at least one subtype 11 record will be written for every connection that lasts less than 10 seconds.
- For every TCP connection that lasts 10 seconds or longer, and for Enterprise Extender connections, at least two subtype 11 records will be written.

- The size of each subtype 11 record depends on the type and number of cryptographic security protocols being used to protect the subject connection. Remember that a single connection can be protected by zero or more protocols. All of the following are valid protection scenarios:
 - A connection is protected by a single TLS, SSL, SSH, or IPsec session.
 - A connection is protected by an IPsec tunnel as well as TLS, SSL or SSH.
 - Although it would be unusual, all three protocols could be applied to a single connection.
 - No cryptographic protection is applied (even in this case, the appropriate subtype 11 records will be written since it is a valid protection state).

If SMF 119 subtype 11 records are only needed for certain types of traffic or only in specific exception cases, you can use zERT policy-based enforcement to generate a targeted set of subtype 11 records.

A second zERT function called zERT aggregation can be used to report zERT information in a summarized format that requires far fewer SMF records than zERT discovery might generate.

What does zERT aggregation collect?

The zERT aggregation function creates summary records of the information collected by the zERT discovery function. The zERT aggregation function summarizes, or aggregates, the zERT discovery information in terms of the security sessions. These summary records are reported at regular intervals as SMF Type 119 subtype 12 records. The reporting interval is the global SMF interval unless a zERT aggregation-specific recording interval is configured with the INTVAL parameter on the GLOBALCONFIG ZERT AGGREGATION statement.

How does zERT aggregation summarize the information?

The zERT discovery information is aggregated into separate security session records according to the following rules:

- The connections must use the same server IP address and client IP address.
- The connections must use the same individual server port or server port range (see [“How does zERT aggregation determine the server port?”](#) on page 193 for more information).
- The job name associated with the local endpoint is the same for all connections.
- The local endpoint acts in the same server or client role for all connections. When the server and client for a TCP connection use the same IP address, separate session records are maintained for the server view and for the client view of the security session.
- The connections must use the same significant security cryptographic attributes for the security session being aggregated.
 - **Significant security cryptographic attributes** are characteristics of the security session, such as cipher, authentication method, etc., that make a substantial difference to the strength of the security coverage being provided by the security session.
 - The zERT discovery function also collects and records **informational security cryptographic attributes**, such as tunnel ID, handshake time limits, etc. These attributes are of interest for a given TCP connection but do not have any impact on the protection strength provided. The zERT aggregation function does not report or consider informational security cryptographic attributes when aggregating connection information.

Consider the following example:

- Client-A at 10.11.1.2 establishes a series of six TCP connections to server at 10.12.3.3 using port 50. All connections use the same TLS security coverage characteristics.
- Client-B at 10.11.1.4 establishes a series of three TCP connections to the same server at 10.12.3.3, port 50. All connections use both IPsec and TLS security coverage.
- Client-C at 10.11.1.4 also establishes three connections to the same server, and all connections use the same IPsec tunnels and TLS sessions as the Client-B connections.

The zERT discovery function would generate at least 12 SMF records for this example if all TCP connections were all short-lived, meaning less than 10 seconds in duration, or at least 24 records if all TCP connections were long-lived (more than 10 seconds in duration).

The zERT aggregation function would instead generate just three SMF records:

- The connections involving Client-A would be aggregated into a single SMF record.
- The connections involving the other clients would be aggregated into two SMF records:
 - One SMF record would report the use of an IPsec tunnel for the connections involving both Client-B and Client-C.
 - One SMF record would report the use of the TLS session for the connections involving both Client-B and Client-C.

How does zERT aggregation provide the information?

You can direct zERT aggregation to write the summarized records to the z/OS System Management Facility, to a network management application using the real-time NMI for zERT summary information, or to both. Regardless of the destination, the information is recorded using SMF 119 subtype 12 (zERT summary) records.

zERT summary records have the following general format:

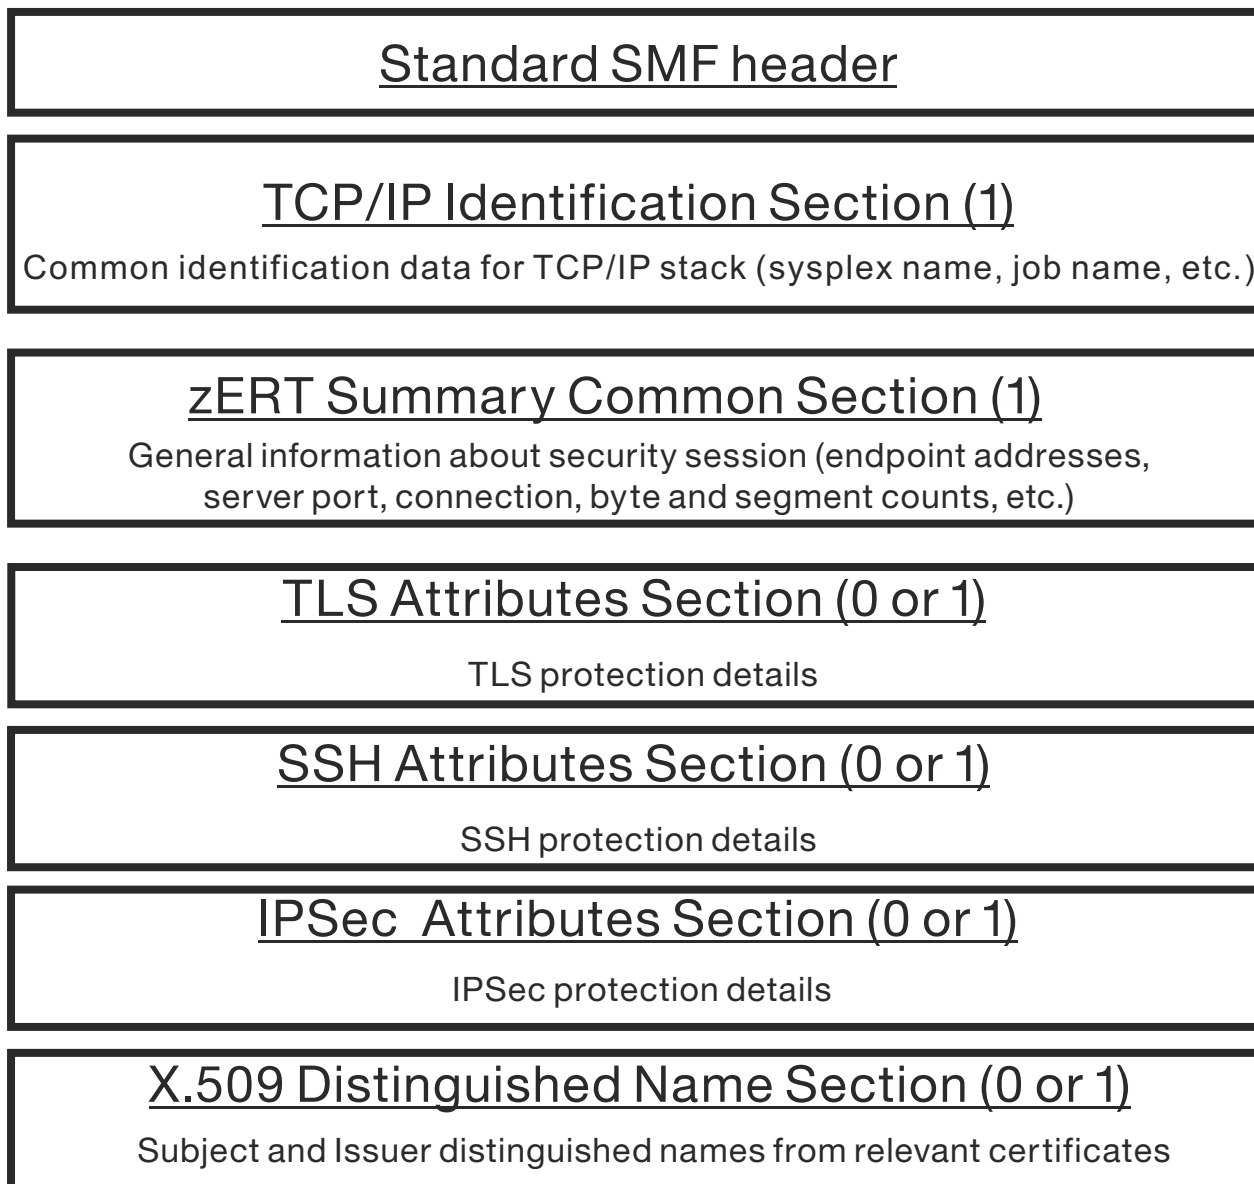

Figure 42. zERT summary (SMF 119 subtype 12) record layout

One zERT summary record is generated at the end of each SMF/INTVAL interval for each unique security session that was used during that interval. Each zERT summary record contains information about the security session in the zERT Summary Common Section. This includes the server and client security session endpoints, the server port or port range, attributes of the owner of the local socket such as userid and job name, and statistical information about the usage of the security session. This statistical information includes the following information for the security session:

- The total number of TCP or EE connections that were ever covered by this session.
- The number of active TCP or EE connections that are covered by this session at the time of reporting.
- The number of partial TCP or EE connections that were ever covered by this session. A *partial TCP connection* is one that changed significant security attributes at some point, for instance changed from having no recognized cryptographic protection to having a recognized cryptographic protection.
- The number of short lived TCP connections that were covered by this session. EE connections are never considered to be short lived connections.
- The number of inbound and outbound data bytes and segments processed by the TCP or EE connections when they were covered by this security session.

- The number of TCP connections with failed TLS or SSH handshakes that were covered by this security session.

The record contains both the values for these statistics at the end of the current reporting period as well as the values at the start of the current reporting period. You can subtract the ending values from the starting values to determine the activity for the SMF interval.

Security sessions that provide no recognized cryptographic protection, meaning they represent connections flowing as clear text or are protected in a way that zERT discovery does not recognize, will only contain the TCP/IP Identification and zERT Summary Common sections. For security sessions that represent TLS, SSL, SSH or IPsec attributes, the record contains a protocol-specific section that records the significant cryptographic attributes of the security session. A special case is security sessions that represent TLS, SSL, or SSH failed handshakes. In this case, the record contains a non-zero failed handshake count in the zERT Summary Common section and a protocol-specific section with all cryptographic attributes indicating unknown.

Guideline: A zERT summary SMF record will have at most one protocol-specific section since it represents a single security session rather than individual connections.

If X.509 Distinguished Names are used by the security session, the record also includes that section.

Subtype 12 records are also written in two special cases: when zERT aggregation is enabled or disabled through the GLOBALCONFIG parameter.

For more information on the SMF 119 zERT summary (subtype 12) records, see [zERT Summary record \(subtype 12\)](#) in *z/OS Communications Server: IP Programmer's Guide and Reference*.

How does zERT aggregation determine the server port?

For most server applications, determining the server port is simple: it is the port that the server is listening on for new TCP connection requests. For FTP processing, however, there are some complications to that simple scheme.

- For IPv4 *active* data connections, meaning those that are not firewall-friendly, the connections are initiated outbound from the FTP server to the FTP client. In this case, even though outbound connections are typically considered to indicate a client connecting outbound to a server, the zERT aggregation function recognizes these outbound connections as server-side connections. For typical FTP servers that listen on port 21, these data connections are aggregated using server-side port 20.
- For IPv4 *passive* data connections, meaning those that are firewall-friendly, or for all IPv6 data connections, the connections are initiated outbound from the FTP client to the FTP server using an ephemeral server port that was previously provided to the client. The z/OS FTP server can be configured, using the PASSIVEDATAPORTS parameter, to limit the ephemeral server port value to a specific range of values. When PASSIVEDATAPORTS is in use:
 - At the FTP server, all inbound data connections using a port within the configured port range are aggregated into a single aggregation record. When the aggregation record is written as an SMF record, the SMF record reports a starting and ending server port range that matches the active PASSIVEDATAPORTS definition.

Results: If multiple FTP servers (for instance, ports 21 and 621) operate at the same server IP address, and one or more FTP servers use the same PASSIVEDATAPORTS range for their data connections, the data connections to the FTP servers with the same PASSIVEDATAPORTS range are aggregated into the same zERT summary SMF record, assuming all other aggregation criteria is the same for the connections. If you want separate zERT summary records for the data connections for the different FTP servers, specify a different PASSIVEDATAPORTS range for each individual FTP server.

- At the FTP client, the use of PASSIVEDATAPORTS by the server to assign the ephemeral port is unknown, so all FTP data connections are aggregated into a single aggregation record. When the aggregation record is written as an SMF record, the SMF record reports a starting and ending server port range equal to the entire ephemeral port range (1024-65535).

Results: If clients connect to multiple FTP servers (for instance, ports 21 and 621) at the same server IP address, all the data connections to the multiple FTP servers are aggregated into the same zERT summary SMF record, assuming all other aggregation criteria is the same for the connections.

How does zERT enforcement work?

zERT enforcement depends upon the data collected by zERT discovery. zERT enforcement policy rules describe acceptable or unacceptable cryptographic protection attributes for different types of z/OS connections and any appropriate actions to take when a connection matches the rule. You create zERT enforcement rules and actions through the IBM Configuration Assistant for z/OS Communications Server in z/OSMF. These rules should reflect your local network encryption standards and requirements. Once the rules and actions are defined, the NCA creates a policy file that is stored on the z/OS system and processed by the Policy Agent. The Policy Agent processing installs the zERT enforcement rules into the TCP/IP stack which then compares each new TCP connection that terminates on that stack against the set of zERT enforcement rules. If the connection matches a rule, the actions associated with that rule are taken. The following actions are supported:

- Log a message through syslogd
- Log a message to the console (TCP/IP job log)
- Write an audit record (SMF zERT Connection Detail (type 119, subtype 11) with an event type 7 which indicates that it was written by zERT Enforcement)
- Reset the connection

These actions can be used in combination on a single rule. The default action is to silently allow the connection.

A connection is evaluated against zERT enforcement policy rules based on the security protocol(s) used to protect it. If a connection is protected by multiple protocols, it could match to more than one rule.

For example: when a connection is protected by IPsec and TLS, the connection can map to a zERT enforcement rule for IPsec and a zERT enforcement rule for TLS. If both the rules request an audit action, then two zERT Enforcement records will be written for the connection.

For a connection where a TLS, SSL, or SSH handshake is attempted but fails, the connection is evaluated against the zERT enforcement policy rules for the security protocol that is attempted. No cryptographic information beyond the attempted handshake type (TLS or SSH) is known for a failed handshake. For example, a connection with a failed attempt to negotiate a TLS security session will not match a TLS rule with specific TLS protocol values defined. However, it will match a TLS rule with no other characteristics defined.

zERT enforcement can act upon the data collected by zERT observational discovery and from the IPsec function within the TCP/IP stack.

Restriction: zERT enforcement policy rules are not supported for Enterprise Extender (EE) connections.

Using z/OS Encryption Readiness Technology

Separate parameters in the TCP/IP profile control whether zERT discovery or aggregation is enabled and where the SMF 119 subtype 11 or 12 records should be written. If you want to collect zERT information, it is important to remember to not only enable zERT discovery or aggregation, but also to enable recording to one or both of SMF and real-time NMI, since each of these have separate controls. To use zERT policy-based enforcement, zERT discovery must be enabled and the Policy Agent must be configured to process and install the zERT enforcement policy you create through the IBM Configuration Assistant for z/OS Communications Server in z/OSMF.

Enabling zERT discovery

You turn the zERT discovery function on in the TCP/IP stack by specifying the GLOBALCONFIG ZERT parameter in the TCP/IP profile data set. Enabling zERT causes the TCP/IP stack to record and collect cryptographic protection information for new TCP and Enterprise Extender connections that terminate at the stack.

Guidelines:

- Enabling zERT discovery is required for zERT aggregation, but does not automatically enable zERT aggregation. See [“Enabling zERT aggregation”](#) on page 195 for details.
- Enabling zERT discovery is required to use zERT policy-based enforcement but there are additional requirements. See [“Enabling zERT policy-based enforcement”](#) on page 196 for details.

Results: If you dynamically enable zERT discovery using VARY OBEYFILE, zERT does not collect information about TCP and Enterprise Extender connections that were established before enabling zERT.

For more information on enabling zERT, see [GLOBALCONFIG statement in z/OS Communications Server: IP Configuration Reference](#).

Enabling zERT aggregation

You turn the zERT aggregation function on in the TCP/IP stack by specifying the GLOBALCONFIG ZERT AGGREGATION parameter in the TCP/IP profile data set. Enabling zERT aggregation causes the TCP/IP stack to collect cryptographic protection summary information for security sessions involving TCP and Enterprise Extender connections that terminate at the stack.

Guideline: Because zERT aggregation summarizes information collected by zERT discovery processing, zERT discovery must be enabled for zERT aggregation to operate; however, you do not have to enable SMF recording of zERT connection detail records for zERT aggregation to function correctly.

Results: If you dynamically enable zERT aggregation using VARY OBEYFILE, zERT does not collect summary information about TCP and Enterprise Extender connections that were established before enabling zERT aggregation.

Defining the zERT aggregation recording interval

By default, zERT aggregation writes the data it has collected in the form of SMF 119 subtype 12 (zERT summary) records on each SMF interval. If you want to reduce the frequency at which these records are written, you can specify a zERT aggregation-specific recording interval between 1 and 24 hours (in one hour increments) by specifying the INTVAL sub-parameter of the GLOBALCONFIG ZERT AGGREGATION parameter in the TCP/IP profile data set.

Specifying a long INTVAL value (for example, 12 or 24 hours) can greatly reduce the amount of generated SMF data compared to relying on the system's SMF interval. This reduction can also improve import and query performance of the IBM zERT Network Analyzer. Since the maximum SMF interval is 60 minutes, relying on that interval would generate at least 24 SMF 119-12 records per day for a security session that is active throughout the entire 24 hour period. Your systems may use a shorter SMF interval, which would result in even more records. In contrast, by specifying INTVAL 24, you reduce that number to a single SMF 119-12 record per 24 hours. For systems that have thousands of unique security sessions per day, this can result in a huge reduction in the amount of data over which the zERT Network Analyzer needs to operate.

If you specify an INTVAL value, it is recommended that the value divides evenly into 24 hours to ensure the SMF 119-12 records are written at the same times each day.

To specify exactly when the INTVAL intervals are to begin, you can specify the SYNCVAL sub-parameter of INTVAL. SYNCVAL defines the reference time from which the INTVAL intervals begin to be applied. SYNCVAL is specified as a time of day in 24 hour clock format (hh:mm). For example, if SYNCVAL is specified as 06:00 (6 AM) and INTVAL is set to 12 hours, then zERT aggregation will write its SMF records at 6 AM and 6 PM daily. If not specified, the default SYNCVAL is midnight (00:00).

For more information on enabling zERT aggregation, see [GLOBALCONFIG statement in z/OS Communications Server: IP Configuration Reference](#).

Decreasing the frequency at which zERT summary records are written may increase the amount of 64-bit pageable, private memory needed, because the zERT aggregation information is held longer in memory before being written out to SMF. Any increase in memory usage will be dependent on the nature of network connections as well as the length of the recording interval. Environments where the majority of the connection patterns are consistent throughout a 24 hour period will require less memory than those

where connection patterns vary significantly throughout the day. A longer recording interval increases the likelihood of greater memory consumption. In environments where 64-bit private storage is limited, consider configuring a smaller zERT aggregation recording interval in order to allow for more frequent flushing of zERT Aggregation information.

For more information on displaying zERT aggregation storage information, see [DISPLAY TCPIP,,STOR command](#) in [z/OS Communications Server: IP System Administrator's Commands](#).

Enabling zERT policy-based enforcement

A few steps are required to enable zERT policy-based enforcement:

1. Since zERT enforcement depends on data that zERT discovery collects for each TCP connection, the first step is to enable zERT discovery as described in [“Enabling zERT discovery”](#) on page 194.
2. Configure the Policy Agent with the name of the z/OS Unix file or z/OS dataset that contains the zERT enforcement policy rules and actions. Specify the policy file path or data set name on the ZERTConfig statement in the image configuration file for the affected TCP/IP stack.
3. If you plan to use the audit action on any of your zERT enforcement rules, specify the appropriate by policy parameters on the SMFCONFIG and/or NETMONITOR statements in the TCP/IP profile data set. See [“Selecting a destination for zERT discovery SMF records”](#) on page 196 for more information.
4. Use the IBM Configuration Assistant for z/OS Communications Server in z/OSMF to create your zERT enforcement policy rules and save the generated zERT enforcement policy file in the file or data set specified in step 2 above.
5. Start or refresh the Policy Agent to process and install your zERT enforcement policy rules.

Selecting a destination for zERT discovery SMF records

If you enable zERT discovery, then you can decide where you want the collected data to be recorded as SMF 119 subtype 11 records. By default, the SMF records are not written anywhere, so you must choose one of the following destinations in order to get the SMF records.

- If you want the zERT connection detail (SMF 119 subtype 11) records to be written to the z/OS System Management Facility for connection initiation, termination and when security characteristics for the connection change (event types 1-4), specify the SMFCONFIG TYPE119 ZERTDETAIL parameter in the TCP/IP profile data set. Note that you must also have the recording of SMF 119 records specified in your SMF parmlib member.
- If you want the policy-driven zERT connection detail records (SMF 119 subtype 11, event type 7) to be written to the z/OS System Management Facility, specify the SMFCONFIG TYPE119 ZERTDETAILBYPOLICY parameter in the TCP/IP profile data set.

Note: You must also have the recording of SMF 119 records specified in your SMF parmlib member.

- If you use a network management application that consumes zERT connection detail SMF records for connection initiation, termination, and when security characteristics for the connection change (event types 1-4) through the real-time zERT Detail NMI service (SYSTCPER), specify the NETMONITOR ZERTSERVICE parameter in the TCP/IP profile data set. When this service is active, network management applications with the necessary SAF permission can connect to the service to receive zERT connection detail SMF records in near real-time.
- If you use a network management application that consumes policy-driven zERT connection detail SMF records through the real-time zERT Detail NMI service (SYSTCPER), specify the NETMONITOR ZERTSERVICEBYPOLICY parameter in the TCP/IP profile data set. When this service is active, network management applications with the necessary SAF permission can connect to the service to receive zERT connection detail SMF records in near real-time.

Note: If GLOBALCONFIG ZERT is not configured, then no zERT information will be collected, so even if you configure a recording destination, no SMF 119 subtype 11 records are generated.

For more information on configuring SMFCONFIG or NETMONITOR, see [SMFCONFIG statement](#) and [NETMONITOR statement](#) in [z/OS Communications Server: IP Configuration Reference](#).

Selecting a destination for zERT aggregation SMF records

If you enable zERT aggregation, then you can decide where you want the collected data to be written as SMF 119 subtype 12 records. By default, the SMF records are not written anywhere, so you must choose one of the following destinations in order to get the SMF records.

- If you want the zERT summary (SMF 119 subtype 12) records to be written to the z/OS System Management Facility, specify the SMFCONFIG ZERTSUMMARY parameter in the TCP/IP profile data set.

Note: You must also enable the recording of SMF 119 records, and enable interval record processing, in your SMF parmlib member.

Note: If you want to use IBM zERT Network Analyzer, you must specify the SMFCONFIG ZERTSUMMARY parameter in the TCP/IP profile data set.

- If you use a network management application that consumes zERT summary SMF records through the real-time zERT Summary NMI service, specify the NETMONITOR ZERTSUMMARY parameter in the TCP/IP profile data set. When this service is active, network management applications with the necessary SAF permission can connect to the service to receive zERT summary SMF records in near real-time.

Note: You must also enable interval record processing in your SMF parmlib member.

Note: If GLOBALCONFIG ZERT AGGREGATION is not configured, then no zERT aggregation information will be collected, so even if you configure a recording destination, no SMF 119 subtype 12 records are generated.

Results: If you dynamically change your destination selection by specifying SMFCONFIG NOZERTSUMMARY, a final set of zERT summary SMF records are written to the z/OS System Management Facility. This final set is not written to the real-time zERT Summary NMI service if that has also been selected as a destination for the zERT summary records.

For more information on configuring SMFCONFIG or NETMONITOR, see [SMFCONFIG statement](#) and [NETMONITOR statement](#) in [z/OS Communications Server: IP Configuration Reference](#).

Disabling zERT discovery

You turn the zERT discovery function off in the TCP/IP stack by specifying the GLOBALCONFIG NOZERT parameter in the TCP/IP profile data set.

Guideline: zERT discovery is disabled by default.

Results:

- Disabling zERT discovery also disables zERT aggregation.
- Disabling zERT discovery also disables the data collection upon which zERT policy-based enforcement depends.

Disabling zERT discovery causes the TCP/IP stack to not monitor the cryptographic characteristics of TCP and Enterprise Extender connections that terminate at the stack.

Results: If you dynamically disable zERT discovery using VARY OBEYFILE, any previous information collected by zERT discovery and aggregation is discarded.

For more information on disabling zERT, see [GLOBALCONFIG statement](#) in [z/OS Communications Server: IP Configuration Reference](#).

Disabling zERT aggregation

You turn off the zERT aggregation function in the TCP/IP stack by either specifying either the GLOBALCONFIG ZERT NOAGGREGATION parameter or the GLOBALCONFIG NOZERT parameter in the TCP/IP profile data set.

Guideline: This is the default behavior.

Results: Using GLOBALCONFIG ZERT NOAGGREGATION to disable zERT aggregation has no effect on zERT discovery processing or zERT enforcement.

Disabling zERT aggregation causes the TCP/IP stack to not maintain summary statistics of the cryptographic characteristics of TCP and Enterprise Extender security sessions that terminate at the stack. Before disabling the zERT aggregation function, a final set of SMF Type 119 subtype 12 records is generated, if recording of zERT summary records is active. The final set of records is written to the z/OS System Management Facility (SMF), the real-time zERT Summary NMI service, or both, depending on your choice of destination at the time zERT aggregation is disabled.

Results: If you dynamically disable zERT aggregation or zERT discovery using VARY OBEYFILE, any previous information collected by zERT aggregation is discarded.

For more information on disabling zERT aggregation, see [GLOBALCONFIG statement in z/OS Communications Server: IP Configuration Reference](#).

Using IBM zERT Network Analyzer

z/OS Management Facility (z/OSMF) provides a web browser interface for a variety of z/OS system management functions. IBM zERT Network Analyzer runs as a z/OSMF task and provides a structured interface for analyzing cryptographic protection data about your TCP and Enterprise Extender (EE) traffic that is collected in the form of zERT summary (Type 119 subtype 12) SMF records.

You can use the IBM zERT Network Analyzer task to perform the following functions:

- Import one or more SMF dump data sets into the IBM zERT Network Analyzer database. As the SMF data set is imported, IBM zERT Network Analyzer extracts information from the zERT Summary SMF records in the data sets and organizes the information into representations of security sessions reported in the SMF records.
 - If the SMF records are written to an SMF data set, the records must be dumped to the data set using the IFASMFDP program.
 - If the SMF records are written to an SMF log stream, the records must be dumped to the data stream using the IFASMFDL program.
- **Note:** SMF data sets that you intend to import into IBM zERT Network Analyzer must be a cataloged sequential file.
- Create and run queries to filter the imported security session data by date, system, endpoint or cryptographic protection attributes.
- Examine the results of your query.
 - The summary view provides an overall view of security sessions organized by endpoint role of the local z/OS system: TCP server, TCP client, or Enterprise Extender (EE) peer.
 - Expand each summary row to examine details about the foreign endpoints that established connections with the local endpoint in the summary row.
 - The security session view provides the cryptographic details about the security sessions that are used by the application connections.
- Export your query results to a comma-separated values (CSV) format file for additional analysis using a spreadsheet or analysis tool of your choice.

For additional information about using IBM zERT Network Analyzer in z/OSMF, see [IBM z/OS Management Facility Configuration Guide](#).

Defining a zERT enforcement policy

Options for configuring a zERT enforcement policy

zERT enforcement is configured using a set of configuration statements and parameters coded in a file, which is parsed by the Policy Agent to establish the zERT enforcement policy for each TCP/IP stack. There are two alternatives for creating the Policy Agent files.

- [“Option 1: Use the IBM Configuration Assistant for z/OS Communications Server” on page 199](#)
- [“Option 2: Manual configuration” on page 199](#)
- The policy agent configuration must also be considered when configuring zERT enforcement policy. See [“Specifying the zERT enforcement configuration file based on Policy Agent role” on page 199](#).

Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server (Network Configuration Assistant), an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the Network Configuration Assistant to generate the Policy Agent files.

The Network Configuration Assistant is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the Network Configuration Assistant in z/OSMF, the Network Configuration Assistant runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the Network Configuration Assistant to create zERT policy configuration files for any number of z/OS images with any number of TCP/IP stacks per image. The Network Configuration Assistant provides the following reusable objects for the zERT enforcement technology:

- Traffic descriptors that define a traffic pattern or application, by describing the TCP traffic with ports, jobname, userid, and the direction the connection is established.
- Protection characteristics that describe how the traffic is protected including the symmetric encryption, message authentication, and key exchange algorithms.
- Address groups that define one or more IP addresses or subnets.
- Reusable rules that link the characteristics of an application (traffic descriptor and IP addresses), protection characteristics, and the actions to take.
- Reusable rule sets group together all rules for a particular security protocol. There can be a rule set for the TLS/SSL protocol, for the IPsec protocol, and for the SSH protocol. There can also be a rule set for traffic that has no recognized protection, which will be referred to as having a "None" security protocol.

For each TCP/IP stack, you can include up to four reusable rule sets, one for each security protocol – TLS/SSL, IPsec, SSH, and None. If a rule set is included for a security protocol, then the rule set will be searched for each TCP connection protected by that protocol.

The Network Configuration Assistant comes with a number of IBM-supplied traffic descriptors that are easily applied. You can also create your own traffic descriptors.

The Network Configuration Assistant can dramatically reduce the amount of time that is required to create zERT enforcement policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing zERT policy-based enforcement.

Option 2: Manual configuration

You can manually create the zERT enforcement policy configuration files by coding all the required statements in a z/OS UNIX file or MVS™ data set. [zERT enforcement rules and zERT enforcement actions](#) provide guidance on manually configuring the zERT enforcement policy, along with general tips that are helpful regardless of the configuration option being used. For details about the [zERT policy statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Specifying the zERT enforcement configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see [“Policy types and infrastructure overview” on page 813](#). Regardless of which option is used to configure zERT enforcement policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are not using a policy client/policy server environment, specify the configuration files using the ZERTConfig statement on the single Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves zERT enforcement policies from the policy server, specify the configuration files using the DynamicConfigPolicyLoad statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve zERT enforcement policies from the policy server, specify the configuration files using the ZERTConfig statement on the policy client.

When information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

Configuring a zERT enforcement policy

zERT enforcement policies are processed by Policy Agent and installed into a z/OS Communications Server TCP/IP stack.

Within the zERT enforcement policy file, zERT rules are defined for different security protocols:

- TLS/SSL
- IPsec
- SSH

zERT enforcement rules can also be defined for connections that have no recognized cryptographic protection. This will be referred to as security protocol None.

It is helpful to design your zERT enforcement rules by security protocol. For example, if you use both TLS and IPsec to protect TCP traffic, you can create a group of rules that describe your TLS/SSL requirements and a group of rules that describe your IPsec requirements. This grouping of rules by security protocol, or "rule sets", reflect the way the TCP/IP stack evaluates zERT enforcement rules. When a specific type of cryptographic protection is detected for a TCP connection, or when it is determined that there is no recognized cryptographic protection for a TCP connection, the TCP/IP stack evaluates the connection and its protection attributes against rules in the appropriate rule set.

The grouping of rules into a rule set in the policy agent file is based on the setting of the SecurityProtocol parameter on the ZERTRule. You can configure one or more of the following types of rule sets:

- TLS rule set (zERT enforcement rules with a SecurityProtocol of TLS) - Rules within this rule set are searched when zERT discovery detects that a TCP connection is protected by TLS or SSL.
- IPsec rule set (zERT enforcement rules with a SecurityProtocol of IPsec) - Rules within this rule set are searched when zERT discovery detects that a TCP connection is protected by IPsec.
- SSH rule set (zERT enforcement rules with a SecurityProtocol of SSH) - Rules within this rule set are searched when zERT discovery detects that a TCP connection is protected by SSH.
- No recognized protection rule set (zERT enforcement rules with a SecurityProtocol of None) - Rules within this rule set are searched when zERT discovery determines that a TCP connection has no recognized cryptographic protection.

An effective approach for creating a rule set is to use a model where you have a general rule that covers the acceptable levels of protection for the security protocol, followed by one or more specific rules that define exceptions to the general rule. These rules can either define an exception that is acceptable or one that requires notification for further investigation. Finally, you can have a catch-all rule. Any connection that does not match the general rule or the specific rules will match the catch-all rule.

For example, the general rule in a TLS rule set might indicate that TLSv1.2 and TLSv1.3 are the acceptable TLS versions. This general rule might also include various acceptable algorithms. A specific rule might allow clients connecting to a specific application from a defined subnet to use TLSv1.1. A second specific rule might ban all use of SSLv2 and SSLv3. Finally, a catch-all rule might audit any connections using TLS that do not match the higher priority rules in the TLS/SSL rule set.

Tip: The IBM Configuration Assistant for z/OS Communications Server helps you create and organize rule sets, as well as, configuring general, specific, and catch-all rules.

zERT enforcement rules

This topic provides guidance on manually configuring a zERT enforcement rule, along with general tips that are helpful for both manual configuration and configuration with the Network Configuration Assistant. For details about zERT enforcement policy statements, see [zERT policy statement in z/OS Communications Server: IP Configuration Reference](#).

A ZERTRule statement consists of a set of conditions that are compared against a TCP connection. When a connection's attributes match the conditions specified in a rule, zERT enforces the actions configured on the ZERTAction referenced by the rule. The rule conditions must include SecurityProtocol with one of the following values - TLS, IPsec, SSH, or None.

A ZERTRule with SecurityProtocol TLS can include the following additional conditions which describe the TLS cryptographic protection characteristics for a connection that matches the rule:

- ZERTTLSProtocol – one or more TLS protocol versions, such as TLSv1.2
- ZERTSymmetricEncryption – one or more symmetric encryption algorithms, such as AES_GCM_128
- ZERTMessageAuthentication – one or more message authentication algorithms, such as HMAC_SHA2_256
- ZERTKeyExchange – one or more key exchange algorithms, such as ECDHE_RSA

A ZERTRule with SecurityProtocol SSH can include the following additional conditions which describe the SSH cryptographic protection characteristics for a connection that matches the rule:

- ZERTSSHProtocol – one or more SSH protocol versions, such as SSHv2
- ZERTSymmetricEncryption – one or more symmetric encryption algorithms, such as AES_CTR_256
- ZERTMessageAuthentication – one or more message authentication algorithms, such as HMAC_SHA2_256
- ZERTKeyExchange – one or more key exchange algorithms, such as Curve_25519_SHA256

A ZERTRule with SecurityProtocol IPsec can include the following additional conditions which describe the IPsec cryptographic protection characteristics for a connection that matches the rule. Note that these are the characteristics negotiated for a phase 2 IPsec tunnel which protects the connection data:

- ZERTSymmetricEncryption – one or more symmetric encryption algorithms, such as AES_CBC_256
- ZERTMessageAuthentication – one or more message authentication algorithms, such as HMAC_SHA2_384_192

A rule with SecurityProtocol None has no recognized cryptographic protection, so none of the cryptographic protection conditions are allowed.

All ZERT rules, regardless of the SecurityProtocol setting can also include the following conditions which describe the traffic characteristics of a connection that matches the rule:

- LocalAddr - Local IP address or addresses
- RemoteAddr - Remote IP address or addresses
- Protocol – Transport protocol (TCP is the only supported value)
- LocalPortRange - Local port or ports
- RemotePortRange - Remote port or ports
- Jobname - Job name of the local z/OS application
- Userid – z/OS user ID that opened the local socket
- TcpConnectionDirection – Direction in which the TCP connection is initiated

The LocalAddr and RemoteAddr can be specified directly on the ZERTRule. The other conditions are parameters on a ConnectionDescriptor statement.

Each ZERTRule statement also has a priority which determines the order in which the rules are searched within a rule set. Priority values can be integers in the range 1 - 2000000000, with 2000000000 being the highest priority. When assigning priorities, you should skip some values to allow for future rule insertion between existing rules.

Finally, the ZERTRule references a ZERTAction which indicates the actions that should be taken for connections that match the ZERTRule.

If you are using a model where you have a general rule to cover the acceptable levels of protection for a security protocol, the rule would typically indicate the cryptographic protection characteristics but not include any traffic characteristic conditions. Specific rules that define exceptions to the general rule would use a combination of traffic characteristics and cryptographic protection characteristics to describe the connections that map to the rule. A catch-all rule, intended to match any connection that does not match the general or specific rules, would include only the SecurityProtocol value with no traffic characteristic conditions and no protection conditions.

zERT enforcement actions

This topic provides guidance on manually configuring a zERT enforcement rule, along with general tips that are helpful for both manual configuration and configuration with the Network Configuration Assistant. For details about zERT enforcement policy statements, see [zERT policy statement in z/OS Communications Server: IP Configuration Reference](#).

The ZERTAction provides the following actions that can be taken when a TCP connection matches a zERT enforcement rule.

- Write an audit record to SMF and/or the NMI SYSTCPER service. The audit record is an SMF zERT Connection Detail record (type 119, subtype 11) with an event type 7. This action is configured with the AuditRecord parameter and is off by default.

Restriction:

- SMFCONFIG TYPE119 ZERTDETAILBYPOLICY must be configured in the TCP/IP profile for SMF records to be generated.
- NETMONITOR ZERTSERVICEBYPOLICY must be configured in the TCP/IP profile for the records to be written to the SYSTCPER NMI service.
- Log a message through syslogd. This action is configured with the LogSyslogd parameter and is off by default. If ResetTCPConn is also specified as an action, message 'EZZ8584I Connection reset by ZERT Policy Enforcement' is written. Otherwise, message 'EZZ8583I Connection logged by ZERT Policy Enforcement' is written. Both messages include a detailed description of the TCP connection characteristics (such as IP addresses, ports, etc) and the cryptographic protection being used for the connection. The message is logged to syslogd using facility LOCAL5. The syslogd priority is determined by the LogLevel parameter.

Restriction:

- The syslog daemon must be started. See [Syslog daemon in z/OS Communications Server: IP Configuration Reference](#) for more information.
- TRMD must be started for the affected TCP/IP stack. See [Starting the traffic regulation manager daemon \(TRMD\) from the z/OS® shell or Starting the traffic regulation manager daemon \(TRMD\) as a started task in z/OS Communications Server: IP Configuration Reference](#) for more information.

Tip: To avoid flooding syslogd, zERT enforcement limits the number of messages that are written to syslogd during a 5-minute interval. See [zERT enforcement syslogd message suppression](#) for a description of the message suppression approach. If a complete record of connections matching this ZERT rule is needed, use AuditRecord action.

- Log a message to the console (i.e. TCP/IP job log). This action is configured with the LogConsole parameter and is off by default. If ResetTCPConn is also specified as an action, message EZZ856I CONN RESET BY ZERT POLICY is written. Otherwise, message EZZ8551I CONN LOGGED BY ZERT POLICY is written. Both are multi-line messages that include a detailed description of the TCP connection characteristics (such as IP addresses, ports, etc) and the cryptographic protection being used for the connection.

Tips:

- To avoid flooding the TCP/IP joblog, zERT enforcement limits the number of messages that are written to the joblog during a 5-minute interval. See [zERT enforcement syslogd message suppression](#)

for a description of the message suppression approach. If a complete record of connections matching this ZERT rule is needed, use AuditRecord action.

- To prevent the TCP/IP job log from growing very large and filling up the spool space, ensure that the TCP/IP job log is being spun-off on a regular basis. See [Writing your own master scheduler JCL in z/OS MVS Initialization and Tuning Reference](#), [Determining the source JCL for the started task in z/OS MVS JCL Reference](#) and [JESLOG parameter in z/OS MVS JCL Reference](#) for more information.
- Reset the TCP connection. This action is configured with the ResetTCPConn parameter and is off by default.

Tips:

- Before enabling the ResetTCPConn action, enable logging or auditing for the rule for a trial period to ensure that no legitimate connections are matching the rule.
- When the ResetTCPConn action is enabled, enable logging to the console (LogConsole) or syslogd (LogSyslogd) as well to provide notification that a TCP connection has been reset.

For a ZERTRule that describes acceptable cryptographic protection, you might want to use the default settings for the actions which silently allow the connection. For a ZERTRule that describes traffic where notification is required, you can enable one or more of the log and audit actions. For a ZERTRule that describes traffic that is unacceptable and should be blocked, the reset TCP connection action and one of the log actions can be enabled.

Additional zERT enforcement policy considerations

Discretionary TLS

Certain applications can turn TLS protection on and off during the lifetime of a connection. This is referred to as "discretionary TLS". Common examples of applications that use discretionary TLS are:

- File Transfer Protocol (FTP): FTP always begins with an FTP 220 response being sent from the FTP server to the client in the clear. After that, a TLS session can be established. The TLS session might be used to protect the user logon and password. The TLS session could then be cleared allowing additional data to be sent in the clear. Or the TLS session could remain in effect throughout the life of the connection.
- Simple Mail Transfer Protocol (SMTP): SMTP can switch TLS on and off by using the STARTTLS command. An example of a use case is SMTP connecting to different mail servers with different levels of security supported or required.
- Some modes of TN3270E connections negotiate the use of TLS, requiring a small amount of cleartext traffic before TLS is enabled. Once the connection security is enabled, it remains enabled for the life of the connection.
- IBM Sterling Connect:Direct® connections always begin with a small amount of cleartext before connection security (which could be TLS) is enabled. Once the connection security is enabled, it remains enabled for the life of the connection.

In many cases an application that uses discretionary TLS starts in the clear, and then switch TLS on. It might reset TLS security again later and possibly repeat the pattern. Each time a connection changes its security characteristics, zERT is notified and evaluates the connection against your zERT enforcement policy rules.

Your zERT enforcement policy must account for these discretionary TLS applications in both the zERT TLS rule set and the zERT rule set for "No recognized protection" (or None rule set). For example, you cannot ban FTP traffic in the clear because FTP always begins in the clear and can then transition to TLS. You can ensure that if TLS protection is being used for FTP that it is an acceptable TLS version with acceptable cryptographic protection characteristics.

If you have a rule set defined for the None security protocol and if those rules do not generally allow connections with no recognized protection, you need a specific rule with Security Protocol None to allow a discretionary TLS connection to run in the clear without being reset. In most cases, you would also want

to avoid any logging or auditing actions for such a rule as well. And, you also need a TLS rule for the same connection to verify that it is using acceptable levels of protection, when it is protected by TLS.

Tip: The Network Configuration Assistant provides checking and guidance for Discretionary TLS applications for your zERT enforcement policy.

zERT enforcement syslogd message suppression

Under certain conditions, zERT enforcement suppresses syslogd messages to avoid flooding the syslogd daemon.

Within a 5-minute interval, a maximum of 10 syslogd messages are written by a single zERT enforcement rule and a maximum of 100 syslogd messages are written across all zERT enforcement rules. An exception is made to ensure that at least one syslogd message is written for every unique zERT enforcement rule that is matched within the 5-minute interval. So, if the 100-message limit has already been reached when a connection maps to a rule with a syslogd logging action and that rule has not yet been matched during the interval, a message will be written for that connection. Any subsequent matches to that rule during the 5-minute interval will be suppressed.

Logging to syslogd resumes after the 5-minute interval ends. When a connection maps to a rule for which syslogd messages were suppressed in the previous interval, message EZZ8585I is written to syslogd for that rule. It includes the count of suppressed syslogd messages, the name of the zERT enforcement rule, and an indication of whether the rule had a reset TCP connection action or not.

Messages in syslogd can provide an awareness that connections are matching a particular zERT enforcement rule. However, a complete record of matching connections cannot be guaranteed with the syslogd logging action due to built-in message suppression. If a complete record of connections matching a rule is needed, enable the audit action for the rule.

zERT enforcement console message suppression

Under certain conditions, zERT enforcement suppresses console messages to avoid flooding the TCP/IP job log.

Within a 5-minute interval, a maximum of 10 console messages are written by a single zERT enforcement rule and a maximum of 100 console messages are written across all zERT enforcement rules. An exception is made to ensure that at least one console message is written for every unique zERT enforcement rule that is matched within the 5-minute interval. So, if the 100-message limit has already been reached when a connection maps to a rule with a console logging action and that rule has not yet been matched during the interval, a message will be written for that connection. Any subsequent matches to that rule during the 5-minute interval will be suppressed.

Logging to the console resumes after the 5-minute interval ends. When a connection maps to a rule for which console messages were suppressed in the previous interval, message EZZ8564I is written to the TCP/IP job log for that rule. It includes the count of suppressed console messages, the name of the zERT enforcement rule, and an indication of whether the rule had a reset TCP connection action or not.

Messages in the TCP/IP job log can provide an awareness that connections are matching a particular zERT enforcement rule. However, a complete record of matching connections cannot be guaranteed with the console logging action due to built-in message suppression. If a complete record of connections matching a rule is needed, enable the audit action for the rule.

Relationship between zERT enforcement policy and AT-TLS and IP Security policies

At first glance, it might appear that zERT enforcement policy overlaps or even clashes with AT-TLS policy or IPsec policy. While it is true that all these policies focus on cryptographic protection of z/OS IP traffic, the perspective that each policy takes is the differentiator.

AT-TLS and IPsec policies apply cryptographic protection to TCP connections (AT-TLS and IPsec) and other IP traffic (IPsec only) when those connections or traffic flow through the z/OS TCP/IP stack.

zERT policy analyzes the established cryptographic protection of each TCP connection and, if so configured, provides notifications or even defensive actions when specific cryptographic conditions match a zERT enforcement rule. Another key point regarding zERT enforcement is that it applies to all TLS/SSL

protection, whether that protection was applied by AT-TLS, JSSE, direct application calls to System SSL, or even the use of third-party TLS libraries like OpenSSL. Similarly, zERT enforcement applies to all SSH protection, whether provided by IBM z/OS OpenSSH or a third party SSH implementation running on z/OS.

Security event reporting: Integrated intrusion detection services

Intrusion is a broad term encompassing many undesirable activities. The objective of an intrusion may be to acquire information that a person is not authorized to have (*information theft*). It may be to cause business harm by rendering a network, system or application unusable (*denial of service*). Or it may be to gain unauthorized use of a system as a stepping stone for further intrusions elsewhere. Most intrusions follow a pattern of information gathering, attempted access and then destructive attacks. Some attacks can be detected and neutralized by the target system. Other attacks cannot be effectively neutralized by the target system. Many of the attacks also make use of spoofed packets which are not easily traceable to their true origin. Many attacks now make use of unwitting accomplices - machines or networks that are used without authorization to hide the identity of the attacker. For these reasons, detecting information gathering, access attempts and attack accomplice behaviors is a vital part of intrusion detection.

Attacks can be initiated from outside the internal network or from inside the internal network. Particularly vulnerable is an open system such as a public web server or any machine that is placed in service to serve those outside the internal network. A firewall can provide some level of protection against attacks from outside. However, it cannot prevent attacks after the firewall has authorized an external host to communicate with hosts in the internal network, nor can it provide protection in the case where the attack is initiated from inside the network. In addition, end to end encryption limits the types of attacks that can be detected by an intermediate device such as a firewall.

An intrusion detection system can provide detection of some types of attacks. Common intrusion detection system types currently deployed are network sniffers or sensors and vulnerability scanners. Sniffers, placed at strategic points in the network (in front or behind a firewall, in the network, or in front of a host), operate in promiscuous mode, examining traffic real time that passes through on the local network. Sniffers use *pattern matching* to try to match a packet against a known attack which is expressed as an *attack signature*. Sniffers work best against single packet attacks. Limitations are that they cannot deflect the attacking packet, and they cannot evaluate against encrypted data. Scanners do not detect intrusions in real time. They examine a system periodically looking for vulnerabilities or evidence of intrusion. Some scanners evaluate historical data and can identify behavioral anomalies and patterns associated with intrusions.

The z/OS Communications Server provides intrusion detection services (IDS) that enable the detection of attacks and the application of defensive mechanisms on the z/OS server. The focus of IDS is self-protection. IDS can be used alone or in combination with an external network-based intrusion detection system. The IDS is integrated into the z/OS Communications Server stack and can provide the following functions that are unavailable from an external intrusion detection system.

- z/OS CS IDS evaluates data that has been encrypted by IPsec end to end after decryption on the target server system.
- z/OS CS IDS avoids the overhead of per packet examination against a table of signatures for many known attacks. This is accomplished by integrating the attack detection probes into existing error detection logic. This detection is done in real time. IDS policy is examined when an attack is detected to determine the action to be taken.
- z/OS CS IDS detects statistical anomalies real time. Real-time detection is achieved because it is easier for the target system to keep stateful data/internal thresholds and counters.
- z/OS CS IDS implements prevention type of policies that are executed on the system that is the target of the attack. Prevention policies include packet discard and connection limiting.

The IDS is policy driven and the policies are kept in IDS configuration files or LDAP. These policies determine what actions to take for various IDS events. IDS events detected include scans, single packet attacks against the TCP/IP stack, and flooding. Actions include packet discard, connection limiting, and reporting. IDS events can be recorded in syslog files and/or the console. IDS statistics can be recorded in syslog. Packet traces can be taken to document suspicious activities. The TRMDSTAT command provides summary and detailed reporting of IDS events and statistics.

Figure 43 on page 206 shows the z/OS Communications Server IDS architecture.

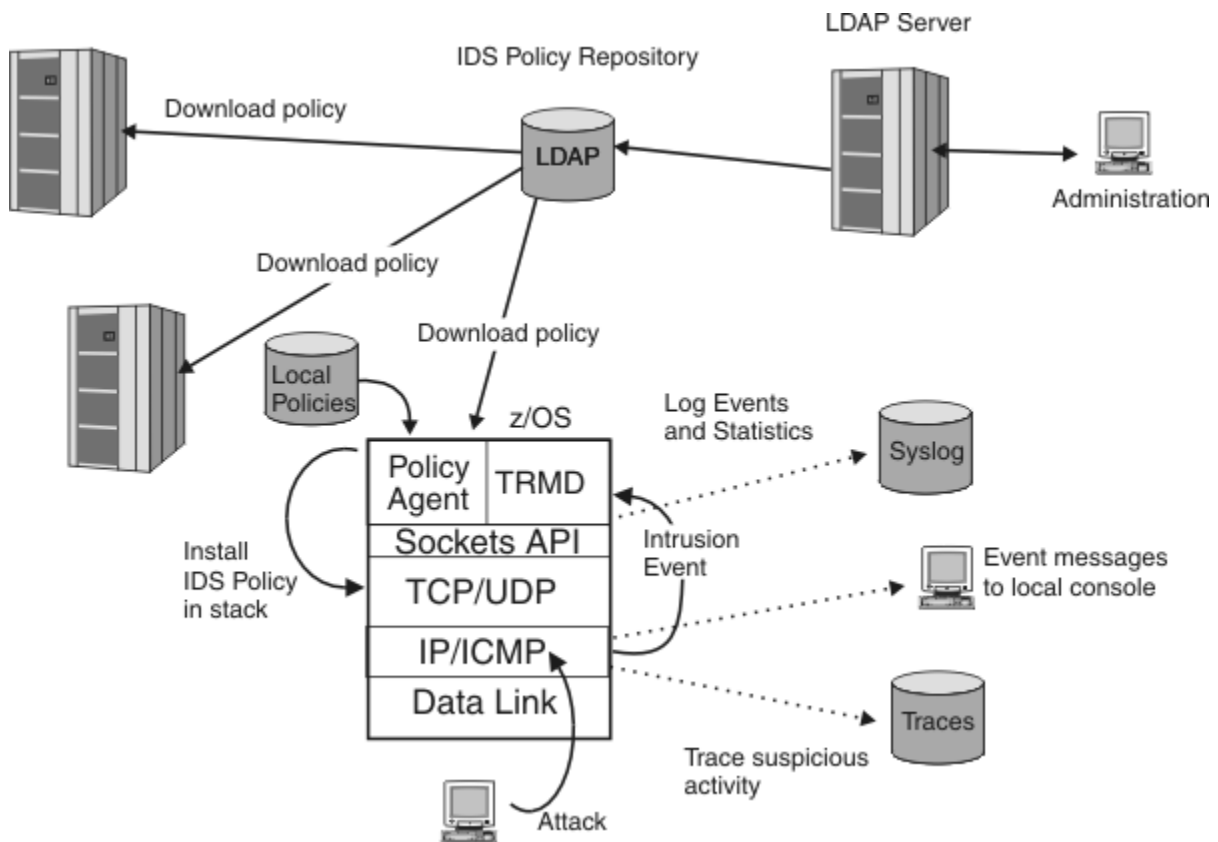

Figure 43. Intrusion detection services overview

For more information on IDS, see [Chapter 16, “Intrusion detection services,”](#) on page 877.

Defensive filtering

An external security information and event manager, through analysis and correlation of messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in the TCP/IP stack. A defensive filter is a rule to discard packets, separate from IP security filters. Filter processing matches a defensive filter rule to data traffic, based on any combination of IP source or destination address, protocol, source or destination port, or direction of flow. Filter processing checks defensive filters before IP security filters.

The z/OS UNIX **ipsec** command provides the ability to add and manage defensive filters. Defensive filters are typically added automatically as a result of an external security information and event manager's analysis. However, you can also add a defensive filter by manually issuing the **ipsec** command. The Defense Manager daemon (DMD) is an integral part of managing the defensive filters.

Figure 44 on page 207 shows an overview of defensive filtering and the DMD.

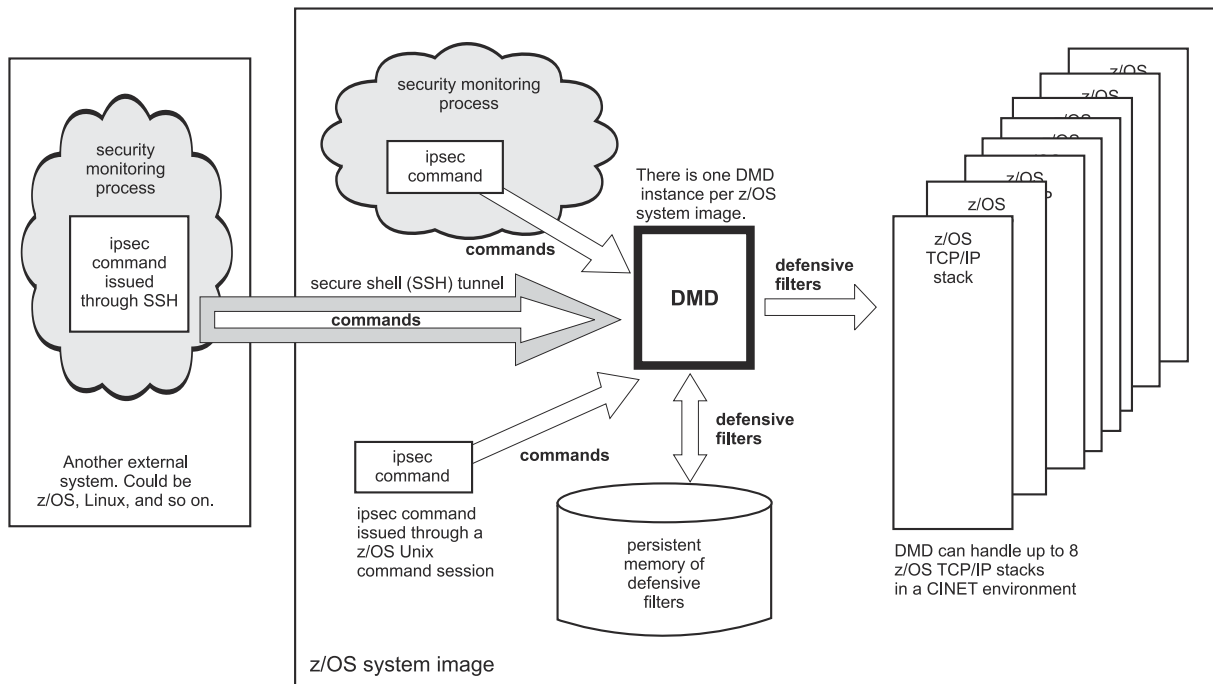

Figure 44. Defensive filtering overview

For more information about defensive filters and the DMD, see [Chapter 19, “Defensive filtering,”](#) on page 1135.

Network security services for the IPsec discipline

The network security services (NSS) server provides a set of network security services for the IPsec discipline. These services include a certificate service and a remote management service. The certificate service and remote management service are used by NSS IPsec clients. When an NSS IPsec client uses the certificate service, the NSS server creates and verifies digital signatures on the behalf of the NSS IPsec client. The need to store certificates and keying information at the client, which might be in a less secure zone of the network, is eliminated. When an NSS IPsec client uses the remote management service, the NSS server routes IPsec network management interface (NMI) requests to that NSS IPsec client, which enables the NSS IPsec client to be managed remotely. The NSS IPsec client provides the NSS server with responses to these requests.

You can configure the IKE daemon to act as an NSS IPsec client on behalf of multiple TCP/IP stacks. Each stack appears as a separate NSS IPsec client to the NSS server. Use the **-z** option on the **ipsec** command or use the IPsec NMI to manage NSS IPsec clients that use the remote management service provided by the NSS server. For details about using the **ipsec** command to manage NSS IPsec clients, see [z/OS Communications Server: IP System Administrator's Commands](#). For details about using the IPsec NMI to manage NSS IPsec clients, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

An NSS IPsec client requires a SAF user ID on the NSS server system. To use the services provided by the NSS server, this user ID must have read access to specific SERVAUTH resource profiles. The following SERVAUTH resource profiles apply to an NSS IPsec client:

- EZB.NSS.sysname.clientname.IPSEC.CERT

This profile authorizes an NSS IPsec client to access the IPsec certificate service of the NSS server.

- EZB.NSS.sysname.clientname.IPSEC.NETMGMT

This profile authorizes an NSS IPsec client to use the IPsec remote management service of the NSS server. The IPsec remote management service of the NSS server enables an NSS IPsec client to be managed by the NSS server.

- EZB.NSSCERT.sysname.mappedlabelname.HOST

This profile authorizes an NSS IPSec client to access a personal certificate or a site certificate on the key ring of the NSS server. A profile entry is required for each personal certificate or site certificate associated with an NSS IPSec client. The certificates are used during a phase 1 security association negotiation that uses the digital signature mode of authentication.

- EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH

This profile authorizes an NSS IPSec client to access a CERTAUTH certificate on the key ring of the NSS server. A profile entry is required for a CERTAUTH certificate that is connected to the key ring of the NSS server if the following conditions are true:

- That certificate's label is configured on the CaLabel parameter of a RemoteSecurityEndpoint statement within the IPSec policy definitions for an NSS IPSec client. For details about the [RemoteSecurityEndpoint statement](#), see [z/OS Communications Server: IP Configuration Reference](#).
- An NSS IPSec client wants to include information about the corresponding certificate authority (CA) to a remote security endpoint. The information is part of the default set of CAs sent when the CaLabel parameter is not specified on the matching RemoteSecurityEndpoint statement.

For additional details about the definition of these profiles, see [Chapter 18, “Network security services,” on page 1111](#).

The following SERVAUTH resource profiles apply when you use the -z option of the **ipsec** command or the IPSec NMI to manage NSS IPSec clients:

- EZB.NETMGMT.sysname.clientname.IPSEC.DISPLAY

This profile authorizes a user ID to issue the **ipsec** command with the -z option to obtain information about an NSS IPSec client, or to make IPSec NMI requests to obtain information about an NSS IPSec client.

- EZB.NETMGMT.sysname.tcpname.IPSEC.CONTROL

This profile authorizes a user ID to make IPSec NMI requests to modify the IPSec state of a local stack.

- EZB.NETMGMT.sysname.clientname.IPSEC.CONTROL

This profile authorizes a user ID to issue the **ipsec** command with the -z option to modify the IPSec state of an NSS IPSec client, or to make IPSec NMI requests to modify the IPSec state of an NSS IPSec client.

- EZB.NETMGMT.sysname.sysname.NSS.DISPLAY

This profile authorizes a user ID to issue the **ipsec** command with the -x option or to make IPSec NMI requests to obtain information about an NSS server. This profile also authorizes a user ID to issue the **nssctl** command to make NMI requests to obtain information about an NSS server.

For additional details about the definition of the profiles to use the **ipsec** command to manage NSS IPSec clients, see [z/OS Communications Server: IP System Administrator's Commands](#). For additional details about the definition of the profiles to use the IPSec NMI to manage NSS IPSec clients, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

The following SERVAUTH resource profile applies when the -w option of the **ipsec** command or the IPSec NMI is used to display information about an IKE daemon's NSS IPSec clients:

- EZB.NETMGMT.sysname.sysname.IKED.DISPLAY

This profile authorizes a user ID to issue the **ipsec** command with the -w option or make IPSec NMI requests to obtain information about an IKE daemon's NSS configuration.

For additional details about the definition of this profile to use the **ipsec** command to manage NSS IPSec clients, see [z/OS Communications Server: IP System Administrator's Commands](#). For additional details about the definition of this profile to use the IPSec NMI to manage NSS IPSec clients, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Before accessing an IPSec network security service, an NSS IPSec client must present a valid credential. A valid credential consists of the user ID representing the NSS IPSec client and a valid password or PassTicket. For additional information about using a PassTicket, see [z/OS Security Server RACF Security Administrator's Guide](#).

Certificates and private keys that represent an NSS IPSec client are stored on a single SAF key ring. The NSS server must have access to the certificates on this key ring. The private key associated with a certificate is never sent to the NSS IPSec client. When an NSS IPSec client uses the authentication mode of a digital signature, the NSS server creates a digital signature on the client's behalf. Before the NSS server accesses a personal certificate to create a digital signature on behalf of an NSS IPSec client, the NSS server verifies that the NSS IPSec client is authorized to use that certificate (and its associated private key) by checking the EZB.NSSCERT.*sysname.mappedlabelname*.HOST profile.

Certificates of certificate authorities that are supported by NSS IPSec clients must also be stored on this single key ring. The NSS server provides NSS IPSec clients with information about certificate authorities to which the client has access. The NSS IPSec client advertises certificate authority information to its peer when digital signature mode is used for authentication. The EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH profile identifies which certificate authorities an NSS IPSec client can advertise to its IKE peers. For information about this profile name, see [“NSS server certificate label naming considerations”](#) on page 1120.

[Figure 45 on page 210](#) shows an example of the IKE daemon acting as an NSS IPSec client for a single TCP/IP stack. The IKE daemon's configuration file identifies which network security services are to be used by a stack, as well as the information about the NSS server from which these services are to be obtained. If the NSS certificate service is enabled for a stack, the IKE daemon uses this service during a phase 1 negotiation when a digital signature mode of authentication is used. If the NSS IPSec remote management service is enabled for a stack, the IKE daemon responds to management requests initiated from the NSS server.

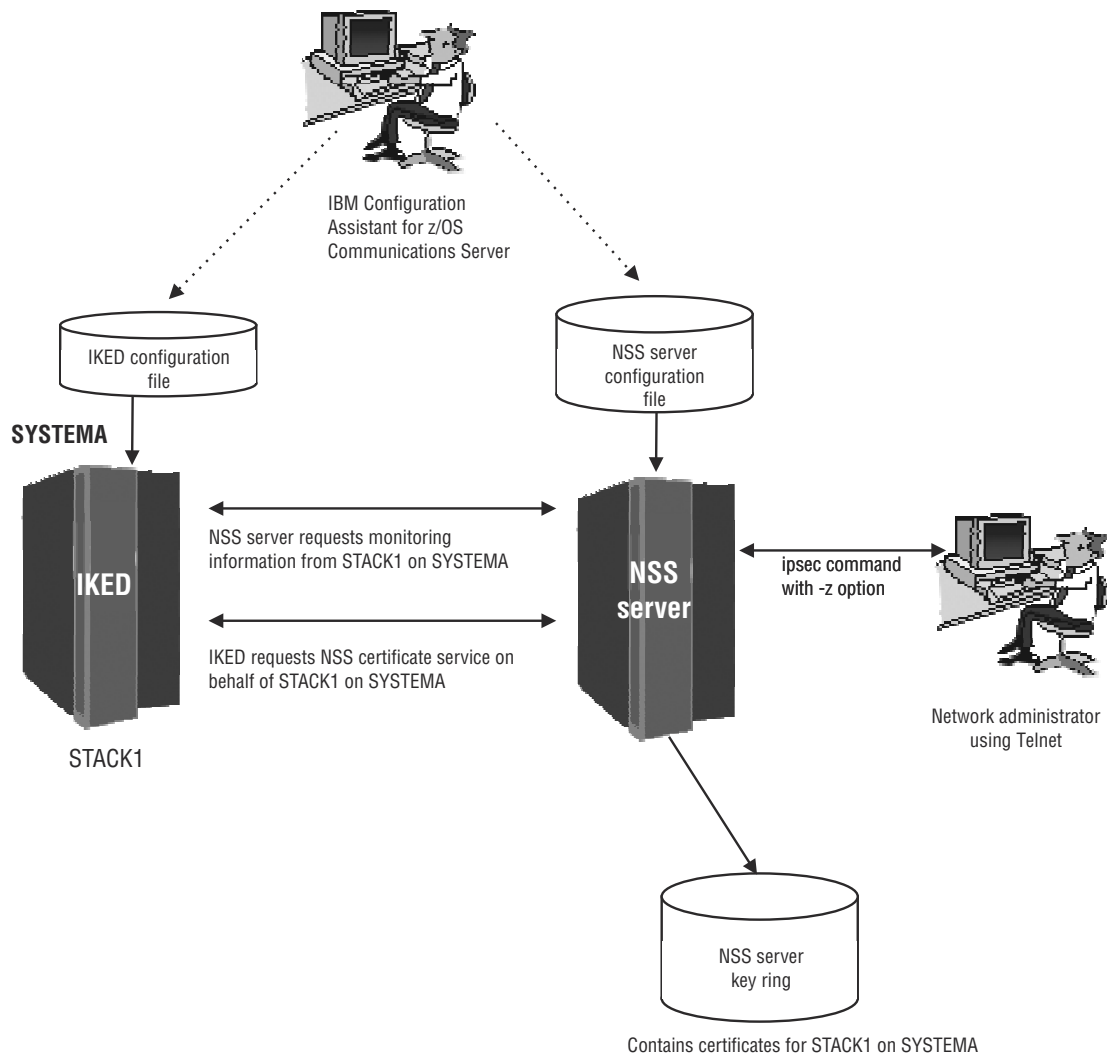

Figure 45. IKE daemon acting as an NSS client for a single TCP/IP stack

The example in Figure 45 on page 210 is a trivial example involving one TCP/IP stack acting as an NSS client. As shown in Figure 46 on page 211, the NSS server can provide services to many NSS clients. The IKE daemon on a z/OS system can act as an NSS client for up to eight TCP/IP stacks (that is, one for each stack running on that system). Multiple IKE daemons can simultaneously access network security services. These IKE daemons do not have to be within the same sysplex as the NSS server.

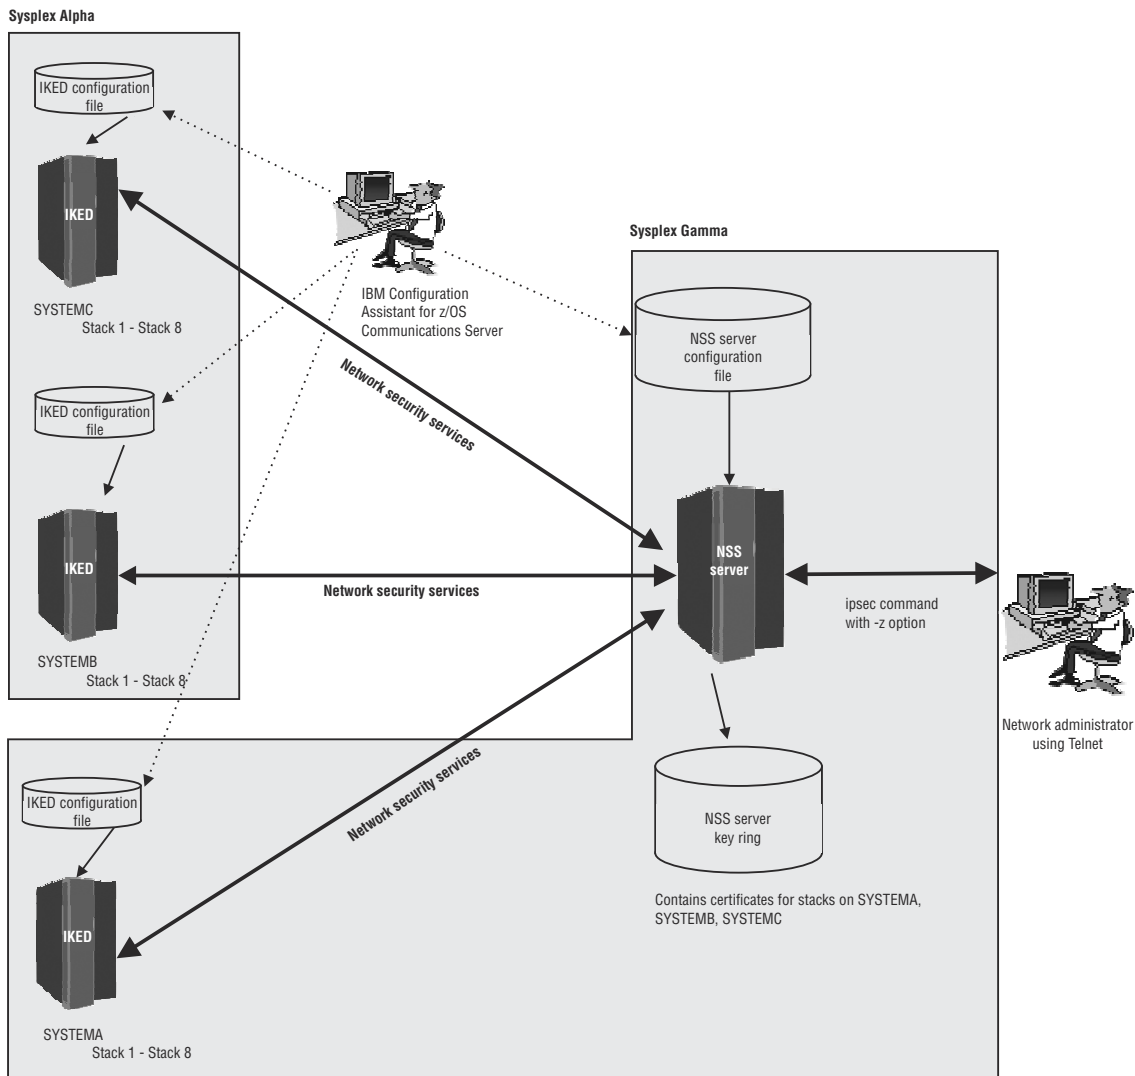

Figure 46. IKE daemon acting as an NSS client for multiple TCP/IP stacks

Network security services for the XMLAppliance discipline

The network security services (NSS) server provides a set of network security services for the XMLAppliance discipline. Services include the SAF access service, the certificate service, and the private key service. NSS XMLAppliance clients can use the network security services in the XMLAppliance discipline. When an NSS XMLAppliance client uses the XMLAppliance SAF access service, the NSS server performs SAF user authentication and access control checks on behalf of the NSS XMLAppliance client. The XMLAppliance certificate service allows an authorized NSS XMLAppliance client to list and retrieve certificates on the configured key ring of the NSS server. The XMLAppliance private key service allows an authorized NSS XMLAppliance client to retrieve private keys that are stored in RACF, generate digital signatures using private keys protected by Integrated Cryptographic Service Facility (ICSF), and perform decryption using ICSF-protected private keys. The NSS server does not support retrieval of ICSF-protected private keys. The NSS server uses its z/OS SAF database to protect unauthorized access to individual certificates and private keys.

Restrictions:

- Because support for digital signature generation and decryption requires the use of ICSF-protected private keys, the applicable Crypto Express2 feature must be defined as a coprocessor, not as an accelerator.
- The XMLAppliance private key service requires that public and private keys be associated with X.509 certificates.

An NSS XMLAppliance client requires a SAF user ID on the NSS server system. To use the XMLAppliance services provided by the NSS server, this user ID must have read access to SERVAUTH resource profiles for each XMLAppliance service. The following SERVAUTH resource profiles apply to an NSS client using XMLAppliance services:

- EZB.NSS.*sysname.clientname*.XMLAPPLIANCE.SAFACCESS

This profile authorizes an NSS XMLAppliance client to access the XMLAppliance SAF access service of the NSS server.

- EZB.NSS.*sysname.clientname*.XMLAPPLIANCE.CERT

This profile authorizes an NSS XMLAppliance client to access the XMLAppliance certificate service of the NSS server.

- EZB.NSS.*sysname.clientname*.XMLAPPLIANCE.PRIVKEY

This profile authorizes an NSS XMLAppliance client to access the XMLAppliance private key service of the NSS server.

- EZB.NSSCERT.*sysname.mappedlabelname*.HOST

This profile authorizes an NSS XMLAppliance client to access a certificate on the key ring of the NSS server. Use the .HOST or .CERTAUTH profile to authorize an NSS XMLAppliance client to list or retrieve a particular certificate.

- EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH

This profile authorizes an NSS XMLAppliance client to access a certificate on the key ring of the NSS server. Use the .CERTAUTH or .HOST profile to authorize an NSS XMLAppliance client to list or retrieve a particular certificate.

- EZB.NSSCERT.*sysname.mappedlabelname*.PRIVKEY

This profile authorizes an NSS XMLAppliance client to access the private key associated with a certificate on the key ring of the NSS server. Access to the private key is allowed only if all of the following conditions are true:

- The private key of the certificate is stored in RACF
- The private key of the certificate is not stored in the ICSF public key data set (PKDS)
- The ring usage of the certificate is personal
- The user ID of the NSS XMLAppliance client has read access to the appropriate certificate label profile (EZB.NSSCERT.*sysname.mappedlabelname*.PRIVKEY).

- EZB.NETMGMT.*sysname.sysname*.NSS.DISPLAY

This profile authorizes a user ID to issue the **nssctl** command to make NMI requests to obtain information about an NSS server.

Tip: You can specify a wildcard in the profiles to reduce the number of profile entries that you must define.

Before accessing the XMLAppliance services, an NSS XMLAppliance client must present a valid credential. A valid credential consists of the user ID that represents the NSS XMLAppliance client and a valid password or PassTicket. For additional information about using a PassTicket, see [z/OS Security Server RACF Security Administrator's Guide](#).

You control access to certificates and private keys using SAF profiles. The profile name contains a mapped label name that represents the label of the certificate. For information about this profile name, see [“NSS server certificate label naming considerations” on page 1120](#).

Chapter 4. Preparing for IP networking in a multilevel secure environment

Use this information to configure a z/OS Communications Server stack and applications in a multilevel secure environment.

Tip: Many of the tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.

The documentation for many of the applications described in this information references the EZARACF member of sample data set SEZAINST. For examples of the RACF commands used for multilevel security, see the EZARACFM member of sample data set SEZAINST.

Understanding multilevel security concepts

IBM's multilevel security for z/OS has access control implications for your entire system. z/OS Communications Server TCP/IP is only one element of a multilevel secure z/OS system environment. Before planning your multilevel secure IP network, you should be familiar with the concepts and terminology presented in [z/OS Planning for Multilevel Security and the Common Criteria](#).

Multilevel secure networking

The security administrator is responsible for defining the security levels and categories required in a multilevel secure environment. These become part of the set of security labels used to enforce mandatory access control policies when applications access resources on behalf of users. All of the systems enforcing mandatory access control policies in a multilevel secure network must have equivalent definitions of these security labels and the systems in the network to which they apply.

In the networking environment, the information that is being protected is the data being read and written through sockets. Sockets are opened and used by applications running under user IDs. In a z/OS multilevel secure environment:

- Each user ID is permitted to use one or more security labels.
- Every job or login session is associated with a user ID.
- A user ID can use only one security label for each job or login session.
- The security label used is limited by the port of entry (source type and location) of the job or login session.

Applications can have read access to information from many sources that can have various security labels. This information might be commingled in the buffers used to write information to the network. TCP/IP treats all socket data buffers as having the security label of the writing task. All sockets are inherently read/write, so TCP/IP requires communicating partners to have equivalent security labels in a multilevel secure environment.

Nonsecure systems

Most systems do not support mandatory access control processing. If these systems are not physically managed, they normally should not participate in a multilevel secure network. Some installations might need to permit them to participate. In these cases, it is recommended that they be assigned a security label with the lowest security level and a single security category that is not common with any other security label.

Managed systems

Systems that do not support mandatory access control processing can participate in a multilevel secure network, if they are physically managed to guarantee that all information on the system has the same single security label and all users of the system are permitted to that security label. These systems are referred to as single-level security or managed systems in this information. This management requires both physical control of the systems and careful management of the network. Managed systems must be prevented from communicating with other managed systems that do not have equivalent security labels.

Systems that support mandatory access control and are configured to implicitly associate the correct security label with each managed system can also communicate with managed systems. The systems that perform mandatory access control are responsible for ensuring that only information from applications with an equivalent security label is sent to a managed system, and that information received from a managed system is given only to applications with an equivalent security label.

Multilevel secure systems

Some systems in the network provide multilevel secure environments. These systems have mechanisms to associate security labels with information accessed through the system and with users logged into the system. The system enforces mandatory access control policies to ensure appropriate separation of information.

Other systems cannot normally associate a single security label with IP addresses owned by a multilevel secure system. The packets being sent from a single IP address on the multilevel secure system might have originated from applications running under different security labels.

Applications on a multilevel secure system can securely communicate with applications on a managed system. Mandatory access control enforcement occurs only on the multilevel secure system. The multilevel secure system is responsible for ensuring that it sends only information from an application with an equivalent security label to any managed system. It also is responsible for ensuring that information received from a managed system is delivered only to an application with an equivalent security label.

When two applications on multilevel secure systems communicate, the security label of the sending application must be communicated to the receiving system so that the receiving system can enforce mandatory access control prior to delivering the information to an application. One mechanism to accomplish this is for the sending system to pass the security label with each packet. The two multilevel secure systems must share a common definition and representation of the security labels that are passed.

z/OS Communications Server TCP/IP stacks on z/OS multilevel secure systems

A z/OS CS TCP/IP stack running in a z/OS multilevel secure environment can optionally be configured as either a restricted stack or an unrestricted stack. A restricted stack is configured with a user ID that is defined with a security label other than SYSMULTI. An unrestricted stack is configured with a user ID that is defined with a security label of SYSMULTI. A single z/OS system can concurrently run up to eight z/OS CS TCP/IP stacks, which can be any mix of restricted and unrestricted stacks.

In either mode of operation, appropriate mandatory access control processing is performed at the transport layer. z/OS Communications Server stacks can be host systems on trusted subnetworks. z/OS Communications Server stacks do not perform mandatory access control processing at the link or network layers, so security labels are not considered in packet forwarding with the exception of sysplex distributor, as described in [“Configuring stack sysplex features in a multilevel secure environment” on page 220](#). Packets that contain security labels are not forwarded by a restricted stack. These packets are discarded by the restricted stack.

Restricted stacks

In this mode of operation, the stack ensures that all sockets are opened by applications running with a security label that is equivalent to the security label of that stack. This guarantees that all information

sent by the stack can be implicitly associated with that stack's security label. The stack also ensures that all information received from the network and delivered to an application is equivalent to the stack's security label. A restricted stack can be viewed by other multilevel secure systems as if it were a managed system.

It is important to note that even though a restricted stack is running under a specific security label, it still receives packets from the network with information covered by different security labels. A restricted stack discards this information rather than deliver it to any local applications. However, this information can appear in storage dumps, logic traces, and packet traces. Diagnostic information should always be protected under the highest security label (SYSHIGH).

Unrestricted stacks

In this mode of operation, the stack allows sockets to be opened by applications with any security label. The stack supports mandatory access control processing that allows its applications to communicate securely with any other managed system or restricted stack.

For applications on unrestricted stacks to communicate securely with each other, Communications Server must be able to determine the security label of the sending application. Unrestricted stacks are permitted to define VIPAs in network security zones with security labels other than SYSMULTI. When one of these is used as either the source or destination IP address of a packet, it implicitly identifies the security label of the information. When both IP addresses in a packet are in security zones with the SYSMULTI security label, the application security label must be explicitly transmitted in the packet. This is known as packet tagging.

Communications Server implements a proprietary form of packet tagging to pass the security label of the sending application to the receiving stack for mandatory access control enforcement against the receiving application. Because of this proprietary format, communications between applications on unrestricted stacks that require packet tagging are supported only when both of those stacks are on the same z/OS system and are communicating over an IUTSAMEHOST link, or are members of the same z/OS sysplex and are communicating over an XCF link.

Stack recognition of a multilevel secure environment

You can activate the SAF SECLABEL class and define security labels on SERVAUTH profiles. This causes the security server to enforce mandatory access control policies for those resources without fully activating a multilevel secure environment. The z/OS Communications Server stack does not perform its extra mandatory access control policy enforcement until you issue the RACF command SETROPTS MLACTIVE. When running with SETROPTS NOMLACTIVE, you should not use unrestricted stacks or define network security zones with a SYSMULTI security label.

When a NetAccess statement is encountered in TCPIP profile processing and MLACTIVE has been set, the stack activates extra mandatory access control policy enforcement in both restricted and unrestricted stacks as follows:

- New sockets are allowed only if a STACKACCESS profile covers this stack.
- Network access is allowed only to IP addresses that are mapped into network security zones covered by NETACCESS profiles.
- Restricted stacks do not normally allow SYSMULTI tasks to have network access to security zones with security labels that are not equivalent to the stack's security label. For more information, see [“Exempting certain users of certain programs from full Network Access Control” on page 220.](#)
- Unrestricted stacks transmit packet labels both internally and externally to enable an extra mandatory access control check, between the sending task's security label and the receiving task's security label, when both IP addresses are in security zones with a SYSMULTI security label.
- Distributing stacks consider security labels in choosing target applications.
- TN3270E Telnet servers consider security labels in mapping connections to LU names.
- Internal configuration consistency checks are performed whenever PROFILE.TCPIP or certain SERVAUTH class profile changes are made.

Common INET in a multilevel secure environment

When you start several TCP/IP stacks under OMVS, you are using the Common INET (CINET) PFS. Users and jobs can optionally establish affinity to a single stack, or they can allow CINET to choose a stack. If stack affinity is not set, CINET replicates the `socket()` command to all stacks attached to it. If a job or user does not have READ access to any of the attached stacks, RACF might generate audit failure messages for those stacks. As long as at least one stack accepts the `socket()` command, CINET will return success to the application. CINET then routes subsequent commands on that socket to one or more of the stacks that accepted the `socket()` call. For further information on CINET, see [z/OS UNIX System Services Planning](#).

Network security zones

A network security zone is an administrative name for a collection of systems that require the same access control policy. IP addresses are used to map systems into security zones. This requires that the IP addresses used in your multilevel secure network be predictably associated with a single system or group of systems with the same access control policy. A network security zone can contain a single IP address or any combination of IP addresses and subnetworks. All of the IP addresses in a security zone must have the same security label, though all IP addresses with the same security label do not have to be in the same security zone.

IBM zEnterprise System ensemble

An IBM zEnterprise System (zEnterprise) node participating in an ensemble has access to the following networks:

- Intraensemble data network (IEDN)

The IEDN is accessed through OSA-Express for zBX (OSX) interfaces and through a HiperSockets channel path that is configured to use the Internal Queued Direct I/O extensions (IQDX) function.

- Intranode management network (INMN)

The INMN is accessed through OSA-Express for Unified Resource Manager (OSM) interfaces.

The IEDN should be treated the same way as any other data network in a multilevel secure environment. The INMN is handled differently.

The INMN is for only IPv6 and provides a path for some authorized zEnterprise applications, such as those providing platform performance management functions, to communicate with another authorized system performing platform management. For more information about these applications, see *IBM z Systems Ensemble Planning Guide*.

All traffic flowing over an OSM interface is protected by OSM access control rather than network access control. The INMN uses automatically generated IPv6 link-local addresses, so individual systems do not have statically assigned addresses. OSM interfaces provide isolation so that traffic can flow only between a stack connected to an OSM interface and the authorized system performing platform management.

Where your z/OS systems fit in your network

z/OS systems that are not configured with RACF SETROPTS MLACTIVE must be physically managed, as any other managed system.

z/OS systems at V1R5 or later that are configured with RACF SETROPTS MLACTIVE, have appropriate TCP/IP configuration, and have appropriate RACF SERVAUTH class profiles defined, can be placed in trusted subnetworks. Firewalls can allow any managed subnetworks to communicate with these trusted subnetworks. The trusted subnetworks will often be defined as a SYSHIGH security zone and will likely contain several individual IP addresses in other security zones, depending on the mix of restricted and unrestricted stacks within the trusted subnetwork.

Planning stacks on your z/OS systems

Before you begin, determine what z/OS systems need to participate in your multilevel secure network. For each z/OS system, determine what release level it will be running, what sysplex it is a member of, which other multilevel secure systems it needs to communicate with, and what security labels will be used.

The following subtopics include some references to additional information; more information is in [z/OS Communications Server: IP Configuration Reference](#) and [z/OS Security Server RACF Security Administrator's Guide](#).

Required configuration in a multilevel secure environment

Some configuration statements that are optional in a discretionary security environment are required in a multilevel secure environment. The default behavior of the stack in a discretionary security environment is to permit most applications when these statements are not defined. The default behavior of the stack in a multilevel secure environment is to fail every application when these statements are not defined. Every stack must have an EZB.STACKACCESS profile in the SAF SERVAUTH class. All referenced IP addresses, except intranode management network (INMN) link-local addresses, must be mapped into security zones by NetAccess statements in the TCPIP profile. A profile that covers the resource EZB.FTP.sysname.ftpddaemonname.ACCESS.HFS must be defined in the SAF SERVAUTH class for file system access by FTP users. The EZB.SOCKOPT profile must be defined for the following options in the SAF SERVAUTH class:

- IPV6_DSTOPTS
- IPV6_HOPOPTS
- IPV6_NEXTHOP
- IPV6_PKTINFO
- IPV6_RTHDR
- IPV6_RTHDRDSTOPTS
- IPV6_TCLASS
- SO_BROADCAST

In addition, if setting a hop limit greater than the default hop limit, the EZB.SOCKOPT profile must also be defined for the following options in the SAF SERVAUTH class:

- IPV6_HOPLIMIT
- IPV6_MULTICAST_HOPS
- IPV6_UNICAST_HOPS

For more information, see [“TCP/IP resource protection” on page 146](#).

Considerations for IPv6-enabled stacks

IPv6 architecture provides for a plug-and-play environment by automatically generating IP addresses when they are not manually configured. To guarantee predictable IP address association with specific systems, you must disable this capability on z/OS Communications Server stacks through manual configuration.

The stack automatically generates link-local IP addresses using the link-local prefix and the interface ID. To make these addresses predictable, you must manually configure the INTFID parameter on all IPv6 INTERFACE statements. If you are enabling dynamic XCF, you must also manually configure the DYNAMICXCF INTFID parameter on the IPCONFIG6 statement.

Some IPv6 interface types support router autogeneration. When this is enabled, the responsible router informs the stack about prefixes that are supported and the stack generates IP addresses from those prefixes and the interface ID. You must disable this capability on all interfaces that support it, by manually configuring at least one prefix or address using the IPADDR parameter on the INTERFACE statement.

These considerations for IPv6-enabled stacks do not apply to the IBM zEnterprise System (zEnterprise) intranode management network (INMN) that is accessed through OSA-Express for Unified Resource Manager (OSM) interfaces. Traffic over that network is protected by OSM access control rather than network access control.

Deciding whether to use restricted or unrestricted stacks

Many installations will find it easier to run a single unrestricted stack on each z/OS system. The following situations might require you to run one or more restricted stacks on a given system:

- Your installation has administrative requirements that prohibit the use of stacks that allow sockets with different security labels.
- You must allow applications to communicate with applications on a multilevel secure system that is not a z/OS system.
- You must allow applications to communicate with applications on a z/OS multilevel secure system that is not z/OS V1R5 or later.
- Your stacks are not on the same system and are not members of the same sysplex.

Configuring a restricted stack

To configure a restricted stack, take the following actions:

1. Determine the appropriate security label for this restricted stack. Associate a user ID with the stack job, and permit the user ID to the intended stack security label. Make that security label the default security label in the user ID profile.
2. Define a STACKACCESS profile for this stack in the SERVAUTH class with the same security label. This profile might often be UACC(READ).
3. Determine the interface and VIPA addresses needed for this stack.
4. Define one or more security zone names for this stack.

If you have discretionary access control policies that require different treatment for some of the IP addresses on this stack, they will need to be in different security zones.

5. Define NETACCESS profiles for this stack in the SERVAUTH class with the same security label.

If your access control policy requires only mandatory access control enforcement, this profile can be generic with respect to the z/OS system name and the TCP stack job name. It might often be UACC(READ).

6. Define a NETACCESS statement that maps this system's external IP addresses into security zone names. This can be placed in a shared data set and included in the PROFILE.TCPIP of other z/OS CS systems in the network.
7. If you define a SOURCEVIP address for this stack, it must be an IP address in a security zone covered by a NETACCESS profile with the stack's security label.

Configuring an unrestricted stack

To configure an unrestricted stack, take the following actions:

1. Unrestricted stacks must run with the SYSMULTI security label. Associate a user ID with the stack job, and permit the user ID to the SYSMULTI security label. Make SYSMULTI the default security label in the user ID profile.
2. Define a STACKACCESS profile for this stack in the SERVAUTH class with the SYSMULTI security label. This profile might often be UACC(READ).
3. Determine the interface and VIPA addresses needed for this stack.

If you are running server applications that require multiple instances running under different security labels, you will need at least one VIPA for each security label.

4. Define security zone names for this stack.

If you have discretionary access control policies that require different treatment for some of the IP addresses on this stack, they will need to be in different security zones.

VIPAs defined for use with specific security labels will need to be in separate security zones.

5. Define NETACCESS profiles for this stack in the SERVAUTH class.

Profiles created for VIPAs used with specific security labels are defined with the appropriate security label. If your access control policy requires only mandatory access control enforcement, these profiles can be generic with respect to the z/OS system name and TCP stack job name. They might often be UACC(READ).

Profiles for other zones on this stack are defined with the SYSMULTI security label. If there are z/OS systems sharing the RACF database that are not members of the same sysplex, or that are not z/OS V1R5 or later, any generic profile should have UACC(NONE). A fully qualified profile might often be UACC(READ).

6. Define a NETACCESS statement that maps this system's IP addresses into security zone names. This can be placed in a shared data set and included in the PROFILE.TCPIP of other z/OS CS systems in the network.

Tip: If you have multiple unrestricted stacks and you use the OMROUTE routing daemon, for more information on local address security zones, see [“OMROUTE” on page 225](#).

7. If you enable SOURCEVIPa on IPCONFIG and IPCONFIG6 statements, in many circumstances you might be able to avoid explicit packet tagging. The source ip address selection algorithm is enhanced to consider security labels. For IPv4 interfaces defined with the LINK statement, the backward search of the HOME list stops at the first VIPa with a security label that is the same as the security label of the application, or with a security label of SYSMULTI. Place IPv4 source VIPAs in the HOME list preceding the physical interface IP addresses that can use them. VIPAs in SYSMULTI security zones should precede those in other zones. For IPv4 interfaces defined with the INTERFACE statement, use the SOURCEVIPaINTERFACE parameter to select the source VIPa. For IPv6 addresses, only addresses that have security labels the same as that of the application or SYSMULTI are considered. Addresses with equal security labels are preferred over those with a security label of SYSMULTI. Place IPv6 VIPAs on VIRTUAL6 INTERFACE statements. Use the SOURCEVIPaINTERFACE parameter on other INTERFACE statements to associate the set of source VIPAs that can be used with each IPv6 interface.
8. If you define TCPSTACKSOURCEVIPa for this stack, to avoid application failures, it must be in a security zone with a SYSMULTI security label.

Steps for configuring global definitions for all stacks

Define a security zone name for the INADDRANY and LOOPBACK addresses. Define a security label and security zone name for all unknown systems in the multilevel secure network.

Procedure

Perform the following steps to configure global definitions for all stacks:

1. Define a security zone name for the INADDRANY and LOOPBACK addresses.
 - a) Define a NETACCESS profile for this zone in the SERVAUTH class for each stack. This profile should be specific with respect to the z/OS system name and TCP stack job name, and should have the same security label as the stack job. You are most likely to make this profile UACC(READ).
 - b) Define a NETACCESS statement that maps the INADDRANY and LOOPBACK IP addresses of any system into this security zone name. You can place this statement in a shared data set and include it in the PROFILE.TCPIP file of other z/OS systems in the network.
2. Define one security label that has the lowest security level and one category that is not used in any other security labels.

This security label can then be used for all unknown systems. Mandatory access control access under this security label will be more restrictive than under SYSLOW.

A task using this security label will have R/O access to resources with SYSLOW, W/O access to resources with SYSHIGH, and R/W access to resources with this security label and SYSMULTI. The task will have no access to resources with any other security labels because they will be disjoint.

Any resources created under this security label will be readable only by tasks running under this security label, SYSHIGH, and SYSMULTI. This significantly reduces the risk from unintended and publicly readable or executable SYSLOW resources.

3. Define a security zone name for all unknown systems in the multilevel secure network.
 - Define a NETACCESS profile for this zone in the SERVAUTH class. This profile can be generic with respect to the z/OS system name and TCP stack job name. If your installation supports communications with unknown systems on all z/OS systems, make this profile UACC(READ). If your installation does not support communications with unknown systems on all z/OS systems, make this profile UACC(NONE).
 - Define a NETACCESS DEFAULT statement that maps all unspecified IP addresses into this security zone name. You can place this statement in a shared data set and include it in the PROFILE.TCPIP file of other z/OS systems in the network.

Exempting certain users of certain programs from full Network Access Control

There are certain network administration programs that, to be fully functional, need to be exempted from some aspects of Network Access Control. For instance, the Ping and Traceroute functions test the network path to a destination system. They often need to traverse routers or firewalls that are at IP addresses mapped into security zones that are not normally mandatory access control accessible from a particular restricted stack. ICMP error messages from these systems will not be delivered to the function, if they are not exempted from the Network Access Control check that limits all traffic to security labels equivalent to the stack security label. Also, routing protocol daemons, such as OMPROUTE, frequently need to exchange routing table information with adjacent nodes that are in security zones that might not be mandatory access control accessible from a particular restricted stack. To operate correctly, these programs must also be exempted from some aspects of Network Access Control.

A SYSMULTI user with UPDATE authority to the EZB.STACKACCESS profile will be exempt from the Network Access Control restriction that all traffic must be with partners that are in security zones with security labels that are equivalent to the stack security label or the security label that is associated with the local IP address. Limit this authority to their usage of the programs that must be exempted, which can be accomplished by first specifying UACC(READ) when you are defining the STACKACCESS profiles, and then granting conditional update access to each by specifying the following command:

```
PERMIT stackaccess_profile_name CLASS(SERVAUTH) ID(*) ACCESS(UPDATE) -  
WHEN(PROGRAM(ping,oping,tracerte,otracert,omproute))
```

Note: The WHEN(PROGRAM()) conditional access parameter is not supported on profiles in the SERVAUTH class, except where explicitly stated. PERMITs with WHEN(PROGRAM()) on other profiles might be ignored.

Configuring stack sysplex features in a multilevel secure environment

The following considerations apply to stack sysplex features in a multilevel secure environment:

- If TCPSTACKSOURCEVIPA is configured on a stack, the specified VIPA must be in a NetAccess security zone with a security label that is identical to the stack security label.
- If you use job-specific source IP addressing (see [SRCIP statement in z/OS Communications Server: IP Configuration Reference](#)), the specified IP address must be in a NetAccess security zone with a security label that is permitted on the stack and is equivalent to the specified job. If an interface name is used, at least one of the IP addresses configured on that interface must be in a network security zone with a security label that is either SYSMULTI or equal to the specified job.
- If you use destination-specific source IP addressing (see [SRCIP statement in z/OS Communications Server: IP Configuration Reference](#)), the specified IP address must be in a NetAccess security zone

with a security label that is permitted on the stack and is equivalent to the specified destination. If an interface name is used, at least one of the IP addresses configured on that interface must be in a network security zone with a security label that is either SYSMULTI or that is the same as the specified destination.

- For sysplex distributor, the distributing stack must either be an unrestricted stack or a restricted stack with a security label that is the same as all target stacks. The distributing stack will use the security label of the source security zone and the security labels of the active target applications when selecting a target. The distributing stack will also honor SECLBYSYSTEM when the target application is running under SYSMULTI on an unrestricted stack. In an environment using SECLBYSYSTEM, a distributing stack must be on a system where all security labels are active.
- VIPA takeover must be configured only between stacks with the same security label.
- Distribution of connections that require packet tagging are restricted to flowing over XCF or IUTSAMEHOST links. This restriction applies to the route from the client to the distributor, from the distributor to the target server, and from the target server back to the client.

Defining security labels on other profiles in the SERVAUTH class

A z/OS system with RACF SETROPTS MLACTIVE requires all resource profiles defined in the SERVAUTH class to have a security label. All z/OS Communications Server profiles in the SERVAUTH class have EZA, EZB, or IST as the first qualifier. Resource profiles that require meaningful security labels, such as EZB.STACKACCESS and EZB.NETACCESS, are explicitly identified in this information. The following resource profiles can be defined with the SYSNONE security label:

- EZB.SOCKOPT.*sysname.tcpname*.IPV6_DSTOPTS
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_HOPLIMIT
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_HOPOPTS
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_NEXTHOP
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_PKTINFO
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_RTHDR
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_RTHDRDSTOPTS
- EZB.SOCKOPT.*sysname.tcpname*.IPV6_TCLASS
- EZB.SOCKOPT.*sysname.tcpname*.SO_BROADCAST
- EZB.FTP.*sysname.ftpdemonname*.ACCESS.HFS
- EZB.RPCBIND.*sysname.rpcbindname*.REGISTRY
- EZB.TRCCTL.*sysname.tcpname*.OPEN

Some installations might want to define SO_BROADCAST with the SYSLOW security label to further reduce the exposure of data write_down by restricting datagram broadcast to users running with SYSLOW or SYSMULTI. All other z/OS Communications Server resource profiles can be defined with the SYSNONE security label.

Planning your multilevel secure network

Separate your network into security zones. Each subnetwork of physically managed systems should be defined as a single security zone. Several subnetworks with identical security labels and discretionary access control policy requirements can be assigned the same security zone name. Each trusted subnetwork of self-managed multilevel secure systems likely requires several security zones. The trusted subnetwork can also contain physically managed resources, such as routers and network administrator workstations. The trusted subnetwork security zone is likely to require a SYSHIGH security label. Multilevel secure stacks within the trusted subnetwork must have their interface addresses in security zones with the security label of the stack. VIPAs are usually placed in separate subnetworks dedicated to VIPAs and containing no real interface addresses. Multicast addresses, loopback addresses, and unspecified addresses (IPv4 INADDR_ANY and IPv6 in6addr_any) require security zones as well.

The security administrator takes the following actions:

- Defines security labels in the z/OS security server.
- Creates user IDs in the security server with appropriate security labels.
- Defines common discretionary access control policies.
- Defines the security zone name for each required combination of security label and discretionary access control policy.
- Identifies groups of managed machines that belong in each security zone.
- Provides physical security for each group of machines to ensure only users with appropriate security clearance can use them.
- Configures managed machines so that only the network administrator can set IP addresses.

The network administrator takes the following actions:

- Isolates each group of machines into a subnetwork.
- Configures IP addresses on the machines.
- Configures a firewall to limit each group to communicate only with other subnetworks that have the same security label.
- Assigns network security zone names to subnetworks.
- Defines a NETACCESS statement that maps subnetworks and systems into network security zones. This can be placed in a shared data set that can be included in the PROFILE.TCPIP of all z/OS CS stacks in the network.

Planning for interactive UNIX System Services users in a multilevel secure environment

Create a separate home directory for each security label, set stack affinity by security label, and set host and domain name by security label.

Steps for creating a separate home directory for each security label

Interactive users of z/OS UNIX System Services that are permitted to log on with more than one security label must have a separate home directory for each security label.

Before you begin

This approach is similar to the approach shown in [z/OS Planning for Multilevel Security and the Common Criteria](#).

Procedure

Perform the following steps to create a separate home directory for each security label:

1. For each supported security label:
 - a) Log on to an administrative user ID with that security label.
 - b) Create a directory with the name of that security label under the /u directory.
 - c) For each user permitted to that security label, create a home directory under that security label directory.
2. Create a symbolic link in the /u directory using the special value "\$SYSSECR/", perhaps named symsecl as follows:

```
ln -s "$SYSSECR/" /u/symsecl
```

Tip: When issuing this command from the shell, use double quotation marks around the \$SYSSECR/ string so that the shell does not attempt variable substitution before passing it to the ln command.

3. Define all users' home directories to be '/u/symsecl/user' as follows:

```
ALTUSER user OMVS(HOME('/u/symsecl/user'))
```

Results

This approach is useful in many other situations where a different configuration is required for different security labels.

Steps for setting stack affinity by security label

Installations that start several TCP/IP stacks under UNIX System Services common INET (CINET) often find it useful to set stack affinity for most interactive users. You can set the environment variable `_BPXK_SETIBMOPT_TRANSPORT` to the name of the stack that users are to use during login profile processing.

Procedure

Perform the following steps to set stack affinity by security label:

1. Create a directory for each security label under the /etc directory.
2. Create a profile script file in each directory that contains:

```
export _BPXK_SETIBMOPT_TRANSPORT=stackname
```

3. Create a "\$SYSSECL/" symbolic link in the /etc directory, perhaps named `seclbl` as follows:

```
ln -s "$SYSSECL/" /etc/seclbl
```

4. Edit the /etc/profile script file and add the following lines:

```
if test -f /etc/seclbl/profile
then
. /etc/seclbl/profile
fi
```

Host and domain name by security label

Installations that start several TCP/IP stacks under UNIX System Services CINET often find it necessary to define a different host name or domain name for interactive users based on their security label. The first decision that needs to be made is what host name and domain name each TCP/IP stack will have. Two common approaches are to:

- Assign each of the stacks a different host name in the same domain name.
- Assign each of the stacks on the same z/OS image the same host name, but define a different domain name for each security label.

These names are then implemented by creating a separate resolver configuration file for each security label.

Steps for creating a separate resolver configuration file for each security label

You can define a different host name or domain name for interactive users based on their security label. Implement these names by creating a separate resolver configuration file for each security label.

Procedure

Use the same directory structure under the /etc directory as follows:

1. Log in as a file system administrator with each security label.
2. Create a copy of your current resolver configuration file in each security label directory using the following command:

```
cp /etc/resolv.conf /etc/seclbl/rsv.cfg
```

3. Edit these new files as follows:

- a) Change the TCPIPJOBNAME statement to the appropriate stack job name.
- b) Change the HOSTNAME statement to the appropriate host name.
- c) Change the DOMAINORIGIN or first SEARCH statement to the appropriate domain for this security label.

Tip: For information about interactions between the DOMAINORIGIN and SEARCH statements, see the [TCPIP.DATA configuration statements](#) topic in [z/OS Communications Server: IP Configuration Reference](#).

4. Replace your current resolver configuration file with a symbolic link as follows:

```
ln -s "$SYSSECR/rsv.cfg" /etc/resolv.conf
```

Planning for applications in a multilevel secure environment

In planning for applications in a multilevel secure environment, you must first understand the multilevel security programming rules that apply to socket applications.

Trusted network administration server applications

Applications that are part of the infrastructure, such as DNS and routing. The delivered information is not sensitive and needs to be accessible across many security labels.

Trusted multi-level secure server applications

Applications with a login process using port of entry, that do all resource access under the client's login identity, and that maintain separation of information accessed by different client tasks, such as FTP and otelnet.

Process applications that change identity must take the following actions:

- Issue `_poe()` before identity change (can be done by parent, for example, `INETD`).
- Change identity in parent process before `fork`, `spawn`, or `exec` to ensure interprocess communication (IPC) resources are properly labeled.
- Access any user resources after the identity change.
- Close unnecessary parent resources before `exec`.

Threaded applications that set identity on a thread must take the following actions:

- Issue `_poe()` on handling thread before `_pthread_security_np()`.
- Ensure all related processing occurs on threads that have the same identity.
- Change identity on thread before `spawn`, `fork`, or `exec`.
- Access any user resources after identity change on the thread.
- Not access any other thread's resources.
- Close all user resources before removing identity from thread.
- Remove user identity from thread before acquiring new work.

All SYSMULTI applications must ensure that they do not put user data on server resources or other user resources. Pay special attention to debugging, logging, or tracing output. Many servers include user level data in output.

Network administration commands and client applications

Local commands, requiring special controls and privileges, that are used to query, configure, or diagnose the network infrastructure.

IBM zEnterprise System (zEnterprise) platform management applications

Authorized zEnterprise applications that perform platform management functions. For more information about these applications, see *IBM z Systems Ensemble Planning Guide*.

General user commands and client applications

Local commands that access resources (including network resources) under the invoking user's security environment.

Network management interfaces

Application programming interfaces that provide sensitive information.

Unsupported applications

Applications that have not been inspected, or have been inspected and are not trusted in a multilevel secure environment.

Configuring z/OS CS applications in a multilevel secure environment

This topic describes configuration for each of the z/OS CS application categories.

Trusted network administration server applications

The following applications are trusted network administration server applications:

- OMPROUTE
- Resolver
- SNTPD
- TIMED
- TRMD
- z/OS syslog daemon (syslogd)
- z/OS UNIX Policy Agent

They can run under a user ID with the SYSMULTI security label in a multilevel secure environment, provided that they adhere to the following configuration instructions.

OMPROUTE

You should run one instance of OMPROUTE for each stack that is using dynamic route configuration. Each instance of OMPROUTE must run under a user ID with SYSMULTI. OMPROUTE communicates with multicast IP addresses. These addresses must be configured into NetAccess security zones. If OMPROUTE must communicate with adjacent nodes that are not in network security zones with security labels equivalent to the security label of the restricted stack or the security label associated with the local IP address, OMPROUTE must run under a user ID that is SYSMULTI and has update authority to the EZB.STACKACCESS resource profile. A SYSMULTI user with UPDATE authority to the EZB.STACKACCESS resource profile is exempt from the restriction that all traffic must be with partners that are in security zones with security labels that are equivalent to the stack's security label or the security label associated with the local IP address. You should carefully protect your routing configuration files to maintain network security. You should consider using any application level security supported by the routing protocol you use. OMPROUTE must be run with stack affinity for the stack that it is servicing.

OMPROUTE uses multicast UDP datagrams to discover adjacent OSPF routing daemons on common subnetworks. Adjacent OMPROUTE instances then establish TCP connections with each other. When two unrestricted stacks running OMPROUTE are attached to a common subnetwork that is neither XCF nor IUTSAMEHOST, adjacency errors will occur. The multicast UDP datagram is successfully transmitted, but the subsequent TCP connection between the two SYSMULTI interface addresses fails because it requires packet tagging. These adjacency failures can be avoided by preventing OMPROUTE from receiving multicast datagrams from partners with which it cannot communicate.

Steps for avoiding adjacency failures

When two unrestricted stacks running OMPROUTE are attached to a common subnetwork that is neither XCF or IUTSAMEHOST, adjacency errors occur. You can avoid these adjacency failures by preventing OMPROUTE from receiving multicast datagrams from partners with which it cannot communicate.

Procedure

Perform the following steps to prevent OMPROUTE from receiving multicast datagrams from partners with which it cannot communicate.

1. Create a network security zone named URXCF for all interface addresses in XCF or IUTSAMEHOST networks on unrestricted stacks:

- a) Define a generic SERVAUTH NETACCESS profile for this zone with the following RACF command:

```
RDEFINE SERVAUTH EZB.NETACCESS.*.*.URXCF UACC(READ) SECLABEL(SYSMULTI)
```

- b) Modify the common NETACCESS profile to define the addresses in this zone:

```
NETACCESS
192.168.10.0/24 URXCF ; xcf subnet perhaps
10.254.254.0/24 URXCF ; IUTSAMEHOST subnet perhaps
ENDNETACCESS
```

2. Create a network security zone named UROTHER for all interface addresses in other network types on other unrestricted stacks:

- a) Define a generic SERVAUTH NETACCESS profile for this zone with the following RACF command:

```
RDEFINE SERVAUTH EZB.NETACCESS.*.*.UROTHER UACC(READ) SECLABEL(SYSMULTI)
```

- b) Prevent the OMPROUTE running for each unrestricted stack from receiving datagrams from this zone with the following RACF command:

```
PERMIT EZB.NETACCESS.*.*.UROTHER CLASS(SERVAUTH) ID(ompuid) ACCESS(NONE)
```

- c) Modify the common NETACCESS profile to define the addresses in this zone:

```
NETACCESS
10.254.1.0/24 UROTHER ; ethernet subnet perhaps
ENDNETACCESS
```

3. Create a network security zone named URLOCAL for all interface addresses in other network types on each specific unrestricted stack. OMPROUTE is permitted to use this local interface to connect to adjacent OMPROUTE daemons on adjacent restricted stacks.

- a) Define a generic SERVAUTH NETACCESS profile for this zone with the following RACF command:

```
RDEFINE SERVAUTH EZB.NETACCESS.*.*.URLOCAL UACC(READ) SECLABEL(SYSMULTI)
```

- b) Modify the local NETACCESS profile for each stack to define the local addresses in this zone:

```
NETACCESS
10.254.1.17/32 URLOCAL ; local address in ethernet subnet perhaps
ENDNETACCESS
```

Resolver

The resolver task is started by z/OS UNIX and runs under the same identity as the OMVS address space. This identity normally has a security label of SYSMULTI. The resolver processes its configuration, system console commands, and its CTRACE under this identity.

The resolver is configured to use a set of files, data sets, and name servers in a given sequence when asked to resolve a name or IP address. For information on configuring the resolver search sequence, see [z/OS Communications Server: IP Configuration Reference](#).

The name resolution process is performed on the requesting thread of execution under the user identity associated with that thread. Each user must have READ access to the files and data sets configured. This is best accomplished by making these UACC(READ) with SECLABEL(SYSLOW). For the resolver to contact a name server on their behalf, each user must also have appropriate STACKACCESS permission and NETACCESS permission to the security zone of the name server.

z/OS UNIX might be configured in a CINET environment with multiple AF_INET Physical File Systems (TCP/IP stacks). In this environment, users and jobs can optionally have affinity for a single stack or allow CINET to choose a stack for them. When stack affinity is not set, CINET replicates some AF_INET calls to all attached stacks. Other calls are routed by CINET to a single stack based on routing information that CINET has extracted from those stacks. The socket() call is one of the calls that is routed to all connected stacks. This might produce RACF Failure Audit messages to any stacks that the resolver user is not permitted to. These messages can be eliminated by setting stack affinity prior to using resolver functions.

SNTPD

You can run as many instances of SNTPD as appropriate for your installation. Time is not considered sensitive information. You can run any SNTPD server under a user identity with a SYSMULTI security label.

TIMED

You can run as many instances of TIMED as appropriate for your installation. Time is not considered sensitive information. You can run any TIMED server under a user identity with a SYSMULTI security label.

TRMD

You should run one instance of TRMD for each stack that has IDS or IP security functions configured. Each instance of TRMD can run under a user ID with the same security label as the stack it is servicing, or with SYSMULTI. TRMD must be run with stack affinity for the stack that it is servicing.

z/OS syslog daemon (syslogd)

You should run one instance of syslogd per z/OS image under a user ID with the SYSMULTI security label. The AF_UNIX socket (default name /dev/log) created by syslogd must have a security label of SYSMULTI, so that applications running under various security labels can log to it.

Syslogd routes application log messages according to filters configured in /etc/syslog.conf. Log messages from applications running under different security labels can be mixed into an output log file by a filter rule. Each output log file created by syslogd should be configured in a directory with a SYSHIGH security label.

z/OS UNIX Policy Agent

You should run one instance of Policy Agent per z/OS image under a user ID with the SYSMULTI security label. The AF_UNIX socket /tmp/unix.str created by Policy Agent must have a security label of SYSMULTI so that applications running under various security labels can connect to it. The user ID that Policy Agent is running under should have READ access to the EZB.STACKACCESS resource profiles of all stacks on the system.

Trusted multilevel secure server applications

The following applications are trusted multilevel secure server applications:

- TN3270E Telnet server
- z/OS UNIX FTP server
- z/OS UNIX REXEC server
- z/OS UNIX rpcbind server
- z/OS UNIX RSH server
- z/OS UNIX Telnet server

These applications can run under a user ID with the SYSMULTI security label in a multilevel secure environment, provided that they adhere to the following configuration instructions.

TN3270E Telnet server

You can run up to eight instances of the TN3270E Telnet server (Telnet), as appropriate for your installation. You can optionally configure the NACUSERID statement to enable Network Access Control for your Telnet, or use the procedure's user ID.

Telnet maps TCP connections to LU names configured in LU groups or supplied by an LU mapping exit. All of the LU names in a single LU group or that are provided by a single exit must have the same security label. Telnet ensures that the mapped LU name has an equivalent security label to the NetAccess profile for the network security zone containing the client. If the security label for the NetAccess profile is SYSMULTI, Telnet ensures that the mapped LU name also has a security label of SYSMULTI. When performing user login authentication, the SNA application should use this LU name as the port of entry TERMID. The LU name profile in the TERMINAL class must have equivalent security label definitions on both the Telnet system and the SNA application system.

z/OS UNIX FTP server

You can run as many instances of the FTP daemon as appropriate for your installation. You can run any FTPD under a user identity with a SYSMULTI security label. A single FTPD can span a mix of restricted and unrestricted stacks in a CINET environment.

To use NetAccess profiles for IPv4 clients, configure PortOfEntry4 SERVAUTH in the FTP.DATA file of the server. If you do not, you must configure profiles in the TERMINAL class covering all IPv4 addresses in your multilevel secure network, with the same security label defined on your corresponding NetAccess profiles.

z/OS UNIX rpcbind server

You should run one instance of rpcbind per z/OS image under a user ID with UID(0) and the SYSMULTI security label. You must define the resource profile EZB.RPCBIND.sysname.rpcbindname.REGISTRY in the SERVAUTH class. Enable applications to register and unregister with rpcbind by granting at least READ access to the resource profile for the user IDs under which the applications run.

Tip: The registration and deregistration procedures PMAPPROC_SET, PMAPPROC_UNSET, RPCBPROC_SET, and RPCBPROC_UNSET are defined in RFC 1833 *Binding Protocols for ONC RPC Version 2*.

Requirements:

- The rpcinfo utility can list and delete rpcbind registrations. You cannot delete rpcbind registrations using rpcinfo unless the user ID has at least READ access to the resource profile.
- Some RPC library calls register and deregister applications with rpcbind or portmapper. These calls include registerrpc(), svc_register(), pmap_set(), and pmap_unset(). An application that uses these library calls must run under a user ID that has been granted at least READ access to the resource profile.

Client programs can request that rpcbind forward RPCs to registered server programs. For each of these target assistance requests, the rpcbind server forks a new process that runs under the security label of the client's network security zone. The user ID under which rpcbind runs must have at least READ access to each of these security labels that you want to support.

Tip: The RPC library routine pmap_rmtcall() issues target assistance requests on behalf of the caller.

z/OS UNIX INET daemon

The z/OS UNIX INET daemon (inetd) can be configured to listen for requests for many different services. You can run inetd under a user identity with a SYSMULTI security label. Each connection to one of its ports causes it to issue the _poe() service and fork a new instance of the server configured to handle that service. The new connection is passed to the server. If a user ID for the forked server is configured in the inetd configuration file, that user ID must be authorized to the SERVAUTH NETACCESS profile for the

network security zone containing the client IP address. If the forked server performs additional user login authentication, that user ID must also be permitted to the NetAccess profile.

The following z/OS CS servers are designed to be forked by inetd. They each perform additional user authentication.

- z/OS UNIX REXEC server
- z/OS UNIX RSH server
- z/OS UNIX Telnet server

Trusted single-level secure server applications

TSO REXEC and RSH servers are trusted single-level secure server applications.

TSO REXEC and RSH servers

The MVRSHD server listens for both rexec and rsh client connections. Requests are submitted as TSO batch jobs and spool output is returned to the client. MVRSHD does perform client authentication and does isolate user data for each connection. However, it does not request port of entry processing during client authentication, and job submission and spool access are performed under the identity of the MVRSHD job rather than the client identity.

RSH client requests are run under the identity and security label of the MVRSHD job. REXEC client requests are run under the user ID specified on the request.

MVRSHD supports an optional startup parameter to control whether or not it inserts the SECLABEL parameter on the generated job card. When SECLABEL=Y is specified at startup, MVRSHD passes its own security label in the SECLABEL job parameter. The user ID specified on the request must be permitted to the MVRSHD server's security label. When the parameter is not specified, or is specified as SECLABEL=N, the default security label of the user ID specified on the request must be identical to the MVRSHD server's security label.

You must run a separate instance of MVRSHD for each security label you need to support. Run each one under a different job name assigned to a user ID with the appropriate security label. You can run multiple MVRSHD servers on the same unrestricted stack. Define a VIPA in a network security zone with the appropriate security label for each server on that stack. Use the PORT reservation statement in the TCPIP profile to override the bind address of each job to the appropriate VIPA.

Network administration client applications

The following applications are network administration client applications:

- nsupdate
- Netstat
- pasearch
- Ping
- Traceroute
- trmdstat

For security implications on the use of these commands, see the following information on configuring these applications for use in your multilevel secure environment.

nsupdate

The nsupdate command is used to update the name server database. Because the name server is often running with a SYSMULTI security label and listening on IP addresses in SYSMULTI network security zones, mandatory access control policy does not limit a general user's ability to use the nsupdate command to contact the server. File system access control lists and security labels should be used to limit execution of this command to intended network administrators. Application level security options should also be considered.

Netstat

Use the Netstat command to display stack settings, and information about open ports and established connections. You might want to restrict the availability of some Netstat options to network administrators. For information on restricting Netstat options, see [“Netstat access control” on page 167](#).

pasearch

The pasearch command is provided to interrogate the stack policies currently in place on a system. It requires that the user have superuser privileges. Only network and security administrators that need to know policy settings should be permitted to issue this command. To limit access, set the file mode access permission bits using the CHMOD command.

Ping

The Ping command is used to verify the network path to a given destination. It sends ICMP Echo Request datagrams to the destination and listens for ICMP Echo Reply responses. Normal Network Access Control limits a user's ability to send and receive these datagrams. On a restricted stack, all users are limited to sending and receiving datagrams to destinations in network security zones with security labels equivalent to the stack. On an unrestricted stack, users are limited to destinations equivalent to their own security label. Users with a SYSMULTI security label on an unrestricted stack are limited to those security zones with which they are authorized to communicate.

You can permit SYSMULTI users to use the Ping command for IP addresses in security zones with security labels that are not equivalent to that stack by using the RACF PERMIT command to give them UPDATE access to the STACKACCESS profile for that stack. You can configure this permission so that it is in effect only for specific programs invoked by the users. For example, to permit users to invoke the Ping command, specify the WHEN(PROGRAM(OPING,PING)) parameter on the PERMIT command.

Traceroute

The Traceroute function is used to verify the network path to a given destination and identify each intermediate system. It sends UDP datagrams to the destination with increasing hop count values, and listens for ICMP TIME EXCEEDED INTRANSIT and PORT UNREACHABLE responses. Normal Network Access Control limits a user's ability to send and receive these datagrams. On a restricted stack, all users are limited to sending datagrams to destinations in network security zones with security labels equivalent to the stack, and receiving datagrams from intermediate systems in equivalent security zones. On an unrestricted stack, users are limited to destinations equivalent to their own security label. Users with a SYSMULTI security label on an unrestricted stack are limited to those security zones with which they are authorized to communicate.

You can permit SYSMULTI users to trace the route to addresses in security zones that are not equivalent to that stack by PERMITting them with UPDATE access to the STACKACCESS profile for that stack. This PERMIT can be limited to apply only when using certain programs, such as Traceroute, by using the WHEN(PROGRAM(tracerte,otracert)) clause on the PERMIT.

trmdstat

The trmdstat command is provided to process syslogd output files and generate IDS reports. The network or security administrator using this command needs to be authorized to read the syslogd output files. This often requires a user security label of SYSHIGH or SYSMULTI.

IBM zEnterprise System platform management applications

Some IBM zEnterprise System (zEnterprise) authorized applications communicate over the intranode management network (INMN), such as those providing platform performance management functions. For more information about these applications, see *zEnterprise System Ensemble Planning and Configuring Guide*.

These applications are not supported in a multilevel secure environment when run under a user ID with a security label of SYSMULTI. They are supported when run under a user ID with a specific security label.

Some of these applications listen using specific multicast IP addresses and ports to determine the remote IPv6 link-local IP address and port number to use for communication with another authorized system performing platform management.

For the zEnterprise authorized platform management application to connect to the INMN, at least one TCP/IP stack on each z/OS image must be connected to an OSA-Express for Unified Resource Manager (OSM) interface. That stack can be an unrestricted stack, or it can be a restricted stack running with a security label that is equivalent to the security label used for the zEnterprise system management agent application.

You must configure TCP/IP and the security server as follows:

- Permit the application to the STACKACCESS resource profile of the stack with one or more OSM interfaces.
- Define an OSMACCESS resource profile on the stack with the OSM interface, using the same security label as that of the application.
- Permit the application to the OSMACCESS resource profile.
- Define a NETACCESS resource profile for the multicast IPv6 address that is used by the application.
- Permit the application to the NETACCESS profile for that multicast address.

General user client applications

The following applications are general user client applications:

- dig
- dnsdomainname, domainname
- host
- hostname
- MISCserv (echo, discard, character generator)
- NSlookup
- TSO REXEC client
- TSO RSH client
- TSO Telnet client
- z/OS UNIX FTP client
- z/OS UNIX REXEC client
- z/OS UNIX RSH client

These commands are supported for use by general users in a multilevel secure environment. Mandatory access control policy enforcement limits the stacks that can be used, the servers that can be contacted, and the local resources that can be used. No extra, application specific, multilevel secure environment configuration is required. For discretionary security environment considerations, see the information for a particular application and see [z/OS Communications Server: IP Configuration Reference](#).

Network management interfaces

This topic describes the multilevel secure networking considerations for those network management interfaces (NMIs) that provide sensitive information.

Real-time application-controlled TCP/IP trace NMI

This NMI can be used to obtain packet and data trace data. For more information about this NMI, see the topic [Real-time application-controlled TCP/IP trace NMI](#) in [z/OS Communications Server: IP Programmer's Guide and Reference](#).

In a multilevel secure environment, define the security labels for the NMI RACF resource profiles and for the user IDs of the NMI applications as follows:

RCCOpen request resource

Define the EZB.TRCCTL.*sysname.tcpname*.OPEN resource profile with a security label of SYSNONE.

RCCSetFilters request packet and data trace resources

The packet and data trace data provided by the NMI are considered sensitive information that must be secured. The following resource profiles are associated with this data:

- EZB.TRCCTL.*sysname.tcpname*.PKTTRACE
- EZB.TRCCTL.*sysname.tcpname*.DATTRACE
- EZB.TRCSEC.*sysname.tcpname*.IPSEC
- EZB.TRCSEC.*sysname.tcpname*.ATTLS

Set the security label associated with these resource profiles to be the same as the security label of the user ID associated with the TCP/IP stack.

User ID of applications

For those applications that request packet or data trace data, the security label associated with the user IDs for the applications can be SYSHIGH (or installation equivalent) if the security label associated with the TCP/IP stack is SYSMULTI or SYSHIGH. However, if the security label associated with the TCP/IP stack is not SYSMULTI or SYSHIGH, the security label associated with the user IDs must be SYSMULTI.

Unsupported applications

The following applications are not supported in a multilevel secure environment:

- HOMETEST command
- LPD
- LPQ command
- LPR command
- LPRM command
- LPRSET command
- NPF
- Portmapper
- SNMP NetView client
- TELNET client command
- TESTSITE command
- TNF
- VMCF
- z/OS UNIX Network SLAPM2 subagent
- z/OS UNIX OMPROUTE SNMP subagent
- z/OS UNIX popper
- z/OS UNIX RSVP agent
- z/OS UNIX SNMP client command
- z/OS UNIX SNMP server and agent
- z/OS UNIX Trap Forwarder Daemon

Any other commands or applications not explicitly mentioned in this information have not been inspected and are not supported in a multilevel secure environment.

Changing your multilevel secure networking environment

Changes to certain parts of your multilevel secure configuration should be well planned. Changes to the NETACCESS statement in PROFILE.TCPIP, the security label associated with the TCPIP started task, the security label associated with the EZB.STACKACCESS or EZB.NETACCESS profiles in the SERVAUTH class, or the definition of profiles in the SECLABEL class can result in an IP address being associated with a different security label. These changes imply that corresponding changes have been implemented that affect the security management of the affected systems. For systems that support mandatory access control policy enforcement, those policies must be updated at the same time. For systems that do not support mandatory access control policy enforcement, the physical user access procedures, system data content, firewall configurations, and router configurations must be updated at the same time.

The safest method of controlling mandatory access control policy changes is to use the RACF options MLSTABLE and MLQUIET. When the RACF options are set to MLACTIVE, MLSTABLE, and NOMLQUIET, TCP/IP does not permit an existing NETACCESS configuration to be changed with a VARY TCPIP,,OBEYFILE command. When the RACF option MLQUIET is set, RACF requires the TCP/IP job user ID to be RACF SPECIAL to open data sets referenced by VARY TCPIP,,OBEYFILE commands. For more information on setting and using these options, see [z/OS Security Server RACF Security Administrator's Guide](#).

In an MLSTABLE environment, all user and application access to data should be halted before entering the MLQUIET environment. All network access can be halted by stopping all TCP/IP stacks. If security administrators must access the system through the TN3270E Telnet server (Telnet), consider running a restricted stack with only Telnet for the security administrators. Permit the Telnet NACUSERID or the procedure's user ID to the EZB.STACKACCESS profile for this stack. Stop all other TCP/IP stacks. After the local policy changes and all coordinated changes on other systems are complete, set NOMLQUIET and restart your production TCP/IP stacks and network servers.

Every stack running on a system with the RACF option MLACTIVE does an internal consistency check on several PROFILE.TCPIP statements and their associated SERVAUTH profiles. This consistency checking occurs at the end of initial profile processing, after the VARY TCPIP,,OBEYFILE command modifies the profile, and whenever RACLIST is issued for the SERVAUTH or SECLABEL classes. Some applications, such as OMPROUTE, also cause the consistency checking to occur because they internally issue an equivalent of the VARY TCPIP,,OBEYFILE command. TCP/IP writes a message to the job log for each inconsistency it finds that could compromise the security of information flowing through the stack. If inconsistencies are found, a final message (EZD1217I) summarizing the number of problems found is written to the system console.

By default, the stack will continue running when inconsistencies are found. It is recommended that you override this default by specifying GLOBALCONFIG MLSCHKTERMINATE in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command, before starting production workloads. Before making security related configuration changes, it is recommended that you first stop all production workloads. You can then specify GLOBALCONFIG NOMLSCHKTERMINATE in PROFILE.TCPIP or in the data set referenced by a VARY TCPIP,,OBEYFILE command. This parameter can be changed only from MLSCHKTERMINATE to NOMLSCHKTERMINATE when the RACF option NOMLSTABLE is set or when both MLSTABLE and MLQUIET are set.

The stack performs the following consistency checks:

- The stack does not currently have a NETACCESS statement configured.
- The TCP/IP job security label must be currently active on this system.
- A STACKACCESS profile for this stack must exist.
- The STACKACCESS profile must have the same security label as the TCP/IP job.
- The NETACCESS statement must have both INBOUND and OUTBOUND turned on.
- A NETACCESS profile must exist for each defined NETACCESS security zone.
- If NETACCESS DEFAULTHOME is configured, it must have a zone with the same security label as the TCP/IP job.

- If NETACCESS TcpStackSourceVIPA is configured, it must be in a zone with the same security label as the TCP/IP job.
- The special address INADDR_ANY (0.0.0.0) must be in a NETACCESS security zone.
- The special address INADDR_ANY (0.0.0.0) must be in a zone with the same security label as the TCP/IP job.
- On an IPv6-enabled stack, the special IPv6 unspecified address [in6addr_any (::)] must be in a NETACCESS security zone.
- On an IPv6-enabled stack, the special IPv6 unspecified address [in6addr_any (::)] must be in a zone with the same security label as the TCP/IP job.
- On an IPv6-enabled stack, every INTERFACE statement must have a manually configured INTFID. (OSA-Express for Unified Resource Manager (OSM) interfaces are exempt from this check.)
- On an IPv6-enabled stack, every INTERFACE that supports autoconfiguration must have at least one manually configured IPADDR. (OSM interfaces are exempt from this check.)
- On an IPv6-enabled stack with dynamic XCF, DYNAMICXCF INTFID must be configured on the IPCONFIG6 statement.
- Every home address on the stack must be in a NETACCESS security zone. (OSM interfaces are exempt from this check.)
- Every home address that is not a VIPA must be in a zone with the same security label as the TCP/IP job. (OSM interfaces are exempt from this check.)
- Every home address that is a VIPA must be in a zone with an equivalent security label as the TCP/IP job.
- On a restricted stack, VIPAs must not be in a security zone with the SYSMULTI security label.

There are several consistency checks that are not performed by the stack. These remain the responsibility of the system security administrator:

- The NetAccess zone definitions must agree across stacks. It is recommended that common definitions from a shared data set be included in all stack profiles.
- Subnetworks or networks are entirely contained in a single NetAccess security zone. NetAccess checks for authorization to a specific destination address, but broadcast packets are delivered to all addresses within a subnetwork or network. Addresses owned by multilevel secure stacks are the only addresses that can be safely configured into a network security zone different than their subnetwork or network.
- RACF definitions must be consistent across RACF data sets. It is recommended that installations use RACF facilities to manage this consistency. SECDATA and SECLABEL class profile consistency is critical to preserve the meaning of SECLABEL profile names. It is suggested that installations define SERVAUTH profiles for all zones that are generic across all systems and stacks, except those containing the loopback address and the unspecified address (IPv4 INADDR_ANY and IPv6 in6addr_any).

Continue making changes to either PROFILE.TCPIP statements or RACF profiles until no consistency errors are reported. Then, specify GLOBALCONFIG MLSCHKTERMINATE in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command. At that point, it is safe to set NOMLQUIET and restart production workloads.

Chapter 5. TCP/IP Customization

Before you begin customizing, it is assumed that you know what configuration data sets are used by the TCP/IP address space, their search order, and considerations for what type of TCP/IP stack you will be running in your environment (for example, Enterprise Extender (EE) and multiple stacks). See [Chapter 2, “IP configuration overview,”](#) on page 11 for this information.

After reading this information, you will know how to configure and start syslogd and the TCP/IP stack. You should understand the relationships of TCP/IP configuration files as they apply to the TCP/IP address space. The four main configuration files that you will be working with are:

- TCPIP.DATA
- PROFILE.TCPIP
- HOSTS.LOCAL
- ETC.IPNODES

You should be able to use the following commands to verify customization:

TSO PING and z/OS UNIX ping

Sends IP datagrams to a specified destination host, requesting a reply, and measures the round trip time. This helps you to verify the interfaces defined to the TCP/IP address space.

TSO NETSTAT, z/OS UNIX netstat, and DISPLAY TCPIP, NETSTAT

Queries TCP/IP about the network status of the local host or the contents of the resolver cache. With Netstat, you can verify most TCP/IP customization values that can be set from PROFILE.TCPIP. You can also display detailed information about the contents of the system-wide resolver cache, or statistical information such as the number of cache queries.

TSO HOMETEST

Verifies your host name and address configuration.

TSO TRACERTE and z/OS UNIX traceroute

Displays the route that a packet takes to reach a requested destination.

Configuring the syslog daemon

The syslog daemon (syslogd) processing is controlled by a configuration file called /etc/syslog.conf, in which you define logging rules and output destinations for error messages, authorization violation messages, and trace data. Logging rules are defined using a *facility* name and a *priority* code. For locally generated messages, the user ID and job name of the program that generated the message can also be specified in the rule. For messages arriving over the network, the rule can include the IP address or host name of the sender. The *facility* name and *priority* code are passed on the logging request from an application when it wants to log a message. The user ID and job name are provided by the system. See [z/OS Communications Server: IP Configuration Reference](#) for more information about logging rules.

You can specify statements and rules in the configuration file using a variety of EBCDIC code pages. Use the SYSLOGD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

As shown in the following sample /etc/syslog.conf file, comments can be added to the configuration file by placing the number (#) character in column one of the comment line. Everything following the number (#) character is treated as a comment. This sample is available in /usr/lpp/tcpip/samples/syslog.conf.

```
# Licensed Materials - Property of IBM
# 5650-Z0S
# Copyright IBM Corp. 2010, 2023
# Status = ZCSV2R5
#
# /etc/syslog.conf - control output of syslogd
#
```

```

# The # sign begins a comment which extends to the end of the line.
#
# Blank lines are ignored.
#
# See IP Configuration Reference for detailed information about
# the syntax. These comments are meant to provide only a general
# overview.
#
# There are two types of configuration information:
#
# 1) Global configuration values that control the behavior of syslogd.
# 2) Rules that specify types of messages which syslogd will
#    store, and where syslogd will store them.
#
# Global configuration statements:
# -----
#
# The following global statements control the syslogd automatic archive
# function. All statements except BeginArchiveParms should only be
# specified once. If you specify them multiple times the last
# instance is used. The BeginArchiveParms statement can be repeated
# multiple times, and each instance pertains to the rules that follow
# it, until another instance is specified. Each instance completely
# replaces the previous instance.
#
# The automatic archive function archives UNIX file destinations to
# MVS sequential or generation data group (GDG) data sets. The
# particular UNIX files that are to be archived must include the -N
# parameter. The -N parameter specifies that the file should be
# automatically archived and then re-initialized when an archive event
# occurs. Alternatively, you can specify the -X parameter. The -X
# parameter specifies that the file should only be re-initialized but
# not archived when an archive event occurs. Use the -X parameter only
# if you do not want to save the contents of the log file. If you
# don't specify the -N or -X parameter, then the file does not
# participate in automatic archival.
#
# Archival occurs for the following events:
#
# - At the time of day configured on the ArchiveTimeOfDay statement.
# - When one or more UNIX file systems reach the percentage full
#   configured on the ArchiveThreshold statement.
# - When the MODIFY procname,ARCHIVE command is issued.
#
# ArchiveTimeOfDay
#   Specifies the local time of day in hours and minutes using a 24
#   hour clock. Syslogd archives all eligible files at the specified
#   time of day. There is no default - if you don't specify this
#   statement, then syslogd does not perform time of day archival.
#
# ArchiveThreshold
#   Specifies the percentage of file system full that triggers an
#   archive. This value applies to all UNIX file systems represented
#   by the set of UNIX files in all rules. When any file system
#   reaches the specified percentage full, files in that file system
#   are archived until the percentage full reaches half of the
#   configured value. Files are archived starting with the largest
#   and working toward the smallest. For example, if you configure
#   80% full, files are archived until the file system is only 40%
#   full. The default is 70%.
#
# ArchiveCheckInterval
#   Specifies the value in minutes for checking the percentage full
#   for UNIX file systems. The default is 10 minutes.
#
# BeginArchiveParms
#   Specifies archive data set details. The following parameters
#   can be specified. DSNPrefix is required but all other parameters
#   are optional (although they might need to be specified for your
#   installation in order for archival to succeed).
#
#   DSNPrefix
#     Specifies the data set name prefix for the archive data set.
#     The complete data set name is formed by concatenating this
#     prefix value with the unique qualifier specified on the -N
#     parameter on a particular rule, and with a unique suffix value.
#     See IP Configuration Reference for complete details on the data
#     set name.
#
#   Unit
#     Specifies the unit for the archive data set.
#
#

```

```

# Volume
#   Specifies the volume for the archive data set.
#
# MgmtClas
#   Specifies the management class for the archive data set.
#
# StorClas
#   Specifies the storage class for the archive data set.
#
# RetPd
#   Specifies the retention period in days for a sequential archive
#   data set. Valid values are 0 - 9999.
#
# The following are example statements that illustrate how to
# configure automatic archival. See the section on syslogd rules for
# details about specifying rules.
#
#   ArchiveTimeOfDay      00:01
#   ArchiveThreshold      70
#   ArchiveCheckInterval  10
#
#   BeginArchiveParms
#     DSNPrefix           USER1.ARCHIVE
#     Volume              VOL001
#     RetPd               30
#   EndArchiveParms
#
# *.SYSLOGD.daemon.notice /var/logs/syslogd/daemon.notice -N daemon.notice
#
# NOTE: The archive data set name for the above example will be:
#
#   USER1.ARCHIVE.DAEMON.NOTICE.Dyymmdd.Thhmmss
#
# Syslogd rules - criteria:
# -----
#
# Four criteria can be used to select locally generated
# messages for processing:
#
# 1) user ID associated with application generating the message
#
#   * can be specified for the user ID if the user ID is not
#   important.
#
# 2) job name of application generating the message
#
#   * can be specified for the job name if the job name is not
#   important.
#
# 3) facility of the message, as specified by the application
#
#   This is user, mail, news, uucp, daemon, auth, cron, lpr, or
#   local0-local7. Consult the documentation for the application
#   to determine which facility the application specifies.
#
#   A special facility, mark, specifies that syslogd should log
#   mark messages on a regular basis. These can be used to verify
#   that syslogd was operational during a specific time interval.
#
# 4) priority of the message, as specified by the application
#
#   This is emerg, panic, alert, crit, err, error, warn, warning,
#   notice, info, or debug. A filter rule condition using a specified
#   priority will match messages with that priority or higher; higher
#   meaning more severe.
#
#   A special priority, none, specifies that messages with the
#   specified user ID, job name, or facility should not be
#   selected.
#
# These criteria are specified together as
#
#   userid.jobname.facility.priority
#
# or, if user ID and job name are both *, as
#
#   facility.priority
#
# This can be combined in a series as
#
#   userid.jobname.facility.priority;userid.jobname.facility.priority
#
#

```

```

# When using syslogd rules with a series of conditions separated by
# semicolons, all of the individual conditions are evaluated
# left-to-right for each message. Each matching condition results in
# either a TRUE (meaning log the message) or a FALSE (meaning don't
# log the message). Conditions that don't match are ignored.
# The final result of evaluating each matching condition left-to-right
# is the result of the last matching condition. Rules that have no
# matching conditions for a message result in a FALSE.
# Matching exclude conditions (those with priority of none) result
# in a FALSE. As an example, consider the difference between the
# following two rules for a message with facility of daemon and
# a priority of emerg.
#
# daemon.none;*.emerg /tmp/mylogfile
# *.emerg;daemon.none /tmp/mylogfile
#
# The first rule, first condition, results in FALSE. The first rule,
# second condition, results in TRUE. Therefore, the message will be
# logged to the destination for this rule.
# The second rule, first condition, results in TRUE. The second rule,
# second condition, results in FALSE. The message will not be logged
# for this rule.
#
# The order of conditions within the filter is significant.
#
# Three criteria can be used to select messages received over the
# network for processing:
#
# 1) IP address or hostname of the sender. The IP address may be in
# IPv4 or IPv6 format or may be a hostname that resolves to an
# IPv4 or IPv6 address. If an IP address is used, an optional prefix
# length may be specified with the /x notation.
#
# 2) facility of the message. See the description of facility above.
# 3) priority of the message. See the description of priority above.
#
# These criteria can be specified together as
#
# (ip_address).facility.priority
#
# or
#
# (hostname).facility.priority
#
# If the the IP address or hostname is not to be considered in selecting the
# rule, then omit it and specify just facility.priority
#
# The following rule will match locally generated messages or
# messages received over the network from any source IP address
# that have the specified facility and priority (or higher).
#
# facility.priority
#
# The criteria for selecting messages for processing are combined
# with a destination, which tells syslogd what to do with selected
# messages.
#
# criteria destination
#
# Syslogd rules - destination:
# -----
#
# The destination can be a file, one or more user IDs, SMF, syslogd
# at a remote host, or all logged-in users, or the operlog log stream.
#
# Syslogd rules - file destination:
# -----
#
# If the destination is a file, it may be optionally followed by two
# options, -F and -D. -F should be followed by an octal number that
# indicates the permissions value to be used if syslogd must create
# the file. -D should be followed by an octal number that indicates
# the permissions value to be used if syslogd must create the
# directory to contain the file. These options are only effective
# if syslogd is started with the -c start option. See the
# Communications Server IP Configuration Reference for details.
#
# The following example stores messages with facility daemon or
# local1 in the file /directory/logfile.
#
# daemon.*;local1.* /directory/logfile
#
# Syslogd rules - remote host destination:

```

```

# -----
# Either the UDP or TCP transport protocol can be used to forward
# messages to a remote host. Select the protocol based on the protocol
# that is supported and active on the remote host.
#
# If the destination is a remote host, there are two forwarding syntax
# options to choose from:
#
# 1) Forwarding action statement -A(...)
#
#   -A(parameter="value" parameter="value" ...)
#
# The -A() forwarding action uses action parameters/values to
# describe where and how messages are being forwarded. Multiple
# parameters can be configured within a forwarding action.
# Forwarding action syntax:
#   -The -A() statement must begin and end with a parenthesis.
#   -Action parameters/values must be configured within the
#     parenthesis of the -A() statement.
#   -A parameter and its value must be separated by the '=' symbol
#     (that is, parameter="value").
#   -Each parameter, along with its value, must be separated by
#     spaces/tabs (that is, parameter="value" parameter="value").
#   -Each value must be enclosed with quotes (i.e. "value").
# Note: The parameters can be configured in any order.
#
# Syslogd will recognize the following forwarding action parameters
# and values on a rule:
#
# Destination
#   The remote host where messages will be forwarded. The host may
#   be specified by an IPv4 address, IPv6 address, or by a name that
#   resolves to an IPv4 or IPv6 address. This parameter is required.
#   If not specified, the rule will be ignored.
#
#   Valid destination syntax:
#       destination="abc.com"
#       destination="192.168.1.9"
#
# Protocol
#   The transport protocol used to forward messages. The supported
#   values are UDP and TCP. A value of UDP indicates that the
#   message should be sent using UDP to the destination and
#   port specified in the forwarding action. A value of TCP
#   indicates that a TCP connection should be established with
#   the destination and port specified in the forwarding action
#   and messages should be sent over the connection.
#   If not specified, the rule will be ignored.
#
#   Valid protocol syntax:
#       protocol="UDP"
#       protocol="TCP"
#
# Port
#   The remote host port where messages will be forwarded. This
#   must be a valid port number ranged from 1-65535.
#   This parameter is optional and a default is used based on the
#   value of the protocol parameter. If the protocol is UDP, the
#   default is the UDP syslog port configured in /etc/services or
#   514 (if the UDP syslog port is not configured).
#   If the protocol is TCP, the default is 514.
#
#   Valid port syntax:
#       port="529"
#       port="30000"
#
# Secure
#   The option to forward messages over a clear TCP socket or a
#   secure TCP socket protected by TLS. When the value is set to
#   "yes", syslogd will require an AT-TLS policy. This parameter
#   is optional, and must only be configured with the TCP protocol
#   parameter.
#   If the protocol is UDP, and this parameter is specified,
#   the rule will be ignored. If the protocol is TCP, the default
#   is "no".
#
#   Valid secure syntax:
#       secure="yes"
#       secure="no"
#
# 2) '@' symbol followed by a hostname or ip address (either IPv4 or IPv6)
#

```

```

# @hostname
#
# or
#
# @ip_address
#
# This syntax can only be used to forward messages using the UDP
# transport protocol. The remote host's port cannot be configured
# on a per rule basis. If a UDP syslog port is specified in
# /etc/services, it will be used as the remote host's port.
# Otherwise, port 514 is used.
#
# Syslogd rules - Using a cron job to manage local files
# -----
#
# The directory structure used in this sample configuration is
# expected to be created automatically by syslogd, with a new
# directory of log files for each day. This requires two types
# of configurations outside of the scope of this configuration
# file:
#
# 1) syslogd command-line option
#
# The syslogd -c command-line option should be enabled, causing
# syslogd to create log files and directories if they do not
# already exist.
#
# 2) cron job
#
# A cron job should be utilized to wake up syslogd at the
# beginning of each day to switch to new log files in a new
# directory. Here is the cron job definition:
#
# 1 0 * * * kill -HUP `cat /etc/syslog.pid`
#
# This job should be defined for a user ID with UID zero so that
# it has permissions to send the signal to syslogd.
#
# See UNIX System Services Planning and UNIX System Services
# Command Reference for more information about cron.
#
# A sample shell script is provided for removing log files which are
# a specified number of days old. It assumes the same directory
# structure which is used in this sample configuration.
#
# This is an alternative to the automatic archive function of syslogd.
# For more information on automatic archiving see "Configuring syslogd
# for automatic archiving" in the IP Configuration Guide.
#
# Example syslogd rules
# -----
#
# All example rules except for the last one are commented-out. Some
# or all of the example rules will need to be changed for your
# environment. Each example rule contains an explanation of changes
# which may be required.
#
#####
# Write all messages with priority crit or higher to the MVS operator
# console. See the UNIX System Services Planning manual for more
# information about the /dev/console special file.
#
# *.crit /dev/console
#
#####
# Write all messages with facility of daemon and a priority of error
# or higher to the operlog log stream. The operlog facility must be
# active in order to be able to log messages to the operlog log
# stream.
#
# daemon.err /dev/operlog
#####
# Write all messages from syslogd itself to the file
# /var/log/YYYY/MM/DD/syslogd.log and to the system console.
#
# Notes:
#
# a) If syslogd is invoked as a started task or from a shell script
# (e.g., /etc/rc) with job name SYSLOGD, the name of the
# long-running syslogd job is SYSLOGD followed by a digit.

```

```

#
# If syslogd runs with a different job name on your system, the
# rule will have to be changed accordingly.
#
# b) During initialization, syslogd writes messages to
# /dev/console. These rules cover messages during steady-
# state.
#
# *.SYSLOGD*.*.*      /var/log/%Y/%m/%d/syslogd.log
# *.SYSLOGD*.*.*      /dev/console
#
#####
#
# Write all messages from inetd to the log file inetd and to the
# console.
#
# Notes:
#
# a) If inetd is invoked as a started task or from a shell script
# (e.g., /etc/rc) with job name INETD, the name of the
# long-running inetd job is INETD followed by a digit.
#
# If inetd runs with a different job name on your system, the rule
# will have to be changed accordingly.
#
# *.INETD*.*.*        /var/log/%Y/%m/%d/inetd
# *.INETD*.*.*        /dev/console
#
#####
#
# Write all messages with priority err or higher from applications
# which specify facility "daemon" to the log file daemon.
# Because we chose to log messages from syslogd and inetd separately,
# we'll filter out those messages from this rule using special
# priority none.
#
# Notes:
#
# a) In this example, SYSLOGD followed by some other character is the
# job name of syslogd. If it is different on your system, change
# the rule.
# b) In this example, INETD followed by some other character is the
# job name of inetd. If it is different on your system, change the
# rule.
#
# daemon.err;*.SYSLOGD*.*.none;*.INETD*.*.none /var/log/%Y/%m/%d/daemon
#
#####
#
# Write all messages from applications which specify facility "auth"
# to the log file auth.
#
# auth.* /var/log/%Y/%m/%d/auth
#
#####
#
# Write all messages from applications which specify facility "mail"
# to the log file mail. Use file permissions of 640 octal if the file
# has to be created. Use permission of 770 octal if the directory has
# to be created. syslogd must be started with -c for these options
# to have any effect.
#
# mail.* /var/log/%Y/%m/%d/mail -F 640 -D 770
#
#####
#
# Write all messages with priority err and higher from otelnetd and
# other applications which specify facility "local1" to the log file
# local1.
#
# local1.err          /var/log/%Y/%m/%d/local1
#
#####
#
# Write all messages from otelnetd and other applications which
# specify facility "local1" when running as user SMITH to the log file
# local1.smith. This could be useful if, for example, otelnetd traces
# need to be collected for a problem which user SMITH is experiencing
# and you do not wish to collect otelnetd traces from all user IDs.
#
# SmITH.*.local1.*    /var/log/%Y/%m/%d/local1.smith
#

```

```

#####
#
# Write all messages with priority err and higher to SMF. These will
# be stored in SMF record type 109. SMF must be active and
# configured to accept record type 109. The user ID associated with
# syslogd must have read access to BPX.SMF. See UNIX System Services
# Planning for more information about BPX.SMF.
#
# *.err          $SMF
#
#####
#
# Write all messages with priority crit and higher to the syslogd on
# host 192.168.1.9 over a UDP socket. The host may be specified by IPv4
# address, by IPv6 address, or by a name that resolves to an IPv4 or
# IPv6 address.
#
# *.crit         @192.168.1.9
#
# Or use the -A forwarding action syntax which allows the remote port
# to be specified on a per rule basis.
#:
# *.crit         -A(destination="192.168.1.9" protocol="UDP" port="514")
#
# Configure one format or the other, not both.
#
#####
#
# Write all messages with priority crit and higher that arrive from
# host 192.168.0.6 to the operlog log stream.
#
# (192.168.0.6).*.crit      /dev/operlog
#
#####
#
# Write all messages with priority crit and higher that arrive from
# any host with IP address in the range 192.168.0.0 to 192.168.0.255
# to the operlog log stream.
#
# (192.168.0.6/24).*.crit    /dev/operlog
#
#####
#
# Write all messages from applications which specify facility "local1"
# with priority err and higher to the syslogd on host abc.com using
# TCP port 30000. When the secure parameter is not specified on the
# -A forwarding action for protocol="TCP", the default is to forward
# data over a TCP connection that is not protected by TLS.
#
# local1.err -A(destination="abc.com" protocol="TCP" port="30000")
#
#####
#
# Write all messages with priority crit and higher that arrive from
# host 192.168.0.6 to the syslogd on host 192.168.1.9 using TCP port
# 514. When the port parameter is not specified on the -A forwarding
# action for protocol="TCP", the default is port 514. When the secure
# parameter is not specified for protocol="TCP", the default is to
# forward data over a TCP connection that is not protected.
#
# (192.168.0.6).*.crit -A(destination="192.168.1.9" protocol="TCP")
#
#####
#
# Write all messages from applications which specify facility "local1"
# with priority err and higher to the syslogd on host abc.com using TCP
# port 30001 over a connection protected by TLS.
#
# local1.err -A(destination="abc.com" protocol="TCP" port="30001" secure="yes")
#
#####
#
# Write all messages with priority crit and higher that arrive from
# any host with IP address in the range 192.168.0.0 to 192.168.0.255
# to the syslogd on host 192.168.1.9 using TCP port 6514 over a
# connection protected by TLS. When the port parameter is not specified
# on the -A forwarding action for protocol="TCP" and secure="yes", the
# default is port 6514.
#

#
# Write all messages with priority err and higher to log file errors.
#
# THIS EXAMPLE STATEMENT IS UNCOMMENTED.
#
*.err /var/log/%Y/%m/%d/errors
#
```

Starting and stopping syslogd

You must start the syslog daemon (syslogd) from a user ID with superuser authority (UID 0). You can start syslogd from the z/OS UNIX System Services shell, from a started procedure using BPXBATCH, or from a started procedure that directly invokes syslogd. To ensure that syslogd services are available to applications during TCP/IP initialization, start syslogd from the z/OS UNIX System Services initialization shell script /etc/rc.

```
#
# Start the syslogd daemon
#   Export any syslogd environment variables before starting syslogd.
#
#   The ampersand (&) symbol is necessary to allow the z/OS Unix System
#   Services initialization to continue while syslogd starts.
#
#
export _BPX_JOBNAME='SYSLOGD1'
/usr/sbin/syslogd -f /etc/syslogd.conf &
```

If there is no TCP/IP transport active when syslogd starts or when TCP/IP is recycled, syslogd remains active until it can establish or reestablish communication with TCP/IP.

Rules:

- If you start syslogd from a shell script, start it as a background shell command by specifying an ampersand (&) as the last character on the command. If you do not specify the ampersand, control does not return to the shell until syslogd ends. When starting syslogd from the /etc/rc script it is especially important to code the ampersand; if you do not code the ampersand, z/OS UNIX System Services initialization cannot complete.
- If you start syslogd from a shell script and you call the shell script from a started procedure using BPXBATCH, you need to add a **sleep** shell command to your script after the start of syslogd. The **sleep** command prevents the shell script from ending before syslogd initialization completes.
- If you start syslogd from a shell script and you call the shell script from a started procedure using BPXBATCH, you must use a z/OS UNIX file for the STDOUT and STDERR DD statements; otherwise the started procedure cannot end.

Guidelines:

- When starting syslogd from a shell script, the resulting job name is the user ID under which the shell script is running. You can override the default job name by setting and exporting the _BPX_JOBNAME environment variable in your shell script.
- When starting syslogd from a started procedure, the resulting job name is the same as the name of the started procedure. You can override the default job name by setting the JOBNAME= parameter. For example:

```
S SYSLOGD1, JOBNAME=SYSLOGD
```

- When starting syslogd from a shell script, export the environment variables before starting syslogd. The following example defines the syslogd configuration file:

```
#
# Shell script to start syslogd
#
export _BPX_JOBNAME='SYSLOGD1'
export SYSLOGD_CONFIG_FILE="//'HLQ.SYSLOGD.CONFIG(DEFAULT)'"
/usr/sbin/syslogd &
```

- When starting syslogd directly from a started procedure, place the syslogd environment variables in a z/OS UNIX file or MVS data set. Use the following technique to pass the environment variables to syslogd.

```
// PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
//STDENV DD PATH='/etc/syslogd.env',PATHOPTS=(ORDONLY)
or
//STDENV DD DSN=HLQ.SYSLOGD.ENV(DEFAULT),DISP=SHR
```

When you use an MVS data set for your syslogd environment variables, place the environment variables in a data set with the VB record format [RECFM(VB)] and a logical record length of 256 [LRECL(256)]. If you use any other record format for the data set, use the _CEE_ENVFILE_S environment variable in place of the _CEE_ENVFILE environment variable in your syslogd started procedure. When the _CEE_ENVFILE_S environment variable is used, the system removes trailing blank spaces from each NAME=VALUE line that is read. For additional information about the _CEE_ENVFILE_S environment variable, see [z/OS XL C/C++ Programming Guide](#).

Modes for running syslogd

Syslogd can run in one of three modes:

- Normal

In this mode, syslogd processes logging requests from the local system and applications using the syslog() function. Additionally, syslogd receives and logs messages sent over the IP network by remote systems running syslogd. These remote systems can be z/OS systems or non-z/OS systems. Only one instance of syslogd can be run on a z/OS system if syslogd is started in this mode.

- Local-only

In this mode, syslogd processes logging requests from only the local system and applications. This instance of syslogd does not receive or process messages sent over the network from remote syslog daemons. Use the -i option to start syslogd in the local-only mode.

- Network-only

In this mode, syslogd processes only messages sent over the network by remote systems running syslogd. This instance of syslogd does not process logging requests from the local system or applications. Use the -n option to start syslogd in the network-only mode.

In all three modes, syslogd can send messages to remote syslog daemons.

Requirement: You must install and activate the AF_UNIX domain prior to starting syslogd in normal or local-only mode.

As shown in [Table 16 on page 244](#), how you choose to run syslogd depends on your logging requirements.

Table 16. Mode to use for different logging requirements	
Logging requirement	How to run syslogd
You have a low volume of messages that you want to process from the network.	Run a single instance of syslogd in normal mode.
You do not want to process any log messages from remote syslog daemons over the network.	Run a single instance of syslogd in local-only mode.

Table 16. Mode to use for different logging requirements (continued)

Logging requirement	How to run syslogd
You have a high volume of log messages from remote syslogd daemons that you want to log with syslogd.	Run two instances of syslogd. Start one instance of syslogd in local-only mode to process all local messages. Start another instance of syslogd in network-only mode to process the remote syslog messages. Two instances of syslogd provide better performance than running a single instance of syslogd in normal mode, especially in high-volume situations.

Restriction: A maximum of two instances of syslogd can be started. If you are going to start more than one instance of syslogd on the same z/OS image, one instance must be started in local-only mode and one instance must be started in network-only mode. Never run just one instance of syslogd in network-only mode. If an instance of syslogd is not processing local system and application messages, these messages are written to the MVS console and might result in message flooding on the MVS console.

Processing messages from remote systems

Syslogd running in normal or network-only mode can receive messages over the network using UDP, TCP, or both. This must be coordinated with the syslogd clients sending messages.

- Receiving messages over the network using TCP provides a more reliable transport than UDP. Use the -T option to allow syslogd to accept TCP connections from remote syslogd clients. When using the -T option there is no guarantee of TLS protection. Use the -S option to require that messages received over the network using TCP must be protected by TLS. Syslogd can be started with both the -S and the -T option to support clients sending messages with and without TLS protection.
- Receiving messages over the network using UDP is less reliable but might be required if a syslogd client only supports sending over UDP. Use the -U option to allow syslogd to accept network messages using UDP.

Note: If neither the -T or -S option is specified for syslogd running in normal or network-only mode, receiving UDP messages over the network is supported by default. If either the -T or -S is specified, then the -U option must be specified explicitly for UDP messages to be supported.

Using the TZ environment variable with syslogd

To record timestamps more accurately, you need to set the TZ environment variable to local time. You can set the TZ environment variable in the following ways:

- When you start syslogd from the z/OS shell

Export the TZ environment variable before you start syslogd. Export it in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States, issue the following command:

```
export TZ=EST5EDT
```

- When you are starting syslogd as a started task, use either of the following methods:
 - Specify TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:

```
// PARM='ENVAR("TZ=EST5EDT")/'
```

- Export the TZ environment variable in a file specified with the STDENV DD statement. For example:

```
// PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
//STDENV DD PATH='/etc/syslogd.env',PATHOPTS=(ORDONLY)
```

Place the following statement in the /etc/syslogd.env file:

```
TZ=EST5EDT
```

Use the STDENV DD statement when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

You can also set the TZ environment variable for all applications in the CEEPRMxx PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

```
CEEEOPT(ALL31(ON), ENVAR('TZ=EST5EDT')) )  
CEEDOPT(ALL31(ON), ENVAR('TZ=EST5EDT')) )  
CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT')) )
```

For more information about [Using the CLER CICS transaction to display and set runtime options](#), see [z/OS Language Environment Programming Guide](#). For details on setting the [Format of the TZ environment variable](#) environment variable, see [z/OS UNIX System Services Command Reference](#).

Syslogd start option syntax

The syntax of the syslogd command is as follows:

The **syslogd** command recognizes the following options:

-c

Create log files and directories automatically. The -c option is required to use the automatic archive function (see [“Configuring syslogd for automatic archiving”](#) on page 258).

-d

Run syslogd in debugging mode (see [“Diagnosing syslogd configuration problems”](#) on page 261 for more information).

-D

Default access permissions (modes) to be used by syslogd when creating directories. This parameter is valid only when specified in conjunction with the -c option. The parameter value is specified as an octal number 1- 4 characters in length. Leading zeros can be omitted. The following values can be ORed together to form the parameter value:

Value

Description

2000

Set GID

1000

Sticky bit (deletion restricted to owner or superuser)

0400

User read

0200

User write

0100	User list directory
0040	Group read
0020	Group write
0010	Group list directory
0004	Other read
0002	Other write
0001	Other list directory

If the -D option is not specified, the default value 0700 is used. The actual permissions are modified by the syslogd process umask value at the time when the file is created. Value 0000 is not valid. Bits other than the ones shown are not valid. For example, you cannot set the set-UID bit for a directory. z/OS does not use the set-GID bit during directory creation regardless of whether the bit was set in the directory permissions.

-f
Configuration file name. You can also specify the configuration file using the SYSLOGD_CONFIG_FILE environment variable. The -f option overrides the environment variable.

-F
Default access permissions (modes) to be used by syslogd when creating log files. This parameter is valid only when specified in conjunction with the -c option. The parameter value is specified as an octal number 1 - 4 characters in length. Leading zeros can be omitted. The following values can be ORed together to form the parameter value:

Value	Description
0400	User read
0200	User write
0040	Group read
0020	Group write
0004	Other read
0002	Other write

If the -F option is not specified, the default value 600 is used. The actual permissions are modified by the syslogd process umask value at the time when the file is created. This parameter is used only when syslogd must create a log file dynamically; it has no effect on log files that already exist. Value 0000 is not valid. Bits other than the ones shown are not valid and are set to 0. For example, you cannot set the execute bits, set-UID, set-GID, or the sticky bit for log files.

-i
Start in local-only mode, and do not receive messages from the IP network. This option is mutually exclusive with the -n option. If syslogd is started with the -i option, another instance of syslogd can be started with the -n option. This is the only supported way to run two instances of syslogd on the

same z/OS image. Syslogd can still send messages to remote syslogd instances when it is running in local-only mode.

-m

Number of minutes between mark messages. The default value is 20 minutes. The following rule must be coded for each logfile that you want a mark record recorded in: mark.info.

-n

Start in network-only mode, and receive messages from only the IP network. This option is mutually exclusive with the **-i** option. If syslogd is started with the **-n** option, another instance of syslogd can be started with the **-i** option. This is the only supported way to run two instances of syslogd on the same z/OS image. Syslogd can write messages locally or send messages to remote syslogd instances when it is running in network-only mode.

-p

Path name of the z/OS UNIX character device for the datagram socket. The default value is /dev/log. You can also specify the path name using the SYSLOGD_PATH_NAME environment variable. The **-p** option overrides the environment variable.

Note: This option is not used frequently. If you use the **-p** option incorrectly, syslogd will not function properly.

-S

Allow messages to be received over the network using TCP connections that are protected using TLS. The TCP port identified for use with the syslog-tls tcp service in /etc/services (or default port 6514) is opened.

This option is mutually exclusive with the **-i** option.

-T

Allow messages to be received over the network using TCP connections without TLS protection. The TCP port identified for use with the syslog tcp service in /etc/services (or default port 514) is opened.

This option is mutually exclusive with the **-i** option.

-U

Allow messages to be received over the network using the UDP port identified for use with the syslog udp service in /etc/services (or default port 514).

This option is mutually exclusive with the **-i** option.

Note: The same UDP socket is used to both receive and send syslogd messages. The port can be open to send messages, but messages can only be received from the network if syslogd was started in normal or network-only mode and one of the following is true:

- **-U** is specified or
- **-T**, **-S**, and **-U** are not specified

-u

For records received over the AF_UNIX socket (most messages generated on the local system), include the user ID and job name in the record. In this case, a forward slash, the user ID, and the job name will follow the local host name for messages received over the AF_UNIX socket. The forward slash, which immediately follows the local host name, can be used to determine whether or not the user ID and job name is being recorded. If not recorded, a blank immediately follows the local host name. When user ID or job name is not available, N/A will be written in the corresponding field.

-x

Disable host name resolution for messages received from the IP network. This option is mutually exclusive with the **-i** option. Using this option can improve the performance of syslogd when processing messages received from the IP network. It has no effect for local messages. When you use this option, the IP address (instead of the host name) of the origin host is logged, along with the message text. If the host name can be determined from the rule without having to make a resolver call, the host name is used instead of the IP address. When the **-x** option is not used, syslogd always attempts to resolve the host name associated with a log message arriving from the IP network. If the

host name cannot be determined, the IP address is logged as the message origin instead of the host name.

-?

Show syslogd command-line options.

Starting syslogd

To specify the job name and pass the appropriate environment variables to the syslogd process, start syslogd by using a shell script such as the following script:

```
#  
# Start the syslog daemon  
#  
  
export _BPX_JOBNAME='syslogd'  
/usr/sbin/syslogd -f /etc/syslog.conf &
```

You can execute this shell script directly from the /etc/rc file to start syslogd at z/OS UNIX initialization.

If an incorrect argument or number of arguments is entered, syslogd exits and the return code is 1. In all other situations in which syslogd exits, the return code is 0.

Stopping syslogd

To terminate syslogd, you can issue the STOP command, issue the MODIFY command, or send a SIGTERM signal.

```
STOP jobname  
  
MODIFY BPX0INIT,TERM=processID  
  
kill -s TERM processID
```

Reprocessing the configuration file

To force syslogd to reread its configuration file and activate any modified parameters without stopping, issue the MODIFY *procname*,RESTART command or send a SIGHUP signal. This also causes any host names specified in rule selectors or destinations to be resolved again to IP addresses. After rereading the configuration file, syslogd continues to append log messages to the files that you specify in /etc/syslog.conf.

```
MODIFY procname,RESTART  
  
kill -s HUP processID
```

Syslogd process ID (PID) files

The syslog daemon stores its process ID in the /etc/syslog.pid file or the /etc/syslog_net.pid file, so that it can be used to terminate or reconfigure the daemon. If syslogd is started in normal or local-only mode, the /etc/syslog.pid file is used to store the process ID. If syslogd is started in the network-only mode, the /etc/syslog_net.pid file is used to store the process ID.

Restrictions:

- If /etc/syslog.pid or /etc/syslog_net.pid is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the syslog daemon.
- If /etc/syslog.pid or /etc/syslog_net.pid is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which /etc/syslog.pid or /etc/syslog_net.pid is stored cannot have write access to the directory. Additionally, write access to /etc/syslog.pid and /etc/syslog_net.pid must be limited to the owning UID or group, for example, --w--w---permissions.

Rule: If the BPX.SMF FACILITY class resource is defined and SMF records are to be written by syslogd, the user ID with which syslogd runs must also be permitted to SAF resource BPX.SMF. See SEZAINST(EZARACF) for more information.

Tips:

- Messages are read from the UNIX domain datagram socket (unless the `-n` option is specified), and from the IPv4 (AF_INET) or IPv6 (AF_INET6) Internet domain sockets (unless the `-i` option is specified).
- Messages written to a local instance of syslogd with the kern facility are converted to the user facility. If syslogd receives a log message over the network with the kern facility, the facility is not changed.

For more information about the facilities used by z/OS Communications Server functions, see [Syslogd facilities](#)

Configuring syslogd to receive remote messages

The ability to receive messages from remote syslogd instances can be very useful in providing a consolidated log of messages from multiple hosts into a consolidated z/OS message log. For example, in scenarios where you are running Linux hosts on zSystems processors, and these Linux hosts are performing processing in cooperation with or on behalf of z/OS systems, you might want to have certain important messages generated on the Linux hosts visible from a z/OS system. This capability would enable z/OS operators to be alerted of specific conditions on the Linux hosts that might require actions to be taken locally or on the Linux hosts.

If you decide that this remote logging capability is useful in your environment, there are several configuration considerations that should be examined prior to enabling this function. It is also important to note that the syslogd remote logging capability can work in both directions; the z/OS syslogd can forward some of its messages to another remote syslogd instance, or the z/OS syslogd instance can be the receiver of remote syslogd messages. The considerations described here focus primarily on the latter scenario, where the z/OS syslogd is the recipient of remote messages.

Improving the efficiency of syslogd remote logging functions

While the ability for the z/OS syslogd to receive remote messages can be very useful, it is important that appropriate planning take place to ensure that the additional remote message traffic that syslogd receives does not create a performance issue or impede the ability for the local z/OS syslogd to perform its processing. The following configuration options can help reduce such risks:

- Configure the remote syslogd instances to forward only messages that are important enough to consolidate on the z/OS system. For example, high-volume debug traces should be collected on the local host instead of having them forwarded to a z/OS system. Syslog daemon implementations typically provide the ability to define configuration statements that dictate which type of messages are forwarded to remote hosts. For example, the z/OS syslogd enables you to filter messages based on the facility and priority associated with a message. For more information about the specific configuration of your remote syslogd instances, consult the documentation available for the platform on which the remote syslogd instance is running.
- If the remote message traffic that the local z/OS syslogd instance is expected to receive is substantial, consider configuring a network-only instance of syslogd and a local-only instance of syslogd. This helps ensure that the logging of locally generated z/OS syslogd messages is not impacted by high-volume remote message traffic.
- When the local z/OS syslogd instance receives a message from a remote syslogd, it determines the disposition of the message based on its own configuration statements. These configuration statements enable you to determine which received messages are of interest and how these messages should be logged. The following guidelines describe how these statements can be configured for remote message receipt:
 - The z/OS syslogd can log messages to various destinations, including z/OS UNIX file system files, the MVS console, the MVS operations log, SMF records, and so on. If the destination for the remote messages is the MVS console or MVS system log designated with the `/dev/console` destination, consider whether logging these messages to the MVS operations log (that is, the OPERLOG log

stream) designated by the /dev/operlog destination is a suitable alternative. Logging messages to the OPERLOG log stream is more efficient and consumes less system resources than logging messages to the MVS console.

The OPERLOG log stream must be configured and active before using the syslogd /dev/operlog destination. If the OPERLOG log stream is not active when syslogd attempts to log a message to the /dev/operlog destination, message FSUM1234 is logged with a facility.priority value of daemon.error. If the OPERLOG log stream later becomes active, message FSUM1235 is logged with a facility.priority value of daemon.error, and logging to OPERLOG automatically begins. For more information about using OPERLOG, see [z/OS MVS Planning: Operations](#).

- You can identify which messages the z/OS syslogd should process by identifying the known remote syslogd instances from which you expect to receive messages. For example:

```
(host1.xyz.com).*.*      /dev/operlog
(host2.xyz.com).*.*      /dev/operlog
```

In this example, syslogd resolves the specified host names to the IP addresses associated with those hosts during initialization by invoking the system resolver services. After initialization is complete and syslogd begins receiving remote messages, it first checks to determine whether the incoming messages match any of the specified configuration statements. In this example, syslogd processes only remote messages that have a source IP address associated with the hosts host1.xyz.com or host2.xyz.com, and logs these messages in the MVS operations log. Assuming that no other configuration statements are specified, any messages received from other hosts are discarded.

Specifying configuration statements that identify each remote host using a host name also has the additional benefit of enabling these remote messages to include a host name identification when they are logged locally, without incurring the overhead of a host name resolver lookup for each incoming message. The per-message host name resolver lookup can be disabled using the -x syslogd option. If the ability to perform a resolver lookup for every message is necessary or useful in your environment, you should use the system resolver cache function (see [“Customizing the resolver”](#) on page 762 and [“Resolver caching”](#) on page 774). If host name resolution is performed, and the message was received over a link-local IP address, the resolved host name might include scope information that identifies the interface over which the message was received. For more details on support for scope information on a host name, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

In addition to host names, remote syslogd instances can also be identified using IPv4 or IPv6 addresses or by specifying an IPv4 subnet or IPv6 network prefix. For example:

```
(10.42.105/24).*.*      /dev/operlog
(10.43.110.15).*.*      /tmp/otherlog
```

In this example, any remote messages received from hosts using an IP address in subnetworks 10.42.105.0 to 10.42.105.255 are logged in the MVS operations log, while messages received from the host identified by 10.43.110.15 are logged in the /tmp/otherlog file.

- In addition to identifying the remote syslogd instances that can forward messages, you can also use additional filters to determine which remote messages you want to log locally. For example:

```
(host1.xyz.com).*crit    /dev/operlog
(host2.xyz.com).*crit    /dev/operlog
```

With these configuration statements, syslogd logs only messages received from hosts host1 and host2 that have a critical priority to the MVS operations log. Assuming that no other configuration statements are specified, any other messages received from those hosts are discarded.

Security considerations

As with all network communication protocols, give careful consideration to the security requirements that might be appropriate to protect this remote message logging function in your environment.

- One option is to deploy a Virtual Private Network (VPN) using IPsec across the remote syslogd instances and the local z/OS syslogd. This option can be used to protect remote messages received over UDP

or TCP. IPsec provides data integrity, data origin authentication, replay protection, and optional data confidentiality.

Configuration is required on both the local z/OS system and the remote hosts of the syslogd instances that are forwarding messages. On the z/OS side, this is accomplished by defining an IP security policy. In this IP security policy, you specify filter rules that indicate all the remote hosts that are allowed to send messages to the local syslogd ports, along with the IPsec actions that define the IPsec attributes for this traffic. The IPsec policy can be defined in such a way that if any UDP datagrams or TCP connections destined for the local syslogd ports are received that do not match the IP security policy, they are discarded by the local TCP/IP stack. This provides an additional level of protection against denial of service attacks for syslogd, as unauthorized messages are discarded without syslogd needing to process them.

- Another option is to use TLS to protect TCP connections to the local z/OS syslogd. TLS provides data integrity, data origin authentication, and data confidentiality. The underlying TCP layer provides replay protection.

Restriction: TLS is only supported for TCP connections. If your implementation requires receiving remote syslogd messages over UDP, IPsec would be needed to protect the UDP traffic.

To implement TLS protection, configuration is required on both the local z/OS system and the remote hosts of the syslogd instances that are forwarding messages. On the z/OS side, this is accomplished by defining AT-TLS rules for inbound connections to the z/OS syslogd server port.

- In conjunction with TLS protection for TCP connections, an IP filtering policy can be implemented to only allow TCP connections destined for the local syslogd port from a configured group of IP addresses or subnets. This provides an additional level of protection against denial of service attacks for syslogd, as unauthorized messages are discarded without syslogd needing to process them.

Obviously, the security considerations for deploying remote syslogd logging depend on your local environment and your local security policies. For more information about the z/OS configuration for IPsec, see “Overview of using IP security” on page 916. For more information about the z/OS configuration for AT-TLS, see Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149. For more information about configuring IPsec or TLS on the remote hosts, consult the documentation for that platform.

Availability considerations

Syslogd availability is important to the logging of both local and remote messages. The following configuration considerations can help improve the availability of the z/OS syslogd remote logging services:

- Ensure that there is a process in place to restart a z/OS syslogd after a failure that results in the termination of syslogd. You can use any available automated operations software package to automate the start and restart of syslogd.
- On z/OS systems that are not part of a sysplex and that have TCP/IP stacks with multiple network interfaces, using a static VIPA address can provide for better availability characteristics should a specific network interface or network experience an outage. This involves configuring a static VIPA in the TCP/IP profile or reusing an existing one. No special configuration of the local syslogd is needed. However, you should configure the remote syslogd instances to use the static VIPA address as the destination address when forwarding messages. This can typically be accomplished by either specifying the static VIPA as the destination address, or specifying a host name that maps to the static VIPA in the remote syslogd configuration.
- When the recipient syslogd instance is running in a sysplex environment, additional availability features are available that should be explored. For example, you can use a multiple application-instance dynamic VIPA (DVIPA) to represent the syslogd instance on a given system, and the remote syslogd instances are configured to use that DVIPA address as the destination IP address for the messages they forward. In this configuration, if a failure to the MVS system or TCP/IP stack on which the syslogd instance is running occurs, the DVIPA is automatically moved to a predefined backup system that is currently active. This enables the syslogd instance on that backup system to begin processing these remote messages in a transparent manner. In this configuration, using the MVS operations log

(OPERLOG) as the destination provides additional benefits, because the operations log is implemented as a coupling facility log stream that any system in the sysplex can access. For additional information related to static and dynamic VIPAs, see [Chapter 7, “Virtual IP Addressing,”](#) on page 389.

Considerations when receiving messages using UDP

Syslogd on z/OS can be configured to receive remote messages as UDP datagrams. Because UDP is a connectionless protocol that does not provide reliable communications, the potential exists that some UDP datagrams containing forwarded syslogd messages can be dropped, either in the network as a result of network congestion or on the z/OS system if the syslogd is overloaded and cannot process incoming messages fast enough. If this occurs, these messages are not seen by the z/OS syslogd instance, nor is the remote syslogd instance made aware of the dropped messages. As a result, make provisions to enable direct access of syslogd messages on the remote hosts. In addition, you should perform a detailed evaluation on the risks associated with the potential for message loss, prior to using any z/OS-based automated operations software to trigger actions based on the remote messages received by the z/OS syslogd.

Tip: For more reliable delivery of syslog messages over an IP network, use TCP connections instead of UDP datagrams where possible.

Guideline: The z/OS syslogd supports receiving messages over UDP in the traditional non-transparent framing format.

Setup steps for the syslogd server to receive remote messages as UDP datagrams:

- Identify the port that will be used for the syslogd server to receive log data from remote syslogd servers using UDP. The Internet Assigned Numbers Authority (IANA) defines UDP port 514 for the syslog udp service, but you can choose any suitable port.
- Update your services file or data set (for example, /etc/services) to include the syslog service for udp with the identified port.

```
Example: syslog          514/udp
```

- Reserve the identified port for use by syslogd by updating the PORT statement in the TCP/IP profile. This example assumes that syslogd runs as job SYSLOGD1.

```
Example: PORT 514 UDP SYSLOGD1
```

- Use the -U option when starting syslogd.

Note: If syslogd is started in normal or network-only mode without specifying UDP (-U), TCP (-T), or TCP with TLS (-S), the UDP port is opened by default for receiving log data from remote syslogd servers.

Considerations when receiving messages using TCP

Syslogd can be configured to receive remote messages over TCP connections. TCP is a connection-oriented protocol that provides reliable communication. However, there is no acknowledgement from a z/OS syslogd server application to the syslogd client application that a message has been received. So, the potential exists for there to be an error on the TCP connection that prevents messages from being received by the z/OS syslogd server.

Messages received over TCP connections can be protected by TLS. When syslogd is started with the -S option, a TCP port is opened and TLS protection is required for clients connecting to the port. When syslogd is started with the -T option, a TCP port is opened, but syslog clients can connect to the port without TLS protection. A syslogd server can be started with the -S option, the -T option, or both.

Message framing considerations

- z/OS syslogd supports receiving messages over TCP connections with octet-counting framing. That is, the message begins with the message length followed by a space. Octet-counting framing is described in RFC 6587 Transmission of Syslog Messages over TCP.

- z/OS syslog supports receiving messages over TCP connections with non-transparent (traditional) framing. Rather than specifying the length of the message, non-transparent framing relies on the use of a trailer character at the end of the message. z/OS syslog recognizes the following ASCII characters as a trailer ending the message - LF (x'0A'), NULL (x'00'), and CRLF (x'0D0A').

Setup steps for the syslogd server to support TCP connections that require TLS protection:

- Identify the port that will be used for the syslogd server to accept TCP connections protected by TLS. The Internet Assigned Numbers Authority (IANA) defines TCP port 6514 for the syslog-tls tcp service, but you can choose any suitable port.
- Update your services file or data set (for example, /etc/services) to include the syslog-tls service for tcp with the identified port.

Example: syslog-tls 6514/tcp

- Reserve the identified port for use by syslogd by updating the PORT statement in the TCP/IP profile. This example assumes that syslogd runs as job SYSLOGD1.

Example: PORT 6514 TCP SYSLOGD1

- Configure an AT-TLS server rule with the local port set to the identified syslog port.

Tip: Syslogd is an AT-TLS-aware application. It verifies that TLS protection is in place before processing any received data. It does not control when the TLS handshake occurs or when the TLS session is terminated. The rule should indicate "ApplicationControlled Off" which is the default.

- Use the -S option when starting syslogd

Setup steps for the syslogd server to support TCP connections without requiring TLS protection:

- Identify the port that will be used for the syslogd server to accept TCP connections that do not require TLS protection. There is not a defined standard port used for the syslog tcp service.
- Update your services file or data set (for example, /etc/services) to include the syslog service for tcp with the identified port.

Example: syslog 529/tcp

- Reserve the identified port for use by syslogd by updating the PORT statement in the TCP/IP profile. This example assumes that syslogd runs as job SYSLOGD1.

Example: PORT 529 TCP SYSLOGD1

- Use the -T option when starting syslogd

Limited number of concurrent TCP connections

When syslogd is started with the -T option, the -S option, or both, syslogd allocates a pool of threads to handle incoming TCP connections. Each inbound connection is assigned to its own thread. The number of concurrent TCP connections is limited by the number of threads in the thread pool. By default, syslogd allocates 128 threads for incoming TCP connections. If a small number of remote syslogd clients are expected to connect and send messages to this syslogd server, the number of threads in the pool can be limited using the SYSLOGD_TCPTHREADPOOL_SIZE environment variable.

Ensure that the MAXTHREADS parameter in the BPXPRMxx parmlib member, which specifies the maximum number of threads that a single process can have active concurrently, is large enough to accommodate these threads. The syslog daemon also has a few threads for internal processing plus one thread for each unique output destination.

Once a client connects to the syslogd server, the connection remains in place until the client disconnects, a receive error is detected, or a 15-minute inactivity timer expires.

IP filter policy should be used to ensure that only expected syslogd clients can connect to the syslogd server.

Configuring the z/OS syslogd to send messages to a remote syslogd

The ability to send messages to a remote syslogd instance can be useful in providing messages from multiple hosts into a consolidated message log. Configure the z/OS syslogd to forward only messages that are important enough to consolidate on a remote system. For example, high-volume debug traces should be collected in a local file instead of forwarding them. Use the syslog configuration file to specify which messages should be forwarded to a remote destination. You can filter messages based on the facility and priority associated with the message.

Considerations when sending messages using UDP

Because UDP is a connectionless protocol that does not provide reliable communications, the potential exists that some UDP datagrams containing forwarded syslogd messages can be dropped, either in the network as a result of network congestion or on the receiving system if the remote syslogd is overloaded and cannot process incoming messages fast enough. If this occurs, the syslogd client is not aware of the dropped messages.

Considerations when sending messages using TCP

Message format

z/OS syslogd sends messages over TCP connections using octet-counting framing. That is, the message begins with the message length followed by a space. Ensure that the remote syslogd is configured to receive messages with octet-counting framing. The concept of octet-counting framing is described in RFC 6587 Transmission of Syslog Messages over TCP.

Reliability

TCP is a connection-oriented protocol that provides reliable communication. However, the syslogd client can discard one or more messages when a condition exists that prevents messages from being sent to a remote host. For example, if the syslogd client is unable to connect to the configured remote host and its internal message queue limit is reached, the queued messages are discarded, and the socket is closed. syslogd attempts to connect again when the next message needs to be sent to the remote host.

Syslogd writes error messages (facility daemon, priority error) when it is unable to open a socket, connect to the remote host, or send data to the remote host.

When queued messages are discarded, eventual action message FSUM1290 is written to the MVS console to alert you that one or more messages have been discarded. More detailed message FSUM1291 is written that indicates the number of messages discarded and the destination. Message FSUM1289 is also written if the messages were discarded because syslogd was unable to connect to the destination. FSUM1291 and FSUM1289 are written to the destination you configure for syslogd error messages.

Guideline: You should include a rule in your syslogd configuration file that writes messages generated by syslogd to a local file. This example assumes that syslogd runs as job SYSLOGD1.

```
*.SYSLOGD1.*.*      /var/syslogd.log
```

Security using TLS

TLS can be used to protect a TCP syslogd connection to a remote host. The steps to setup a syslogd client that requires TLS protection are as follows:

- Contact the owner of the remote syslogd server to determine its destination hostname/IP address and TCP port. Ensure that the server is configured to accept TCP connections protected by TLS.
- Configure a rule in the syslog configuration file using the forwarding action parameter -A.
 - Specify the hostname or IP address
 - Specify the protocol as TCP
 - Specify the port
 - Specify secure="yes" to require TLS protection

- Configure an AT-TLS client rule with the remote IP address and port set to the remote syslogd server's IP address and port.

Note: Syslogd is an AT-TLS-aware application. It verifies that TLS protection is in place before sending any data. It does not control when the TLS handshake occurs or when the TLS session is terminated. The rule should indicate “ApplicationControlled Off” which is the default.

A failure to negotiate a TLS session with the remote syslogd host can result in messages being discarded. Before sending the first message, syslogd issues the SIOCTTLCTL ioctl to ensure that TLS protection is in place for the connection. If the returned information indicates that the connection matched an AT-TLS rule with TTLS disabled, error message FSUM1295 is written.

```
Example: FSUM1295 SYSLOGD1 CLIENT CONNECTION TO (EXAMPLE.REMOTESERVER.COM 192.168.2.1 6514)
MATCHES AN AT-TLS RULE THAT DISABLED TLS
```

If the returned information indicates that the connection matched an AT-TLS rule with ApplicationControlled ON, error message FSUM1295 is written:

```
Example: FSUM1295 SYSLOGD1 CLIENT CONNECTION TO (EXAMPLE.REMOTESERVER.COM 192.168.2.1 6514)
MATCHES AN AT-TLS RULE THAT SPECIFIES APPLICATION CONTROLLED
```

Either of these cases requires that the AT-TLS rule be updated, and new policy installed. The syslogd rule is disabled and an FSUM1300 written. Any messages queued to the destination are discarded. After the AT-TLS policy is updated and installed, the MODIFY SYSLOGD,RESTART command or the SIGHUP signal should be used to force syslogd to reread the configuration file and re-enable the disabled rule.

Other errors detected when issuing the SIOCTTLCTL ioctl result in either an FSUM1295 or FSUM1297 error message. These errors might be transitory, so the rule is not disabled. However, if internal queue limits are reached before the condition is resolved queued messages can be discarded.

If there are TLS negotiation errors, you will receive AT-TLS error messages as you would for any AT-TLS application. See [Diagnosing Application Transparent Transport Layer Security \(AT-TLS\) in z/OS Communications Server: IP Diagnosis Guide](#).

Interactions between syslogd and other components during IPL

Syslogd is typically started early in the IPL process so that application startup messages can be logged. When syslogd is configured to receive messages from or send messages to remote hosts, syslogd relies on the TCP/IP stack. If AT-TLS protection is being used, syslogd also relies on the Policy Agent.

Interactions for syslogd receiving network messages

When configured to receive messages from remote hosts, syslogd attempts to set up the appropriate AF_INET(6) sockets at startup. If the TCP/IP stack is not yet started, syslogd is unable to open AF_INET(6) sockets. syslogd automatically tries to setup the sockets every 30 seconds. Once the TCP/IP stack is up, the sockets can be setup to accept TCP connections from remote hosts.

When syslogd is configured to receive messages over TCP connections protected by TLS (-S start option), Policy Agent must also be started, and AT-TLS policy must be installed in the TCP/IP stack. During the window in time when the TCP/IP stack is started but AT-TLS policies have not been installed in the stack, the SAF resource EZB.INITSTACK.*sysname.tcpname* in the SERVAUTH class is used to block stack access, except for user IDs permitted to the resource.

Syslogd should be denied access to the EZB.INIT.*sysname.tcpname* resource. This ensures that it is not able to open a socket until AT-TLS policy is installed. syslogd retries the socket() call every 30 seconds and once the AT-TLS policy is installed, the sockets can be setup to accept TLS-protected TCP connections from remote hosts.

Interactions for syslogd sending network messages

When configured to send messages to a remote host, syslogd attempts to connect to the destination when the first message is ready to be sent. If the TCP/IP stack is not yet started, syslogd will be unable to open an AF_INET(6) socket. An attempt is made every second to open a socket.

Once the TCP/IP stack is started, the socket can be opened and syslogd attempts to connect to the destination. If routing is not yet in place or the remote host is not yet accepting connections, the connect attempt times out or is reset. syslogd retries to connect to the destination. Depending on the type of connect failure, the retry can be as often as once a second. Once routing is in place and the remote host is accepting connections, syslogd can connect to the remote host.

When syslogd is configured to use TLS to protect messages sent to a remote host, Policy agent must also be started, and AT-TLS policy must be installed in the TCP/IP stack.

Syslogd should be denied access to the EZB.INIT.sysname.tcpname resource. This ensures that it is not able to open a socket until AT-TLS policy is installed. syslogd retries the socket() call every second and once the AT-TLS policy is installed, the socket can be opened and connect processing can continue.

Messages are queued to an output destination. A message remains queued until it can be sent unless an internal queue limit is reached. In that case the message is discarded.

Offloading log files

z/OS Communications Server includes a syslogd configuration file in /usr/lpp/tcpip/samples/syslog.conf, a REXX program for removing old log files in /usr/lpp/tcpip/samples/rmoldlogs, and a JCL procedure for starting syslogd in SEZAINST(syslogd). These are intended to be used together, though each may need to be customized for your installation.

Guideline: You should use this method of offloading or archiving files only if you do not use the automatic archive function of syslogd that is described in [“Configuring syslogd for automatic archiving”](#) on page 258. Because both of these methods rely on creating new log files, results are unpredictable if you try to use both methods together.

The sample syslogd configuration file is installed in /usr/lpp/tcpip/samples/syslog.conf. It can be copied to /etc/syslog.conf after customization. If it is copied somewhere else, the syslogd -f command-line option must be used to tell syslogd where to find the configuration file.

The sample REXX program for removing old log files is installed in /usr/lpp/tcpip/samples/rmoldlogs. It can be copied to an installation-defined directory after customization. The sample JCL procedure can be copied to an installation-defined library after customization.

The sample configuration uses date stamps in the names of directories of log files to organize log files by year (%Y), month (%m), and day (%d) as follows:

```
*.err      /var/log/%Y/%m/%d/errors
```

Log files for February 14, 2001, for example, would be stored in directory /var/log/2001/02/14. Variable substitution occurs using the Language Environment C function strftime(). Variables are case sensitive. For more information and a complete list of variables, see [z/OS C/C++ Runtime Library Reference](#).

A cron job should be used to send the SIGHUP signal to syslogd every day at midnight so that it switches to a new set of files. The cron job should be created for a user ID with UID 0. The definition of the cron job is:

```
0 0 * * * kill -HUP `cat /etc/syslog.pid`
```

Tip: An accent mark (`) is used in this definition, not a single quotation mark.

The log file names vary based on the day, so sending SIGHUP to syslogd after the day changes causes syslogd to create new files.

Because some messages sent just after midnight may be logged by syslogd before it processes the SIGHUP signal, it is possible that a few messages sent after midnight will be stored in the log files for the previous day.

The sample REXX program can be run daily to remove all log files older than the number of days specified in the program. Comments in the REXX program describe how to configure the number of days. The definition of a cron job to run the REXX program every day at 1:00 A.M. is:

```
0 1 * * * localdir/rmoldlogs
```

localdir is the name of the installation-defined directory where the customized version of /usr/lpp/tcpip/samples/rmoldlogs was copied.

Setting permissions for log files and directories

When you specify the `-c` start option, syslogd creates log files and directories dynamically. By default, directories are created with the permissions value 0700, which means that only the owner can read, write, and list the contents of the directory. Similarly, if syslogd needs to create a file, the default permissions value is 600, which again means that only the owner can read and write to the file. Because a user ID with UID 0 must run syslogd, the owner is always a superuser. To change the default permissions used by syslogd, use either the `-F` or the `-D` start option to set the global default permissions for files and directories, respectively.

Tip: The `-F` and `-D` start options have no effect on files or directories that already exist.

You can also use the `-F` and `-D` configuration options to override global defaults for individual syslogd rules. Specify `-F` or `-D` (or both) with octal values following the file name. For example:

```
*.err      /var/log/%Y/%m/%d/errors -F 640 -D 644
```

The file permission bits, whether provided on the rule or as global defaults, are modified by the syslogd process file creation mask (umask), and then used to set the file permission bits of a file that is being created.

If you are considering allowing users other than a superuser to have access to log files, before changing the syslogd default permissions for files and directories, be sure to consider the following options:

- Before starting syslogd, create the log file (and containing directory if necessary) with permissions and ownership that allows the other users to have access. If a single user needs access, you can make the file user ID (UID) match that of the user ID that needs access. If multiple users need access, set a new or existing group ID (GID) as the file's GID, and set the permissions to allow members of the group to have read access, write access, or both. The file or directory UID and GID can be set with the **chown** command. Be sure to give the syslogd user ID write access to the log files. This technique is useful only if the files are not being created dynamically by syslogd.
- If you are not using file access control lists (ACLs), files and directories created by syslogd have the owner UID 0. By default, the owning GID is set to that of the parent directory. However, if the FILE.GROUPOWNER.SETGID profile exists in the UNIXPRIV class, the owning GID is determined by the set-GID bit of the parent directory, as follows:
 - If the set-GID bit of the parent directory is on, the owning GID is set to that of the parent directory.
 - If the set-GID bit of the parent directory is off, the owning GID is set to the effective GID of the process.

When there are no file access control lists, the only way to manage log files with different access requirements that must be accessed by different groups of users is to create the containing directories with the appropriate GIDs before starting syslogd, and let syslogd dynamically create the log files in the appropriate directories. The log files then inherit the GID of the directory, if the directory has the set-GID bit on.

- A third way to provide access to log files for different users or groups of users is to use file access control lists. For information about setting file access control lists, see the **setfacl** command in [z/OS UNIX System Services Command Reference](#). The ACLs for dynamically created directories and files can be inherited from defaults set on the parent directory. When using this method, be sure that the syslogd user ID continues to have write access to the log files.

Configuring syslogd for automatic archiving

You can set up syslogd to perform automatic archival of eligible z/OS UNIX files that are configured as destinations on syslogd rules. Eligible files are those that you tag using the `-N` or `-X` parameter on the rule

definitions. You can choose to archive at a specific local time of day, or when the file systems that contain the eligible files become too full, or both. You can also perform an on-demand archive using an operator command.

Guideline: You should use this method of archiving files only if you do not offload files using the provided sample configuration and procedure that are described in [“Offloading log files”](#) on page 257. Because both of these methods rely on creating new log files, results are unpredictable if you try to use both methods together.

To configure syslogd for automatic archiving, take the following steps:

- Configure the events that trigger automatic archival
- Configure the archive details for each z/OS UNIX file

Steps for configuring the events that trigger automatic archival

You can set up syslogd to perform automatic archival of eligible z/OS UNIX files that are configured as destinations on syslogd rules. Use this method of archiving files only if you do not offload log files.

Before you begin

Automatic archiving can be performed at a specific local time every day, or when one or more of the z/OS UNIX file systems that contain the eligible files become too full. Determine whether you want to configure one or both of these triggers.

Requirement: You must specify the `-c` start option when you are using the automatic archive function.

Procedure

Perform the following steps to configure syslogd archive triggers:

1. Specify the `ArchiveTimeOfDay` statement in the syslogd configuration file to specify the local time of day using hours and minutes in a 24 hour clock format.
2. Specify the `ArchiveThreshold` statement in the syslogd configuration file to specify the percentage of the file system that must be full to trigger an automatic archive.

Guideline: You should set up the syslogd file destinations as one or more separate z/OS UNIX file systems. Threshold-based archiving works best when the file systems contain only data written by syslogd.

3. Specify the `ArchiveCheckInterval` statement in the syslogd configuration file to specify the interval in minutes at which syslogd should check to determine how full the file systems are.

Results

The configuration statements that define archive triggers are global statements. If you configure these statements multiple times, the last instance is used.

Steps for configuring the archive details for each z/OS UNIX file

Automatic archiving operates on eligible z/OS UNIX files. You can configure which files are eligible by specifying parameters on individual rules. You can also configure global parameters that affect the archive process and determine the destination data sets for each file.

Before you begin

You need to protect the syslogd archive data sets using available data set access controls to ensure that only authorized personnel are allowed to read these data sets. Syslogd archive data sets might contain sensitive information.

Procedure

Perform the following steps to configure the archive details for each z/OS UNIX file:

1. Specify the BeginArchiveParms statement in the syslogd configuration file.

The BeginArchiveParms statement specifies a data set name prefix that is extended with a unique qualifier for each file to be archived, for the set of rules that follows this statement.

2. Specify one of the following parameters on each rule that uses a z/OS UNIX file to indicate that the archive function must process the z/OS UNIX file:

- The -N parameter specifies that the file must be automatically archived and then re-initialized when an archive event occurs.
- The -X parameter specifies that the file must be only re-initialized but not archived when an archive event occurs.

If you do not specify the -N or -X parameters on a rule, then nothing happens to the destination file when an archive event occurs. See [Supported destinations for syslogd in z/OS Communications Server: IP Configuration Reference](#) for more information about specifying the -N or -X parameters.

If you use generation data group (GDG) data sets as an archive destination, the GDG base must already be created. The following sample JCL creates a GDG base called USER1.SYSARCH.

```
//USER1X JOB MSGLEVEL=(1,1),MSGCLASS=D,NOTIFY=USER1
//GDGA EXEC PGM=IDCAMS
//*
//GDGMOD DD DSN=USER1.SYSARCH,
//        VOL=SER=CPDLB1,
//        UNIT=SYSALLDA,
//        SPACE=(TRK,(0)),
//        DCB=(LRECL=80,RECFM=FB,BLKSIZE=6800,DSORG=PS),
//        DISP=(,KEEP)
//SYSPRINT DD SYSOUT=*
//SYSIN DD *
DEFINE GENERATIONDATAGROUP -
        (NAME(USER77.MYGDG) -
        EMPTY -
        NOSCRATCH -
        LIMIT(255) )
```

For more information about GDG data sets, see [z/OS DFSMS Using Data Sets](#).

Using syslogd for z/OS UNIX application programs

You can use the logging facilities of the syslogd server with your z/OS UNIX application programs. Include the syslog.h header file with C programs so that they can open a log facility, send log messages to syslogd, and close the facility:

```
#include <syslog.h>

1 openlog("oec", LOG_PID, LOG_LOCAL0);
2 syslog(LOG_INFO, "Hello from oec");
3 closelog();
```

1 Open a log facility with the name of local0. Prefix each line in the log file with the program name (oec) and the process ID.

2 Log an info priority message with the specified content.

3 Close the log facility name.

The preceding statements created the following line in the log file:

```
May 26 11:27:51 mvs18oe oec[3014660]: Hello from oec
```

Restriction: The message length is limited to 4092 characters when written to a z/OS UNIX file. The message length includes any content prepended by syslogd. Any characters beyond the 4092 limit are discarded from the message.

For more information about the syslog function, see *Advanced Programming in the UNIX Environment*, published by Addison-Wesley or [z/OS C/C++ Runtime Library Reference](#).

Usage notes

- It is possible to run two instances of syslogd. One instance must be started so that it processes messages from only the local host (-i option); the other instance must be started so that it processes messages from only the network (-n option).
 - If you run two instances of syslogd, one for local messages and another for network messages, and you also configure the automatic archival function, do not configure the same UNIX file destinations in the two configuration files. The archival function renames, closes, and reopens the UNIX files. If two instances of syslogd are performing the archival function on the same set of files, results of the archival function are unpredictable. The same is true for the configured archive destination data sets. Be sure to configure unique UNIX file destinations and archive data set names for the two syslogd instances.
 - syslogd can run swappable or nonswappable. When an application makes an address space nonswappable, it might convert additional real storage in the system to preferred storage. Because preferred storage cannot be configured offline, allowing syslogd to run in a nonswappable state can reduce the installation's ability to reconfigure storage in the future. Use the following guidelines to set the wanted state:
 - If the FACILITY class resource BPX.STOR.SWAP is not defined to the system:
 - syslogd will run nonswappable.
 - syslogd cannot be prevented from running nonswappable.
 - If the FACILITY class resource BPX.STOR.SWAP is defined to the system with UACC(NONE):
 - syslogd will run swappable by default (no access to BPX.STOR.SWAP).
 - syslogd can run nonswappable (given at least READ access to BPX.STOR.SWAP).
 - To define the FACILITY class resource BPX.STOR.SWAP issue the following commands:
- ```
RDEFINE FACILITY BPX.STOR.SWAP UACC(NONE)
SETROPTS RACLIST(FACILITY)REFRESH
```
- Configuration file errors are written to the operator console because initialization is not complete until the entire configuration file has been read.
  - Facility mark is not affected by the \*.priority usage. Mark messages are written only to the destinations of rules that specify mark.info.
  - If a mark interval of zero minutes is specified, mark messages will be written every thirty seconds.

## Diagnosing syslogd configuration problems

You must install and activate the AF\_UNIX domain before starting syslogd in normal or local-only mode. To determine whether AF\_UNIX was successfully started, check for a message in the console log similar to the following message:

```
BPXF203I DOMAIN AF_UNIX WAS SUCCESSFULLY ACTIVATED.
```

syslogd supports a debug mode, which is selected using the -d command-line option. If you run syslogd from the UNIX shell using this debug mode, syslogd writes debug messages to STDOUT. These messages can be used to diagnose problems in the syslogd configuration or to collect documentation when reporting a syslogd problem to IBM support.

You can use the SYSLOGD\_DEBUG\_LEVEL environment variable to limit the amount of debug messages. You can specify the following debug levels:

### Value

#### Level

**1**

Base debugging information.

**2**

Configuration file processing.

- 4** Message handling information for messages being logged by syslogd.
- 8** Automatic archive processing.
- 16** Operator command processing.
- 32** Thread-specific processing.
- 64** Mutex lock processing. Locks that are specific to threads are logged only if the debug level includes 32.

You can add these values together in any combination to select the type of debug messages to be written. For example, `SYSLOGD_DEBUG_LEVEL=91` includes all debugging information except for message handling and thread-specific processing (including locks). The default debug level is 127, which includes all debug information.

**Rule:** Do not use the `-d` option for normal operations.

If you are running `syslogd` in batch with `-d`, debug output is written to `SYSPRINT`, `SYSTEM`, or `SYSErr`, whichever is found first. The sample `syslogd` procedure `SEZAINST(syslogd)` defines `SYSPRINT` so that debug messages are stored in the job output. The following example shows how to change the `SYSPRINT` DD statement to write debug output to a file.

```
SYSPRINT DD PATH='/var/syslog/syseerr',PATHOPTS=(OWRONLY,OCREAT)
```

Use caution using `-d` when `syslogd` is started from `/etc/rc`. If `-d` is used in this way, the shell background character (`&`) must be used to run `syslogd` in the background. Otherwise, `/etc/rc` does not end and UNIX System Services initialization does not complete.

If you are using the automatic archive function of `syslogd`, it is possible that an archive of a particular file fails. A failure can occur for many reasons, including dynamic allocation errors for the target data set, or read/write errors for the UNIX file or target data set. If a failure occurs, `syslogd` attempts to archive the file again when the next archive trigger event occurs, but it is possible that all archive attempts continue to fail. If all attempts fail, the original UNIX file to be archived still exists in the UNIX file system, renamed with a suffix of the form `Dyymmdd.Thhmmss`, and the target data set might also exist and contain partial data. You should examine the error messages in the `syslogd` destination output file for the daemon facility to determine which files have failed, and manually recover or delete such files and the associated partial archive data sets.

## Syslog daemon name/token pair and ECSA storage mapping

When the syslog daemon (`syslogd`) is started, a system-level name/token pair is created. The token name is `EZBSYSLOGD`, and the token value is the address of the ECSA storage that contains the `syslogd` configuration file location and other related information. For more information about the [syslog daemon name/token pair and its ECSA storage mapping](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

## Configuring TCPIP.DATA

The `TCPIP.DATA` configuration data set is the anchor configuration data set for the TCP/IP stack and all TCP/IP servers and clients running in z/OS. With a z/OS TCP/IP stack, you can define the `TCPIP.DATA` parameters in a z/OS UNIX file or in an MVS data set. The `TCPIP.DATA` configuration data set is read during initialization of all TCP/IP server and client functions. All functions must access this data set in order to find basic configuration information, such as the name of the TCP/IP address space, the TCP/IP host name, and the data set prefix to use when searching for other configuration data sets. The `TCPIP.DATA` file contains the following major groups of configuration parameters:

- Application operating characteristics

- Resolver operating characteristics
- Socket library diagnostic data statements
- Resolver diagnostic data statements

## Use of TCPIP.DATA and /etc/resolv.conf

The TCPIP.DATA data set is also known as one of the resolver configuration data sets. In fact, this name is now more commonly used to refer to this important file in the UNIX System Services environment because the socket library contains a component called the resolver. In a z/OS UNIX system, you use the /etc/resolv.conf file for the same purpose as you use TCPIP.DATA in your MVS system.

TCPIP.DATA specifies the name of the TCP/IP address space. Because the data set search order can vary, your installation will determine which data set you can use. See [Chapter 2, “IP configuration overview,” on page 11](#) for search order, data set, and file retrieval information.

If you use TCPIP.DATA, it can be shared between multiple systems with a system name. But, if TCPIP.DATA is allocated by SYSTCPD DD and an application forks, any allocations from the parent of SYSTCPD are lost to the child process.

In z/OS UNIX System Services, each application that uses the XL C/C++ API can have its own environment variable, RESOLVER\_CONFIG='xxx'. There are no concerns for forked child processes; however, this means that you cannot share the data set or file among multiple systems.

**Note:** For applications running in IBM z/OS Container Platform environments, the resolver configuration information is obtained from the z/OS UNIX files '/etc/resolv.conf' and '/etc/nsswitch.conf' in the container's filesystem namespace.

## Creating TCPIP.DATA

Create a TCPIP.DATA file by copying the sample provided in SEZAINST(TCPDATA) and modifying it to suit your local conditions.

Allocate this data set with either sequential (PS) or partitioned (PO) organization, a fixed (F) or fixed block format (FB), a logical record length (LRECL) between 80 and 256, and any valid block size for a fixed block. This file can also be the file /etc/resolv.conf, or a z/OS UNIX file that is pointed to by either the environment variable RESOLVER\_CONFIG or the SYSTCPD DD in a JCL procedure. If you have a z/OS UNIX file, the maximum line length can be 256. The environment variable RESOLVER\_CONFIG can also point to an MVS data set or PDS.

You can use any name for the TCPIP.DATA data set if you access it using the //SYSTCPD DD statement, or use ENVAR to set RESOLVER\_CONFIG, in the JCL for all the servers, logon procedures, and batch jobs that execute TCP/IP functions. If you are not using the //SYSTCPD DD statement, the environment variable, or /etc/resolv.conf, then the data set name must conform to the conventions described in [“Configuration files for the TCP/IP stack” on page 23](#). Another alternative is to use the well-known data set name SYS1.TCPPARMS(TCPDATA). The HOMETEST command, with Trace Resolver active, can be used to verify the data set name that the system finds for TCPIP.DATA. However, because HOMETEST is an MVS sockets application, it does not use RESOLVER\_CONFIG or /etc/resolv.conf in its search order. For this reason, it is recommended that /etc/resolv.conf and TCPIP.DATA contain exactly the same information or consider using the resolver GLOBALTCPIPDATA setup statement.

**Rule:** Because TCPIP.DATA statements might need to be read and used multiple times by the resolver, the FREE=CLOSE JCL parameter should not be used when allocating SYSTCPD. To allow TCPIP.DATA statements to be changed while still allocated for long running programs, consider using a member of an MVS partitioned data set instead of an MVS sequential data set. For these long running applications, the resolver MODIFY REFRESH command should then be used to indicate that TCPIP.DATA statements have been changed.

## TCPIP.DATA statements

Each configuration statement can be preceded by an optional *system\_name*. This permits configuration information for multiple systems to be specified in a single *hlq*.TCPIP.DATA data set. The *system\_name* is

matched against the name of the system on which you are running. The name of the system is specified as part of the VMCF subsystem initialization, as the *nodename* value on the following parameter and statement:

- P= start parameter of the EZAZSSI started procedure
- VMCF statement of the IEFSSNxx member of parmlib

For more information about starting VMCF, see [“Step 3: Configure VMCF and TNF” on page 139](#).

The statements are processed in the order they appear in the data set. The following rules apply to this processing:

- If the *system\_name* does not match the name of the system, the configuration statement is ignored.
- If *system\_name* is blank, the configuration statement is in effect on every system.
- If the *system\_name* matches the host's name, the configuration statement that follows it is in effect.
- The last statement that matches is effective.

For example, if you have the following three TCPIPJOBNAME statements, MVS6 would look for a TCP/IP cataloged procedure named TCPBTA2, MVSA would look for TCPV3, and all other systems would look for TCPMCWN.

```
TCPIPJOBNAME TCPMCWN
MVS6: TCPIPJOBNAME TCPBTA2
MVSA: TCPIPJOBNAME TCPV3
```

But if you reversed the order, all systems would try to find the procedure named TCPMCWN.

```
MVS6: TCPIPJOBNAME TCPBTA2
MVSA: TCPIPJOBNAME TCPV3
 TCPIPJOBNAME TCPMCWN
```

Take special care with those TCPIP.DATA statements that can be specified multiple times, such as the SEARCH, SORTLIST, NSINTERADDR/NAMESERVER, OPTIONS, and LOADDBCSTABLES statements. Because these statements are cumulative, if you specify a *system\_name* value, it might need to be used on all instances of the same statement. Consider the following examples.

Example 1:

```
 NSINTERADDR 5.5.5.5
 NSINTERADDR 1.1.1.1
TN03: NSINTERADDR 1.1.1.1
TN03: NSINTERADDR 2.2.2.2
TN04: NSINTERADDR 3.3.3.3
TN04: NSINTERADDR 4.4.4.4
```

After these TCPIP.DATA statements are processed, the following ordered list of DNS addresses is available:

```
On TN03:
 5.5.5.5
 1.1.1.1
 1.1.1.1
 2.2.2.2
On TN04:
 5.5.5.5
 1.1.1.1
 3.3.3.3
 4.4.4.4
All others:
 5.5.5.5
 1.1.1.1
```

Example 2:

```
TN03: NSINTERADDR 1.1.1.1
TN03: NSINTERADDR 2.2.2.2
TN04: NSINTERADDR 3.3.3.3
TN04: NSINTERADDR 4.4.4.4
```

```
NSINTERADDR 5.5.5.5
NSINTERADDR 1.1.1.1
```

After these TCPIP.DATA statements are processed, the following ordered list of DNS addresses is available:

```
On TN03:
 1.1.1.1
 2.2.2.2
 5.5.5.5
 1.1.1.1
On TN04:
 3.3.3.3
 4.4.4.4
 5.5.5.5
 1.1.1.1
All others:
 5.5.5.5
 1.1.1.1
```

A sample TCPIP.DATA data set (TCPDATA) can be found in SEZAINST. For detailed information on each of the statements, see [z/OS Communications Server: IP Configuration Reference](#).

## Using MVS system symbols in TCPIP.DATA

For ease of management when configuring a complex environment, use MVS system symbols such as &SYSCONE, &SYSNAME, and &SYSPLEX. The resolver translates these symbols as it reads TCPIP.DATA, reducing the number of TCPIP.DATA files that must be maintained in a multisystem environment. For detailed information about symbols and how to define them, see [z/OS MVS Initialization and Tuning Reference](#).

## Configuring PROFILE.TCPIP

During TCP/IP address space initialization, a configuration profile data set (PROFILE.TCPIP) is read that contains system operation and configuration parameters. A sample data set, SEZAINST(SAMPPROF), can be copied and modified for use as your default configuration profile.

If you are not familiar with the search order for this data set, see “PROFILE.TCPIP search order” on page 23 for information about understanding data set search orders. See [z/OS Communications Server: IP Configuration Reference](#) for the complete statement syntax and descriptions of the configuration statements.

For ease of management when configuring a complex environment, you can use one of the following PROFILE.TCPIP data set features:

- Group related statements into separate files and use the INCLUDE statement in PROFILE.TCPIP to include them in your configuration.
- Use MVS system symbols (such as &SYSCONE, &SYSNAME, and &SYSPLEX). Because TCP/IP translates these symbols as it reads this file, this feature reduces the number of PROFILE.TCPIP data sets that must be maintained in a multi-TCP/IP environment.

**Note:** For detailed information about symbols and how to define them, see [z/OS MVS Initialization and Tuning Reference](#).

The PROFILE data set contains the following major groups of configuration parameters:

- TCP/IP operating characteristics
- TCP/IP physical characteristics
- TCP/IP reserved port number definitions (application configuration)
- TCP/IP routing definitions
- TCP/IP diagnostic data statements

This information explains the first three areas of configuration. For routing configuration information, see [Chapter 6, “Routing,” on page 307](#). For information about configuring diagnostic statements, see [z/OS Communications Server: IP Diagnosis Guide](#).

## Changing configuration information

If you want to change the TCP/IP configuration without stopping and starting the TCP/IP address space, you can dynamically change many of the TCP/IP configuration options established by the PROFILE.TCPIP data set. To make dynamic changes, put the changed configuration statements in a separate data set and process it with the VARY TCPIP,,SYNTAXCHECK and VARY TCPIP,,OBEYFILE commands.

- VARY TCPIP,,SYNTAXCHECK

The VARY TCPIP,,SYNTAXCHECK command checks the syntax of statements in the data set but does not apply any changes to the active configuration.

- VARY TCPIP,,OBEYFILE

The VARY TCPIP,,OBEYFILE command checks the syntax of statements in the data set and also applies changes to the active configuration.

Statements in a VARY TCPIP,,OBEYFILE data set that are coded with syntax errors might not be applied to the active configuration as expected; activating a profile data set that contains syntax errors can lead to unscheduled outages.

**Guideline:** Use the VARY TCPIP,,SYNTAXCHECK command to check for syntax errors in a profile data set before activating it as the initial profile or activating it with the VARY TCPIP,,OBEYFILE command.

**Result:** Changes that are applied to the active configuration with the VARY TCPIP,,OBEYFILE command remain in effect only until you stop the stack. You can retain these configuration changes by integrating them into the initial profile, or by using the VARY TCPIP,,OBEYFILE command each time you start TCP/IP.

For more information about VARY TCPIP commands, see [z/OS Communications Server: IP System Administrator's Commands](#). For information about dynamically changing settings for a particular configuration statement, see the *Modifying* information under each configuration statement in [z/OS Communications Server: IP Configuration Reference](#).

**Guideline:** If you attempt to edit the PROFILE.TCPIP data set while TCP/IP is active, and PROFILE.TCPIP is defined in the TCPIP PROC as a sequential data set (for example, //PROFILE DD DISP=SHR,DSNAME=TCPIP.PROFILE.TCPIP), the Data set in use message might be displayed. To avoid this situation, specify FREE=CLOSE, as shown in the following example:

```
//PROFILE DD DISP=SHR,DSNAME=TCPIP.PROFILE.TCPIP,FREE=CLOSE
```

Specifying FREE=CLOSE enables you to edit the profile while TCP/IP is active. Typically, when TCP/IP starts, it keeps the profile allocated and does not release the allocation until the end of the step (in this case, the end of the job). When you specify FREE=CLOSE, the release occurs after the data set is read, and MVS releases the enqueue on the profile so that you can edit it.

If the profile is a member of a partitioned data set (PDS), such as SYS1.TCPPARMS(PROFILE), FREE=CLOSE is not needed.

## Setting up TCP/IP operating characteristics in PROFILE.TCPIP

Figure 47 on page 269 shows a portion of the sample configuration file for the TCP/IP address space, PROFILE.TCPIP. This sample can be copied from SEZAINST(SAMPPROF). [Figure 47 on page 269](#) includes the portion of the sample that shows how to set up TCP/IP operating characteristics. Descriptions for the statements follow [Figure 47 on page 269](#).

Figure 47. Example of TCP/IP operating characteristics in PROFILE.TCPIP

The following information describes the statements that are shown in [Figure 47 on page 269](#). For more information about any of these statements, see [z/OS Communications Server: IP Configuration Reference](#). For information specific to IPv6 support, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

## GLOBALCONFIG

Use GLOBALCONFIG to print several counters in text format. These counters include number of TCP retransmissions and total number of TCP segments sent from the TCP/IP system. Most installations use the SMF facility of MVS to collect these counters in a more standard way.

Use GLOBALCONFIG to enable use of Shared Memory Communications over RMDA (SMC-R) and Shared Memory Communication - Direct Memory Access (SMC-D). For more details about SMC-R and SMC-D, see [Chapter 10, “Shared Memory Communications,” on page 531](#).

Use the ECSALIMIT parameter on the GLOBALCONFIG statement to limit TCP/IP use of common storage. The POOLLIMIT parameter can be used to limit TCP/IP use of private storage pools.

Use ZERT to enable z/OS Encryption Readiness Technology (zERT). For more information, see [“Monitoring cryptographic network protection: z/OS encryption readiness technology \(zERT\)” on page 184](#).

## IPCONFIG

Use IPCONFIG to configure various settings of the IP layer of TCP/IP.

Use CLAWUSEDoublENOP on vendor devices that document the need for double NOPs on each CCW.

Use DATAGRAMFWD if this TCP/IP is to be a router and must forward datagrams to other routers.

Use IGNOREREDIRECT when a dynamic routing program is used and ICMP redirect packets are to be ignored by the TCP/IP address space. MULTIPATH is used to inform TCP/IP how to distribute traffic across equal cost routes.

Use IPSECURITY to restrict this host to be a network firewall.

SOURCEVIPA enables interface fault tolerance for z/OS clients that establish outbound connections. When SOURCEVIPA is set, outbound datagrams use the corresponding virtual IP address (VIPA) in the HOME list instead of the physical interfaces IP address. SOURCEVIPA has no effect on RIP servers such as OMROUTE.

TCPSTACKSOURCEVIPA allows z/OS clients to specify a sysplex-wide source IP address for TCP connections. When TCPSTACKSOURCEVIPA is set, outbound TCP datagrams use the IP address that is specified in the TCPSTACKSOURCEVIPA statement instead of static VIPA addresses or physical interface addresses.

Use SYSPLEXROUTING to communicate interface changes within a sysplex domain to the workload manager (WLM). DYNAMICXCF allows the cross communication facility within a sysplex to dynamically generate connections within a sysplex domain. If DYNAMICXCF is used with a dynamic routing program like OMROUTE, the BSDROUTINGPARMS and the OMROUTE configuration files must be updated with subnet mask and cost information. For more information about other configuration parameters that are required, see the usage notes related to the DYNAMICXCF parameter under the IPCONFIG statement in [z/OS Communications Server: IP Configuration Reference](#).

Use REASSEMBLYTIMEOUT to specify the TCP/IP reassemble timeout value in seconds, and the TTL specifies the TCP/IP time to live or hop count value.

Use PATHMTUDISCOVERY to indicate to TCP/IP that it is to dynamically discover the path MTU, which is the minimum of MTUs of each hop in the path.

Use STOPONCLAWERROR to indicate to the TCP/IP stack to stop channel programs (HALTIO and HALTSIO) when a device error is detected.

Use QDIOACCELERATOR to request accelerated packet forwarding for OSA-Express QDIO Ethernet and HiperSockets interfaces. Acceleration is also enabled for Network Express EQDIO interfaces (from EQDIO and to EQDIO interfaces only).

### **IPCONFIG6**

Use IPCONFIG6 to update the IP layer of TCP/IP with information that pertains to IPv6.

Use DATAGRAMFWD to enable the transfer of data between networks.

Use DYNAMICXCF to enable Dynamic XCF support for IPv6.

### **SOMAXCONN**

Use SOMAXCON to specify the maximum number of sockets queued on a listener.

### **SRCIP**

Use the SRCIP - ENDSRCIP profile statement block to configure one of the following functions:

- Enable an application to use a designated IP address as its source address for outbound TCP connections, or to enable a TCP server application to bind to a specific IP address when it is establishing its listening socket.
- Indicate that the default source address selection algorithm prefers public or temporary IPv6 addresses for specific jobs.

For outbound TCP connections, when a source IP address was designated for a specified job name or destination address and the source IP address exists at the time the outbound TCP connection is initiated, this source IP address is used, overriding other source IP address selection methods as described in [“Source IP address selection” on page 272](#). This source address selection occurs for applications that issue a connect() call and that did not previously bind the socket to an IP address, or for those applications that bind to the IPv4 INADDR\_ANY address or to the IPv6 unspecified address (in6addr\_any) before they issue the connect() call.

For TCP server applications, when the application issues a bind to INADDR\_ANY or in6addr\_any and a matching JOBNAME rule for SERVER or BOTH is specified, the designated IP address is used on the listening socket. This situation makes the server application bind specific, where client applications can connect to the server by using only the designated IP address. This capability can be useful when the applications do not provide a method for the user to specify a specific IP address for their listening sockets, or in situations when the server application creates listening sockets by using an ephemeral port that is assigned dynamically by TCP/IP. For scenarios when the application binds to specific, well-known ports, the BIND keyword on the PORT reservation statement in the TCP/IP profile can be used instead and has precedence over the SRCIP block specifications.

If you use distributed DVIPAs as a designated source within the SRCIP block, you might also be required to specify the EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG statement. For more information about the [GLOBALCONFIG statement](#) and its parameters, see [z/OS Communications Server: IP Configuration Reference](#).

### **Guidelines:**

- Applications that bind to INADDR\_ANY or in6addr\_any that match on an SRCIP JOBNAME or DESTINATION statement do not have the designated IP address as their source address upon completion of the bind() call. The source address is not set to the designated address until completion of the subsequent connect() (client applications) or listen() (server applications) call. This situation is important to note for applications that issue a getsockname() call after a bind() call to retrieve the source IP address. This processing is different from the processing that occurs when a TCP server application is converted to being bind specific using the BIND keyword on the PORT statements in the TCP/IP profile. When you are using the BIND keyword on the PORT statement, the designated IP address is set upon completion of the bind() call, and some applications such as Db2 depend on this behavior.
- When you are using an SRCIP JOBNAME statement for an IPv6 server application, code an IPv6 address and not an IPv6 interface. Otherwise, the source address that is chosen for that IP interface

might not be the best choice for the server application to be bound to. For information about the default source address selection algorithm, see z/OS Communications Server: IPv6 Network and Appl Design Guide.

## **TCPCONFIG**

Use the TCPCONFIG statement to configure various settings of the TCP protocol layer:

- Use the INTERVAL parameter if necessary to change the default keepalive value to a value other than 120 minutes. Use the KEEPALIVEPROBES parameter to specify the number of probes to send before a connection times out. Use the KEEPALIVEPROBEINTERVAL parameter to specify the amount of time between the sending of each probe.
- Use the FINWAIT2TIME parameter to specify a different timeout value for a TCP connection that is in the FINWAIT2 state.
- Use the TIMEWAITINTERVAL parameter to specify a different timeout value for a TCP connection that is in the TIMEWAIT state.
- Use the SENDGARBAGE parameter to cause the keepalive packet to contain 1 byte of random data and an incorrect sequence number. The random data and incorrect sequence number assure that the remote TCP does not accept the data.
- Use the TCPTIMESTAMP parameter to choose whether to participate in time stamp negotiation.
- Use the MAXIMUMRETRANSMITTIME parameter to limit the length of time before a connection times out.
- Use the RETRANSMITATTEMPTS parameter to indicate the number of packets to retransmit before a connection times out.
- Use the CONNECTTIMEOUT parameter to limit the amount of time before the initial connection times out.
- Use the CONNECTINITINTERVAL parameter to specify the initial retransmit interval for a connect call.
- Use the QUEUEDRTT parameter to specify the round trip time that triggers outbound serialization logic.
- Use the FRRTHRESHOLD parameter to specify the number of duplicates that are needed to trigger Fast Retransmit, Fast Recovery logic.
- Use the DELAYACKS parameter to alter the behavior of acknowledgments and delay their transmission.
- Use the NONAGLE parameter to override use of the Nagle algorithm. The Nagle algorithm is used to delay small packets from being sent.
- If you specify the RESTRICTLOWPORTS parameter, only applications that meet at least one of the following criteria are allowed to bind to low ports (1–1023):
  - The port is reserved for the application by the PORT or PORTRANGE statement.
  - The application runs with APF authorization.
  - The application runs with effective POSIX UID zero.
- If you want to control TCP buffering to limit storage usage or to manage large bandwidth devices, use the TCPSENDERBUFSIZE, TCPRCVBUFSIZE, TCPMAXSENDERBUFSIZE, and TCPMAXRCVBUFSIZE parameters.
- Use the TTLS parameter to configure the TCP/IP stack for AT-TLS support.
- Use the EPHEMERALPORTS parameter to limit the ephemeral port range that the TCP/IP stack uses to assign a port to a socket. The EPHEMERALPORTS port range is used in the following situations when EXPLICITBINDPORTRANGE, SYSPLXEXPORTS, or FTP PASSIVEDATAPORTS processing cannot determine the port number to assign:
  - An application issues an explicit bind() call for port 0
  - An application bypasses issuing an explicit bind() call and issues a connect() call

- The SELECTIVEACK parameter causes the TCP/IP stack to generate selective acknowledgments as defined in RFC 2018 and to use incoming selective acknowledgments to improve TCP retransmission processing as defined in RFC 3517. A TCP connection can experience poor performance when multiple packets are lost from one window of data. With the limited information available from cumulative acknowledgments, a TCP sender can learn about only a single lost packet per round-trip time. A Selective Acknowledgment (SACK) mechanism with a selective repeat retransmission policy can help to overcome these limitations. The receiving TCP sends back SACK packets to the sender to inform the sender of data that was received. The sending TCP can then retransmit only the missing data segments.

## UDPCONFIG

Use UDPCONFIG to configure various settings of the UDP protocol layer. NOUDPCHKSUM can be used to eliminate check summing overhead for IPv4 UDP packets. This option is ignored for UDP datagrams that are flowing over an IPv6 network, as UDP Checksum is a required function on an IPv6 network.

If RESTRICTLOWPORTS is specified, only applications that meet at least one of the following criteria are allowed to bind to low ports (1–1023):

- The port is reserved for the application by the PORT or PORTRANGE statement.
- The application runs with APF authorization.
- The application runs with effective POSIX UID zero.

If an installation wants to control UDP buffering (to limit storage usage or to manage large bandwidth devices), use the UDPSENDBFRSIZE and UDPRCVBUFRSIZE parameters. UDPQUEUELIMIT can be used to set a queue limit for UDP. UDPQUEUELIMIT is useful for installations that want to limit the size of the queue of UDP datagrams that an application can have waiting before the TCP/IP address space starts discarding them.

Use EPHEMERALPORTS to limit the ephemeral port range that the TCP/IP stack uses to assign a port to a socket in the following situations:

- An application issues an explicit bind() call for port 0
- An application bypasses issuing an explicit bind() call

## Source IP address selection

TCP/IP determines the source IP address for a TCP outbound connection, or for a UDP or RAW outbound packet, by using the following sequence, which is listed in descending order of priority.

1. Sendmsg() using the IPV6\_PKTINFO ancillary option specifying a nonzero source address (RAW and UDP sockets only)
2. Setsockopt() IPV6\_PKTINFO option specifying a nonzero source address (RAW and UDP sockets only)
3. Explicit bind to a specific local IP address
4. bind2addrsel socket function (AF\_INET6 sockets only)
5. PORT profile statement with the BIND parameter
6. SRCIP profile statement (TCP connections only)
7. TCPSTACKSOURCEVIPA parameter on the IPCONFIG or IPCONFIG6 profile statement (TCP connections only)
8. SOURCEVIPA: Static VIPA address from the HOME list or from the SOURCEVIPAINTERFACE parameter
9. Local IP address of the interface over which the packet is sent

For a TCP connection, the source address is selected for the initial outbound packet, and the same source IP address is used for the life of the connection. For the UDP and RAW protocols, a source IP address selection is made for each outbound packet. A more detailed description of this sequence follows.

## ***How TCP/IP selects a source IP address***

TCP/IP uses the following sequence to select the source IP address for an outbound packet. For detailed information about the [TCP/IP profile](#), see [z/OS Communications Server: IP Configuration Reference](#).

1. Sendmsg that specifies the source address in the ancillary IPV6\_PKTINFO data

If this is a UDP or RAW socket, and IPV6\_PKTINFO ancillary data is specified on sendmsg() with a nonzero source IP address, this address is used as the source IP address.

2. Setsockopt IPV6\_PKTINFO

If this is a UDP or RAW socket, and the IPV6\_PKTINFO socket option is set and it contains a nonzero source IP address, this address is used as the source IP address.

3. Explicit bind to a specific local address

If the socket is already bound to a specific local IP address other than INADDR\_ANY or in6addr\_any, TCP/IP uses this specific local IP address.

4. bind2addr sel socket function (IPv6 only)

The bind2addr sel socket function, which is available only to AF\_INET6 sockets, binds a socket to a stack-selected local address and port that is appropriate to communicate with a given destination address.

5. PORT profile statement with the BIND parameter

If the socket is bound to a source port and to the INADDR\_ANY or in6addr\_any IP address, and there is a corresponding PORT profile statement with the BIND parameter specified, TCP/IP uses the address specified by the BIND parameter.

6. SRCIP profile statement

If this is a TCP socket and either the socket is not yet bound or the socket is bound to the INADDR\_ANY or in6addr\_any IP address, TCP/IP checks the job name and destination IP address against the SRCIP entries in the following order:

- a. JOBNAME entries, other than JOBNAME \*
- b. DESTINATION entries
- c. JOBNAME \* entries

If a match is found, TCP/IP uses the designated source in the most specific matching entry to provide the source IP address to be used.

**Restriction:** JOBNAME entries that specify a source of PUBLICADDRS or TEMPADDRS apply to only IPv6 source IP address selection. The JOBNAME entries do not influence the setting of the source IP address during this step of the source IP address selection sequence. For information about how PUBLICADDRS or TEMPADDRS entries influence the selection of the source IP address and the [default source address selection algorithm](#), see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

7. TCPSTACKSOURCEVIPA parameter on the IPCONFIG or IPCONFIG6 profile statement

All of the following conditions must be met:

- This is a TCP socket.
- SOURCEVIPA is enabled on IPCONFIG or IPCONFIG6.
- SOURCEVIPA is not disabled for the socket.
- The application has not issued a specific bind for this socket, even to the INADDR\_ANY or in6addr\_any IP address.
- The address specified on the TCPSTACKSOURCEVIPA parameter is a static VIPA or active dynamic VIPA.

For a static VIPA, it is defined on a DEVICE/LINK/HOME statement and not the INTERFACE statement.

If these conditions are met and this is an IPv4 packet, TCP/IP uses the address specified on the TCPSTACKSOURCEVIPA parameter.

If these conditions are met and this is an IPv6 packet, TCP/IP uses the default source address selection algorithm to select one of the addresses configured for the VIPA interface referenced by the TCPSTACKSOURCEVIPA parameter. For information about the [default source address selection algorithm](#), see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

**Guideline:** Because the SRCIP profile statement provides all of the functionality of the TCPSTACKSOURCEVIPA parameter and additional granularity, consider using the SRCIP statement instead of specifying the TCPSTACKSOURCEVIPA parameter. Specifying JOBNAME \* in a SRCIP profile statement provides the same result as specifying the TCPSTACKSOURCEVIPA parameter for implicit bind scenarios, and also applies to applications that issue a bind to the INADDR\_ANY or in6addr\_any IP address.

8. SOURCEVIPA: Static VIPA address from the HOME list (IPv4 interface defined with the LINK statement) or from the SOURCEVIPAINTERFACE parameter (IPv6 or IPv4 interface defined with the INTERFACE statement)

All of the following conditions must be met:

- SOURCEVIPA is enabled on IPCONFIG or IPCONFIG6.
- SOURCEVIPA is not disabled for the socket.
- Either the socket is not yet bound, or the socket is bound to the INADDR\_ANY or in6addr\_any IP address.

If these conditions are met, TCP/IP determines the interface over which the initial packet will be sent.

- For an IPv4 packet sent over an interface that is defined with the LINK statement, TCP/IP takes the following actions:
    - a. Locates that interface in the HOME list.
    - b. Starting with that interface, searches backward in the HOME list for the nearest static VIPA.
    - c. If a static VIPA is found in the HOME list, TCP/IP uses that static VIPA found as the source IP address.
  - For an IPv4 packet sent over an interface that is defined with the INTERFACE statement, TCP/IP takes the following actions:
    - a. Determines whether a SOURCEVIPAINTERFACE parameter was specified for the selected interface.
    - b. If a SOURCEVIPAINTERFACE parameter was specified, TCP/IP uses the address of the VIPA interface that is referenced by the SOURCEVIPAINTERFACE parameter.
  - For an IPv6 packet, TCP/IP takes the following actions:
    - a. Determines whether a SOURCEVIPAINTERFACE parameter was specified for the selected interface.
    - b. If a SOURCEVIPAINTERFACE parameter was specified, TCP/IP uses the default source address selection algorithm to select one of the addresses that are configured for the VIPA interface that is referenced by the SOURCEVIPAINTERFACE parameter. For information about the [default source address selection algorithm](#), see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).
9. Local IP address of the interface over which the packet is sent
- For an IPv4 packet, TCP/IP uses the local IP address of the interface over which the initial packet is sent.
- For an IPv6 packet, TCP/IP uses the default source address selection algorithm to select one of the addresses configured for the interface over which the initial packet is sent. For information about the [default source address selection algorithm](#), see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

## Ephemeral port selection

The sequence that the stack uses to determine the ephemeral port for an outbound connection or packet depends on the protocol that is being used. For an outbound UDP packet, the following hierarchy is used:

1. The port number is specified on an explicit bind.
2. The port number is assigned from the pool of ports that the EPHEMERALPORTS parameter on the UDPCONFIG statement defines.

The default ephemeral port numbers are in the range 1024 – 65535.

For an outbound TCP connection, ephemeral port selection can be affected by source IP address selection during bind processing. For more information about source IP address selection, see [“Source IP address selection” on page 272](#).

After a source IP address is selected, the ephemeral port is selected by using the following hierarchy:

1. The port number is specified on an explicit bind.
2. The port number is assigned from the pool of ports that the EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG statement defines.

**Rule:** EXPLICITBINDPORTRANGE ports are used when an application issues an explicit bind() to port 0 and either the IPv4 address INADDR\_ANY or the IPv6 unspecified address (in6addr\_any), before the application issues a connect() request. EXPLICITBINDPORTRANGE ports are unique throughout the sysplex.

3. The port number is assigned from the PASSIVEDATAPORTS range. The PASSIVEDATAPORTS range must also be reserved on a PORTRANGE statement with the AUTHPORT parameter.

**Rule:** The PASSIVEDATAPORTS range is used by the FTP server only, and specifies the range of ports that are used as listening data socket ports.

4. The port number is assigned by SYSPLEXPORTS processing when a client application binds to a distributed DVIPA with SYSPLEXPORTS specified and port 0.
5. The port number is assigned from the pool of ports that the EPHEMERALPORTS parameter on the TCPCONFIG statement defines.

The default ephemeral port numbers are in the range 1024 – 65535.

For more information about ephemeral port selection and the interaction between the different methods of assigning ports, see [“Port selection interactions” on page 275](#).

## Port selection interactions

You can assign or reserve ports by using several methods, and the various methods interact in the following ways:

- EPHEMERALPORTS parameter on the TCPCONFIG and UDPCONFIG statements
  - For TCP sockets, ephemeral ports are port numbers that TCP/IP temporarily assigns to a socket in the following situations:
    - An application explicitly binds to port 0.
    - An implicit bind() call is processed as an application issues a connect() call, and the port number is not known.
  - Ephemeral ports can also be used by servers in some cases, such as the FTP server in passive mode.
  - For UDP sockets, ephemeral ports are port numbers that TCP/IP temporarily assigns to a socket in the following situations:
    - An application explicitly binds to port 0.
    - An implicit bind() call is processed as the application sends data, and the port number is not known.
  - You can use the EPHEMERALPORTS parameter to control the range of ephemeral port numbers that the stack assigns.

- Separate definitions for the TCPCONFIG and UDPCONFIG statements enable different ranges per protocol.
- The default ephemeral port numbers for each protocol are port numbers in the range 1024 – 65535.
- Generally, other methods of assigning ports take precedence over assigning ephemeral ports from the EPHEMERALPORTS range. The ports available for ephemeral port assignment are those ports in the EPHEMERALPORTS range that are left after other methods of assigning ports are applied.
- PORT and PORTRANGE statement
  - Ports can be reserved for specific uses with the PORT and PORTRANGE statements.
  - Ports can be reserved for a protocol by the PORT or PORTRANGE statement and are not available as ephemeral ports for that protocol. If the ports are also within the defined EPHEMERALPORTS range for that protocol, the stack cannot assign them as ephemeral ports.
- EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG statement
  - The EXPLICITBINDPORTRANGE parameter designates a range of unique ports across a sysplex. A participating stack can allocate a port from this range when an application binds explicitly to port 0 and either of the following addresses:
    - IPv4 address INADDR\_ANY
    - IPv6 unspecified address (in6addr\_any)
  - The most recently processed profile or VARY TCPIP,,OBEYFILE command that specifies the EXPLICITBINDPORTRANGE parameter defines the range of ports for the sysplex.
  - An explicitly bound port that is within the EXPLICITBINDPORTRANGE pool is not available for assignment by the stack as an EXPLICITBINDPORTRANGE port.
  - The EXPLICITBINDPORTRANGE pool is not required to be within the EPHEMERALPORTS range.
  - The EXPLICITBINDPORTRANGE pool takes precedence over the EPHEMERALPORTS range. Ports in the EXPLICITBINDPORTRANGE pool that are also within the defined EPHEMERALPORTS range cannot be assigned by the stack as ephemeral ports. Ports in the EXPLICITBINDPORTRANGE pool are available only for EXPLICITBINDPORTRANGE use.
- SYSPLEXPORTS parameter on the VIPADISTRIBUTE statement
  - EPHEMERALPORTS processing controls SYSPLEXPORTS allocation.
    - If a bind is made to a distributed DVIPA with SYSPLEXPORTS and port 0 specified, the coupling facility assigns a block of sysplex ports from the EPHEMERALPORTS range to the stack for use with the DVIPA. The stack chooses a port from this block.
    - If the bind specifies a specific port from the EPHEMERALPORTS range, the coupling facility attempts to assign that port as a sysplex port for that DVIPA.
  - TCP/IP communicates the EPHEMERALPORTS range to the coupling facility to ensure that sysplex port assignments are in the correct range.
- FTP PASSIVEDATAPORTS statement and the AUTHPORT parameter on the PORTRANGE statement
  - The PASSIVEDATAPORTS statement in the FTP server configuration file assigns a range of port numbers for use by the FTP server. The PASSIVEDATAPORTS range must also be reserved on a PORTRANGE statement with the AUTHPORT parameter.
  - Ports in this range are available for assignment only to the FTP server.
  - Ports in this range are not required to be within the EPHEMERALPORTS range.
  - Ports in this range that are also within the EPHEMERALPORTS range are not available for use by the stack when assigning an ephemeral port.
- INADDRANYPORT and INADDRANYCOUNT parameters on the NETWORK statement in BPXPRMxx
  - The range that is specified by the INADDRANYPORT and INADDRANYCOUNT parameters must be restricted by the PORT or PORTRANGE statement to the job name OMVS. These ports are not assigned by the stack unless the user has the job name OMVS.
  - Ports in this range are not required to be within the EPHEMERALPORTS range.

- Ports in this range that are within the defined EPHEMERALPORTS range are not available for use by the stack when assigning an ephemeral port.

Because ports that are reserved by using some of these methods cannot be used by the stack as ephemeral ports, the actual number of available ephemeral ports might not equal the number of ports that are specified in the EPHEMERALPORTS range. You can use the Netstat STATS/-S command to display the actual number of ephemeral ports that are available for assignment by the stack. The CONFIGURED EPHEMERAL PORTS field of the Netstat STATS/-S report accounts for ports that are in the EPHEMERALPORTS range that are unavailable because they are reserved by some other method. This field reflects the actual number of ports that are available for assignment by the stack.

For example, consider the following portion of a TCP/IP profile:

```
GLOBALCONFIG EXPLICITBINDPORTRANGE 30200 100
;
TCPCONFIG EPHEMERALPORTS 30000 39999
;
UDPCONFIG EPHEMERALPORTS 30000 39999
;
PORT 30005 TCP TCPAPPL2
PORT 30015 TCP TCPAPPL3
;
PORTRANGE 30025 5 TCP TCPAPPL6
PORTRANGE 30100 50 TCP AUTHPORT ; FTP passive data ports
PORTRANGE 30500 300 TCP OMVS ; INADDRANYPORT/INADDRANYCOUNT ports
;
PORT 30010 UDP UDPAPPL2
PORT 30015 UDP UDPAPPL3
;
PORTRANGE 30030 5 UDP UDPAPPL6
PORTRANGE 30500 300 UDP OMVS ; INADDRANYPORT/INADDRANYCOUNT ports
```

This configuration results in the following values for the CONFIGURED EPHEMERAL PORTS field of the Netstat STATS/-S report:

```
d tcpip,tcps1,netstat,stats
EZD0101I NETSTAT CS V2R1 TCPCS1
.
.
.
TCP STATISTICS
.
.
.
 CONFIGURED EPHEMERAL PORTS = 9543
 EPHEMERAL PORTS IN USE = 0
 EPHEMERAL PORTS MAX USAGE = 0
 EPHEMERAL PORTS EXHAUSTED = 0
UDP STATISTICS
.
.
.
 CONFIGURED EPHEMERAL PORTS = 9693
 EPHEMERAL PORTS IN USE = 0
 EPHEMERAL PORTS MAX USAGE = 0
 EPHEMERAL PORTS EXHAUSTED = 0
END OF THE REPORT
```

For TCP, the total number of configured ephemeral ports is 10000 (ports 30000 – 39999), and this number is reduced by the following amounts:

- 100 because of the GLOBALCONFIG EXPLICITBINDPORTRANGE setting (ports 30200 – 30299)
- 2 because of the two PORT statements with ports that are within the TCP ephemeral port range (ports 30005 and 30015)
- 355 because of the three PORTRANGE statements with ports that are within the TCP ephemeral port range (ports 30025 – 30029, 30100 – 30149, and 30500 – 30799)

Subtracting these ports results in the CONFIGURED EPHEMERAL PORTS value of 9543. The CONFIGURED EPHEMERAL PORTS value is not affected by any PORT and PORTRANGE statements that include ports outside of the EPHEMERALPORTS range.

For UDP, the total number of configured ephemeral ports is 10000 (ports 30000 – 39999), and this number is reduced by the following amounts:

- 2 because of the two PORT statements with ports that are within the UDP ephemeral port range (ports 30010 and 30015)
- 305 because of the two PORTRANGE statements with ports that are within the UDP ephemeral port range (ports 30030 – 30034 and 30500 – 30799)

Subtracting these ports results in the CONFIGURED EPHEMERAL PORTS value of 9693. The CONFIGURED EPHEMERAL PORTS value is not affected by any PORT and PORTRANGE statements that include ports outside of the EPHEMERALPORTS range.

## Setting up physical characteristics in PROFILE.TCPIP

Figure 48 on page 282 shows a portion of the sample configuration file for the TCP/IP address space, PROFILE.TCPIP. Figure 48 on page 282 includes the portion of the sample that shows how to set up physical characteristics. This sample can be copied from SEZAINST(SAMPPROF). Following Figure 48 on page 282, several of the statements that are used to set up physical characteristics in PROFILE.TCPIP are described.

```
; =====

Figure 48. Example of physical characteristics in PROFILE.TCPIP

The following list describes several of the statements that are shown in Figure 48 on page 282, which are used to set up physical characteristics in PROFILE.TCPIP. For more information about any of these statements, or information about statements that are not described, see [z/OS Communications Server: IP Configuration Reference](#). For information that is specific to IPv6 support, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

#### DEVICE and LINK

Use DEVICE and LINK statements to define each IPv4 network interface to the TCP/IP address space. See [z/OS Communications Server: IP Configuration Reference](#) for more details about the various network interfaces supported by TCP/IP.

#### CTC

Use the CTC DEVICE and LINK statements to define connectivity to another z/OS using channel-to-channel.

#### MPCIPA

Use the MPCIPA DEVICE and LINK statements to define the following connectivity:

- HiperSockets connectivity

Use the IPCONFIG DYNAMICXCF statement to cause TCP/IP to automatically define and activate HiperSockets connectivity between each pair of TCP/IP stacks that is in the same CPC in the same z/OS sysplex.

#### MPCPTP

MPCPTP can be used to define any of the following connections:

- A connection to another host over a series of CTCs (in this case, the device name must be the name of a VTAM TRLE).
- An XCF connection to another TCP/IP in the same z/OS sysplex. For an XCF connection, the device name must be the CP name or SSCP name of the target VTAM on the other side of the XCF connection, and the VTAM ISTLSXCF major node must be active to start the device.
- An IUTSAMEH connection (with no need for any I/O devices) to another TCP/IP on the same z/OS system or to VTAM for Enterprise Extender. For an IUTSAMEH connection, the device name must be the reserved name IUTSAMEH. VTAM automatically activates the IUTSAMEH TRLE.

Use the IPCONFIG DYNAMICXCF statement to cause TCP/IP to automatically define and activate XCF connectivity between each pair of TCP/IP stacks in the same sysplex and IUTSAMEH connectivity between multiple TCP/IP stacks on the same z/OS.

#### VIRTUAL

Use VIRTUAL DEVICE to define a static virtual IP address (VIPA) interface.

The static virtual device requires DEVICE and LINK statements to define a device that is always started, can never be stopped, can be known within the network, yet requires no physical adapters. It is very useful to define VIPAs so that if a physical adapter loses its connection to the network, application traffic using the failed physical adapter can be rerouted over another interface to the network. To the network, the VIPA address appears to be one hop away from the TCP/IP address spaces. The network sends and receives datagrams to and from the physical interfaces to get to the VIPA address. For more information about VIPA, see [Chapter 7, “Virtual IP Addressing,”](#) on page 389.

## **INTERFACE (IPv4)**

Use the INTERFACE statement to define IPv4 OSA-Express QDIO interfaces, Network Express EQDIO interfaces, HiperSockets interfaces, or static VIPA interfaces (instead of using DEVICE and LINK statements).

### **IPAQENET**

Use the IPAQENET INTERFACE statement to define IPv4 LAN connectivity through the OSA-Express feature using QDIO.

### **EQENET**

Use the EQENET INTERFACE statement to define IPv4 LAN connectivity through the Network Express feature using EQDIO.

### **IPAQIDIO**

Use the IPAQIDIO INTERFACE statement to define HiperSockets IPv4 connectivity.

### **VIRTUAL**

Use the VIRTUAL INTERFACE statement to define an IPv4 static VIPA.

## **INTERFACE (IPv6)**

Use INTERFACE statements to define each IPv6 network interface to the TCP/IP address space. See [z/OS Communications Server: IP Configuration Reference](#) for more details about the various network interfaces supported by TCP/IP.

### **IPAQENET6**

Use the IPAQENET6 INTERFACE statement to define IPv6 LAN connectivity through the OSA-Express feature using QDIO.

### **EQENET6**

Use the EQENET6 INTERFACE statement to define IPv6 LAN connectivity through the Network Express feature using EQDIO.

### **IPAQIDIO6**

Use the IPAQIDIO6 INTERFACE statement to define HiperSockets IPv6 connectivity.

Use the IPCONFIG6 DYNAMICXCF statement to cause TCP/IP to automatically define and activate HiperSockets IPv6 connectivity between each pair of TCP/IP stacks that is in the same CPC in the same z/OS sysplex.

### **MPCPTP6**

Use the MPCPTP6 INTERFACE statement to define any of the following IPv6 connections:

- A connection to another host using ESCON channel-to-channel adapters.
- An XCF connection to another TCP/IP in the same z/OS sysplex.
- An IUTSAMEH connection (with no need for any I/O devices) to another TCP/IP on the same z/OS system or to VTAM for Enterprise Extender.

Use the IPCONFIG6 DYNAMICXCF statement to cause TCP/IP to automatically define and activate XCF connectivity between each pair of TCP/IP stacks in the same sysplex and IUTSAMEH connectivity between multiple TCP/IP stacks on the same z/OS.

### **VIRTUAL6**

Use the VIRTUAL6 INTERFACE statement to define IPv6 static VIPAs.

## **VIPADYNAMIC**

Use the VIPADYNAMIC block statement to define dynamic virtual IP address (DVIPA) interfaces. For more information about DVIPA interfaces, see [Chapter 7, “Virtual IP Addressing,”](#) on page 389.

## TRANSLATE

Use TRANSLATE to indicate which LINK has specified network addresses for use as a static ARP table. The first TRANSLATE statement in a configuration data set replaces the entire ARP cache. Subsequent TRANSLATE statements add to the table. If you are using OSPF routing (OMPROUTE), see [Chapter 6, “Routing,”](#) on page 307 for more information about requirements for the TRANSLATE statement.

## HOME

HOME lists the IP addresses and their associated LINK adapter. The first HOME statement within a configuration data set replaces the existing HOME list. If subsequent HOME statements are found within a configuration data set, add entries to the list.

**Guideline:** The order of the HOME list is important if IPCONFIG SOURCEVIPA is specified. For more information, see [“Source IP address selection”](#) on page 272. For more information about the [HOME statement](#) and for precautions when either the VIPA address or a physical adapter used as a source for the VIPA has an IP address that is the network address, see [z/OS Communications Server: IP Configuration Reference](#).

## PRIMARYINTERFACE

Use PRIMARYINTERFACE to specify which interface should be designated as the default local host for use by the GETHOSTID() function. If PRIMARYINTERFACE is not used, the first IP address in the HOME list becomes the default local host address. If there are no HOME statements defined in the profile, PRIMARYINTERFACE defaults to the first IPv4 INTERFACE statement listed in the profile.

## BEGINROUTES

Use the BEGINROUTES statement to add static routes to the IP route table.

After an interface has a DEVICE, LINK, and HOME statement, or an INTERFACE statement, it can be started with the START statement or the VARY TCPIP,,START command.

## Devices that support ARP offload

Certain devices provide an ARP offload function that offloads all ARP processing to the adapter. The function provided by the adapter impacts the ability of TCP/IP to display ARP cache information or ARP counter statistics for these devices.

**Note:** ARP processing is relevant only for IPv4 LAN interfaces.

The following devices provide an ARP offload function and provide ARP cache data or ARP counters to TCP/IP.

- All OSA-Express features.
- All Network Express features.

**Note:** If multiple TCP/IP instances are sharing the device, the ARP data will represent all TCP/IP instances using the device. This information is provided to TCP/IP every 30 seconds from the device.

**Note:** For IPv6 LAN interfaces, TCP/IP performs all the neighbor discovery processing, maintains the neighbor cache, and provides the ability to display neighbor cache information.

## Interface-layer fault-tolerance for local area networks (interface-takeover function)

The TCP/IP stack in the z/OS Communications Server provides transparent fault-tolerance for failed (or stopped) IPv4 devices or IPv6 interfaces, when the stack is configured with redundant connectivity onto a LAN. This support is provided by the z/OS Communications Server interface-takeover function, and applies to the IPv4 IPAQENET interface type, and the IPv6 IPAQENET6 interface type.

At device or interface startup time, TCP/IP dynamically learns of redundant connectivity onto the LAN, and uses this information to select suitable backups in the case of a future failure of the device or interface. This support makes use of ARP flows (for IPv4 devices) or neighbor discovery flows (for IPv6 interfaces), so upon failure (or stop) of a device or interface, TCP/IP immediately notifies stations on the LAN that the original IPv4 or IPv6 address is now reachable through the backup's link-layer (MAC)

address. Users targeting the original IP address will see no outage due to the failure, and will be unaware that any failure occurred.

Because this support is built upon ARP or neighbor discovery flows, no dynamic routing protocol in the IP layer is required to achieve this fault tolerance. To enable this support, you need only to configure redundancy onto the LAN:

- You need redundant LAN adapters.
- For IPv4, you must configure and activate multiple LINKs onto the LAN.
- For IPv6, you need to configure and start multiple INTERFACES onto the LAN.

**Restriction:** An IPv4 device cannot back up an IPv6 interface, and an IPv6 interface cannot back up an IPv4 device.

**Rule:** If static routing is used, there needs to be a static route to the LAN subnet over each interface onto the LAN. There also needs to be a default route and routes to destinations not directly attached to the LAN over each interface.

The interface-layer fault-tolerance feature can be used in conjunction with VIPA addresses, where applications can target the VIPA address, and any failure of the real LAN hardware is handled by the interface-takeover function. This differs from traditional VIPA usage, where dynamic routing protocols are required to route around real hardware failures.

## IPv6 considerations: Stateless autoconfiguration and duplicate address detection

IPv6 provides the capability of autoconfiguring addresses for an interface by using information that is provided by IPv6 routers. Descriptions of this function can be found in RFC 2461 and RFC 2462. The term *autoconfigured IP address* is used here to mean an IP address that is created as a result of information that is received from a router advertisement. z/OS TCP/IP allows autoconfiguration if no IP addresses are defined on the profile INTERFACE statement using the IPADDR keyword. If the INTERFACE statement contains IPADDR definitions, this indicates that the installation is defining its own IP addresses and autoconfiguration is not wanted. The term *manually configured addresses* is used here to describe the addresses that are defined using the IPADDR keyword.

TCP creates an autoconfigured IP address for an interface if all three of the following conditions are met:

- The interface is active.
- A valid router advertisement containing prefix information with the autonomous flag on is received over the interface.
- No manually configured home addresses are defined for the interface at the time the router advertisement is received.

The IP address that is created is formed by appending the interface ID generated by the stack to the prefix supplied by the router advertisement. Autoconfigured IP addresses can be identified in the Netstat HOME/-h report by the Autoconfigured flag. For more information on the interface ID generated by the stack, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

An autoconfigured IP address exists until one of the following events occur:

- The valid lifetime specified by the most recent router advertisement expires. When the valid lifetime expires, the autoconfigured address is removed. Existing connections using this address are terminated when subsequent activity occurs on the connection. The router advertisement that contains the valid lifetime for the autoconfigured address can also specify a preferred lifetime. The preferred lifetime indicates that the IP address can be freely used. When the preferred lifetime expires, the autoconfigured address is considered deprecated. The deprecated state indicates that another IP address should be used if available and provides a transition period before the valid lifetime expires. A deprecated IP address can be identified in the Netstat HOME/-h report by the deprecated flag.
- The installation activates a profile that contains a manually configured IP address on the same interface as the autoconfigured IP address (that is, the INTERFACE statement contains the ADDADDR keyword). If this occurs, any autoconfigured IP addresses on that interface are deleted and existing connections

using this address are terminated when subsequent activity occurs on the connection. The manually configured addresses are added and duplicate address detection for the newly added IP addresses initiated, if applicable.

*Duplicate address detection* is the process described in RFC 2462 which verifies that IPv6 home addresses are unique on the local link before assigning them to an interface. Duplicate address detection is performed on all IPv6 IPAQENET6 home addresses, whether they are manually configured or autogenerated, unless the INTERFACE statement specifies DUPADDRDET 0. Duplicate address detection is not done for LOOPBACK6 or VIRTUAL6 addresses. The duplicate address detection process sends a multicast neighbor solicitation and waits a period of time to see if another neighbor indicates that the address is in use. By default, only one neighbor solicitation is sent and the length of time waited is approximately one second. If no neighbor responds in that interval, the address is considered unique and the interface will start using it. The number of neighbor solicitations sent by duplicate address detection can be modified by the DUPADDRDET keyword on the INTERFACE statement. The duration of the wait interval (awaiting a response from a neighbor already using the address) can be modified by information obtained from routers on the attached network.

Duplicate address detection occurs when the interface is started. Unless the INTERFACE statement indicated duplicate address detection is to be bypassed, IPv6 manually configured addresses are unavailable until the interface is started and duplicate address detection is completed without finding another node on the local link with the same address. Prior to activation of the interface, manually configured addresses are shown in the Netstat HOME/-h report as unavailable with the reason DUPLICATE ADDRESS DETECTION PENDING. While the duplicated address detection is actively in progress for an address, the Netstat HOME/-h report shows the address as unavailable with the reason DUPLICATE ADDRESS DETECTION IN PROGRESS. If another neighbor indicates the address is in use during the duplicate address detection process, message EZZ9780I is issued and the address is not made available to the interface. If the address that was found to be in use is a manually configured address, the address appears in the Netstat HOME/-h report as unavailable with the reason DUPLICATE ADDRESS DETECTED.

A link-local address is required to activate a QDIO IPv6 interface and will be generated automatically by the stack. The link-local address is generated using the link-local prefix and the interface ID. If the link-local address generated from the interface ID is determined to be a duplicate, the interface is not activated if:

- Autoconfigured addresses are allowed.
- A manually configured home address specifying only the prefix was specified on the INTERFACE statement. In such a case, the interface ID needs to be used to form the complete link-local address, and because the interface ID has been found to be in use on the network, the formed link-local address cannot be used.

If duplicate address detection fails on the link-local address and only fully configured manual addresses were specified on the INTERFACE statement, up to two attempts are made to create a unique link local address using a randomly generated value instead of the interface ID. If duplicate address detection succeeds using the randomly generated link-local address, message EZZ9784I is issued indicating the generated address and the interface is activated.

## Setting up reserved port number definitions in PROFILE.TCPIP

Figure 49 on page 289 shows a portion of the sample configuration file for the TCP/IP address space, PROFILE.TCPIP. This sample can be copied from SEZAINST(SAMPPROF). Figure 49 on page 289 includes the portion of the sample that shows how to set up reserved port number definitions. Descriptions for the statements follow Figure 49 on page 289.

```

;
; -----
; PORT: Reserves a port for specified job names
;
; - A port that is not reserved in this list can be used by any user.
; If you have TCP/IP hosts in your network that reserve ports
; in the range 1-1023 for privileged applications, you should
; reserve them here to prevent users from using them.
; The RESTRICTLOWPORTS option on TCPCONFIG and UDPCONFIG will also
; prevent unauthorized applications from accessing unreserved
; ports in the 1-1023 range.
;
; - A PORT statement with the optional keyword SAF followed by a
; 1-8 character name can be used to reserve a PORT and control
; access to the PORT with a security product such as RACF.
; For port access control, the full resource name for the security
; product authorization check is constructed as follows:
; EZB.PORTACCESS.sysname.tcpname.safname
; where:
; EZB.PORTACCESS is a constant
; sysname is the MVS system name (substitute your sysname)
; tcpname is the TCPIP jobname (substitute your jobname)
; safname is the 1-8 character name following the SAF keyword
;
; When PORT access control is used, the TCP/IP application
; requiring access to the reserved PORT must be running under a
; USERID that is authorized to the resource. The resources
; are defined in the SERVAUTH class.
;
; For an example of how the SAF keyword can be used to enhance
; security, see the definition below for the FTP data PORT 20
; with the SAF keyword. This definition reserves TCP PORT 20 for
; any jobname (the *) but requires that the FTP user be permitted
; by the security product to the resource:
; EZB.PORTACCESS.sysname.tcpname.FTPDATA in the SERVAUTH class.
;
; - The BIND keyword is used to force a generic server (one that
; binds to the IPv4 INADDR_ANY address, or the IPv6 unspecified
; address, in6addr_any) to bind to the specific IP address that
; is specified following the BIND keyword. This capability could
; be used, for example, to allow z/OS UNIX telnet and telnet
; 3270 servers to both bind to TCP port 23.
; The IP address that follows bind must be in IPv4 (dotted
; decimal) or IPv6 (colon-hexadecimal) format and may be
; any valid address for the host including VIPA and dynamic
; VIPA addresses.
;
; The special jobname of OMVS indicates that the PORT is reserved
; for any application with the exception of those that use the Pascal
; API.
;
; The special jobname of * indicates that the PORT is reserved
; for any application, including Pascal API socket applications.
;
; Jobname may be 1 - 8 characters including wildcards. The following
; wildcards are supported:
; - An asterisk (*) can be used in any position to indicate zero or
; more unspecified characters.
; - A question mark (?) can be used in any position to indicate
; a single unspecified character.
;
; The special jobname of RESERVED indicates that the PORT is
; blocked. It will not be available to any application.
;
; GUIDELINE: When IPSECURITY is enabled, UDP ports 500 and 4500
; should either be reserved for IKED (if it is in use) or should
; be marked RESERVED.
;
; TIP: The PORT statement can also be used to control application
; access to unreserved ports by configuring PORT entries where the
; port number is replaced by the keyword UNRSV.

```

*Figure 49. Example of reserved port number definitions*

The following list describes the statements that are shown in [Figure 49 on page 289](#). For more information about any of these statements, see [z/OS Communications Server: IP Configuration Reference](#). For information specific to IPv6 support, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

## AUTOLOG

Use AUTOLOG to list the procedure names that should start when the TCPIP address space starts. It is also used to supply a timeout value for detecting hung procedures at TCP/IP initialization time. The timeout value is the time TCP/IP should allow for a procedure to come down when, at startup, it is still active and TCP/IP is attempting to AUTOLOG the procedure again. A hung procedure is active to MVS, but is not listening on the socket that is reserved for it via the PORT statement. When AUTOLOG detects a hung task, TCP/IP checks every 10 seconds (until the timeout value has expired) to see if the procedure has come down. If the procedure comes down during one of these 10 second intervals, it is restarted. If the procedure is still active when the time interval specified by the timeout value expires, then TCP/IP cancels and restarts the procedure.

The AUTOLOG statement shown in [Figure 49 on page 289](#) has a timeout value of five minutes.

In the first AUTOLOG statement the FTP Server shows FTPD JOBNAME FTPD1. This means when the TCPIP address space starts, the FTPD procedure will be started via the MVS START FTPD command. Because FTPD forks a child process that actually listens on PORT 21, the autolog task verifies that FTPD1 is listening on port 21.

Similarly, when the TCPIP address space starts, the autolog task starts the remaining 10 tasks.

Unless the tasks in the AUTOLOG list are in the PORT reservation list, the autolog task does not check for hung tasks every five minutes.

### Note:

1. If you run multiple TCP/IP address spaces, ensure that the second address space AUTOLOG list does not cancel the procedures of the first. In those cases, an installation might require different procedure names for the servers for each address space. For more information about multiple stacks, see [“Port management overview” on page 46](#).
2. You can use the AUTOLOG statement to automatically start generic servers in a single stack environment, but you should be careful using the AUTOLOG statement to start generic servers in a multiple stack environment. Instead, you could use an operations automation software package (IBM and other vendors provide these) to start generic servers automatically. For a list of generic servers provided by TCP/IP, see [“Generic servers in a CINET environment” on page 49](#).

For those procedures that require parameters to be used on the MVS START command, there is a PARMSTRING option.

You should delay the start of AUTOLOG procedures that require AT-TLS services by specifying the optional DELAYSTART parameter with the TTLS subparameter on the AUTOLOG entry for the procedure. If you specify this parameter and subparameter, the procedure will start after the Policy Agent has installed the AT-TLS policy and AT-TLS services are available.

You should delay the start of AUTOLOG procedures that bind to a dynamic VIPA by specifying the optional DELAYSTART parameter with the DVIPA subparameter on the AUTOLOG entry for the

procedure. If you specify this parameter and subparameter, the procedure will not start until the TCP/IP stack has joined the sysplex group and processed the dynamic VIPA configuration.

For a procedure that will bind to a dynamic VIPA and that requires AT-TLS services, you should specify DELAYSTART DVIPA TTLS. When more than one DELAYSTART subparameter is specified, all of the processing steps defined for those subparameters must complete before the procedure is started.

For more information, see [z/OS Communications Server: IP Configuration Reference](#).

## PORT

Use the PORT statement to do the following configuration:

- Reserve ports for different jobs and optionally limit access to these ports by user ID

Use PORT to reserve ports for different jobs and to prevent rogue applications from taking ports intended for specific servers, such as port 21, which is needed by FTP. For each port entry, the port number, protocol, and procedure name are specified. The first port entry shows port 7 UDP reserved for the miscellaneous echo server for procedure MISCSEV. Similarly, port 7 of TCP is also reserved for the same server. In this example, six ports are reserved for the miscellaneous server.

NOAUTOLOG can be specified, as in the port 20 TCP \* in [Figure 49 on page 289](#). In this way, the port is reserved for an OMVS forked task so that the FTP server can fork tasks to port 20 as each FTP user logs in.

Use the DELAYACKS and NODELAYACKS options to allow an installation to delay their acknowledgments so they can be combined with data to be sent to foreign hosts. Unless a performance reason is needed, DELAYACKS should be used to delay the transmission of acknowledgments.

Use the SHAREPORT parameter or the SHAREPORTWLM parameter when reserving a port to be shared across multiple TCP listeners. This is not valid for UDP. To understand how these [PORT statement](#) parameters are used, see [z/OS Communications Server: IP Configuration Reference](#). Use the Netstat ALL/-A report to determine whether port sharing is being used for a TCP listener. If port sharing is being used, this report indicates which type is being used.

Typically, reserving a port for a specific job name is sufficient. If the port must instead be reserved for a specific user ID or a set of user IDs, use the SAF keyword to specify the name of a SAF resource to be associated with the port. The user ID associated with the application that attempts to bind to the port must be permitted to the SAF resource.

The BIND keyword is used to force a generic server (one that binds to INADDR\_ANY or in6addr\_any) to bind to the specific IP address that is specified following the BIND keyword. This capability could be used, for example, to enable the z/OS UNIX Telnet and TN3270E Telnet servers to both bind to TCP port 23 on different IP addresses. The IP address that follows BIND can be any valid address for the host, including VIPA and dynamic VIPA addresses. The address supplied can be either an IPv4 address (in dotted decimal format) or an IPv6 address (in colon-hexadecimal format). IPv4-mapped IPv6 addresses are not supported. For multiple servers to bind to the same port with this function, the IP address for each server must be unique.

RESERVED indicates that the port is not available for use by any user.

- Control application access to unreserved ports

You can also use the PORT statement to control application access to unreserved ports by configuring one or more PORT statements in which the port number is replaced by the keyword UNRSV. The UNRSV keyword refers to any unreserved port (any port number that has not been reserved by a PORT or PORTRANGE statement). If you configure the RESTRICTLOWPORTS parameter on the TCPCONFIG or UDPCONFIG profile statement, PORT UNRSV statements for the corresponding protocol control access only to unreserved ports above port 1023. If you do not configure the RESTRICTLOWPORTS parameter, PORT UNRSV statements control access to all unreserved ports in the range 1-65535. The type of access that is controlled by the PORT UNRSV statement is specified (explicitly or by default) by the WHENBIND or WHENLISTEN keywords.

If you configure one or more PORT UNRSV statements for a protocol, access is unconditionally denied to any application that explicitly binds to an unreserved port and that does not match

the protocol and job name on any of the configured PORT UNRSV statements. Applications that explicitly bind to an unreserved port and that do match the protocol and job name on a PORT UNRSV statement are allowed to access the unreserved port, unless the access is restricted by the SAF or DENY keywords. If the SAF keyword is specified, the user ID associated with the application that attempts to access the port must be permitted to the specified SAF resource. If the DENY keyword is specified, access is unconditionally denied.

For UDP sockets, the access permission is checked when an unreserved port is specified on an explicit bind. The WHENBIND keyword is the only access option that is allowed for UDP ports.

For TCP sockets, access can be controlled when an unreserved port is specified on an explicit bind (WHENBIND) or when a listen is issued on a user-specified port that was not reserved for the application (WHENLISTEN).

For more information about controlling access to unreserved ports, see [“Port access control” on page 159](#). For more information about the [PORT statement](#) and its parameters, see [z/OS Communications Server: IP Configuration Reference](#).

### **PORTRANGE**

PORTRANGE is a statement used to reserve a range of ports for specified job names.

### **SACONFIG**

SACONFIG is the statement used to configure the information about the SNMP TCP/IP subagent. The AGENT keyword on this statement is used to specify the port number to be used when the TCP/IP subagent connects to the SNMP agent. Omission of this statement causes TCPIP to assume the default value of SACONFIG ENABLED COMMUNITY public AGENT 161. For more information on the SACONFIG profile statement, see [z/OS Communications Server: IP Configuration Reference](#).

## **Setting up the System Authorization Facility server access authorization class (optional)**

The TCP/IP address space uses the server access authorization (SERVAUTH) class of the System Authorization Facility (SAF) to protect TCP/IP resources from unauthorized access. The use of SERVAUTH may be optional and is available in degrees so that installations can pick and choose the access needed. Installations may be able to choose to use one, all, or none of the protections provided by SERVAUTH. The customization described here is completely optional when using the IBM security product RACF. Non-IBM security products might require customization. A template of the commands and all other SAF commands appears in SEZAINST(EZARACF). See [Chapter 3, “Security,” on page 145](#) for more detailed information.

## **Configuring the local host table (optional)**

---

You can set up the local host table to support local host name resolution. If you use the local host table for this purpose, your socket applications will be able to resolve only names and IP addresses that appear in your local host table.

If you need to resolve host names outside your local area, you can configure the resolver to use a domain name server (see the NSINTERADDR statement). If you use a domain name server, you do not need to set up any host definitions in your resolver configuration, but you may still do so.

If you have configured your resolver to use a name server, it will always try to do so, unless your TCP/IP C/C++ API applications were written with a RESOLVE\_VIA\_LOOKUP symbol in the source code. You can also configure the resolver to use only a local host table by specifying LOOKUP LOCAL in the TCPIP.DATA configuration file. For both cases, all name resolution calls will always use a local host table. This is probably not a technique you will see for standard socket applications, but it may be a technique you could find useful for when you develop your own socket applications or for testing changes before they are placed in your name server.

It might be a good idea to have a local host table available for the resolver to use if the name server is not reachable. If the name server does not respond to name resolution requests, the resolver tries to use the local host table. If the name server is reachable but returns a negative reply for a name resolution request, the resolver tries to resolve the name using the local host table, if such a file is present.

Assume you try to resolve the host name `friendly` and your `DOMAINORIGIN` is `my.house.com`, the resolver sends a query to the name server for `friendly.my.house.com`. If the name server returns a negative reply (the name is not registered), the resolver looks into the local host table for an entry of `friendly.my.house.com` and, if not found, for an entry of `friendly`.

Due to the flexibility of the Domain Name System, it is recommended you use a domain name server. If you set up a small IP network, the simplicity of the local host table approach might be preferable.

The following types of local host table can be used:

- `HOSTS.LOCAL`

`HOSTS.LOCAL` is used only for IPv4 requests.

- `/etc/hosts`

`/etc/hosts` is used only for IPv4 requests.

- `ETC.IPNODES` and `/etc/ipnodes`

`ETC.IPNODES` and `/etc/ipnodes` can be used for IPv6 requests, and for IPv4 requests when `COMMONSEARCH` is coded in the resolver setup statements.

**Note:** For applications running in IBM z/OS Container Platform environments, resolver uses the z/OS UNIX file `'/etc/hosts'` in the container's filesystem namespace to obtain the local host table, for both IPv4 and IPv6 requests.

## Creating `HOSTS.LOCAL` site host table

The site host table is generated from the `hlq.HOSTS.LOCAL` data set. This data set contains descriptions of local host entries in the HOSTS format. `HOSTS.LOCAL` can contain only IPv4 addresses. A sample `HOSTS.LOCAL` data set is created during installation. This information describes how to update the sample `hlq.HOSTS.LOCAL` data set and use it to generate the two data sets, `hlq.HOSTS.SITEINFO` and `hlq.HOSTS.ADDRINFO`, which function as your site table.

### HOST entries

One line of the `hlq.HOSTS.LOCAL` data set is used for each distinct host and ends with four colons (`::::`). The maximum length of the line is 512 characters. Each host can have multiple IP addresses and multiple names. The line for each host has the following three essential fields, which are separated by colons:

- The keyword `HOST`.
- A list of IP addresses for that host, which are separated by commas. You can specify a maximum of six IP addresses per `HOST` entry.
- A list of fully qualified names for that host, which are separated by commas. The first name is the official host name, or `CNAME` (canonical name), and any additional host names after the `CNAME` are alias names. You can specify a maximum of 20 host names. Only the first six host names are used in the `hlq.HOSTS.ADDRINFO` data set. All 20 host names are used in the `hlq.HOSTS.SITEINFO` data set.

For example, if you have two local hosts, `LOCAL1` (IP addresses `192.6.77.4` and `192.8.4.1`) and `LOCAL2` (with an alias `LOCALB` and IP address `192.6.77.2`), append the following lines to the `hlq.HOSTS.LOCAL` data set:

```
HOST : 192.6.77.4, 192.8.4.1 : LOCAL1 ::::
HOST : 192.6.77.2 : LOCAL2, LOCALB ::::
```

#### Notes:

1. The maximum length for a host that is allowed in the `HOST` tables is 24 characters.
2. If the `HOST` entry has more than the maximum of 6 IP addresses for one host name or more than 20 host names for a single IP address, the `MAKESITE` command completes successfully with no error message issued.

## NET and GATEWAY entries

The NET and GATEWAY statements are not used by TCP/IP for z/OS applications. However, some socket calls require the NET entries. If your programs do not need the NET and GATEWAY statements, delete them before invoking MAKESITE.

### Sample HOSTS.LOCAL data set (HOSTS)

The following sample HOSTS.LOCAL data set is provided in SEZAINST(HOSTS):

```
; HOSTS.LOCAL
; -----
; COPYRIGHT = NONE.
;
; The format of this file is documented in RFC 952, "DoD Internet
; Host Table Specification".
;
; The format for entries is:
;
; NET : ADDR : NETNAME :
; GATEWAY : ADDR, ALT-ADDR : HOSTNM : CPUTYPE : OPSYS : PROTOCOLS :
; HOST : ADDR, ALT-ADDR : HOSTNM, NICKNM : CPUTYPE : OPSYS : PROTOCOLS :
;
; Where:
; ADDR, ALT-ADDR = IP address in decimal, e.g., 26.0.0.73
; HOSTNM, NICKNM = the fully qualified host name and any nicknames
; CPUTYPE = machine type (PDP-11/70, VAX-11/780, IBM-3090, C/30, etc.)
; OPSYS = operating system (UNIX, TOPS20, TENEX, VM/SP, etc.)
; PROTOCOLS = transport/service (TCP/TELNET,TCP/FTP, etc.)
; : (colon) = field delimiter
; :: (2 colons) = null field
; *** CPUTYPE, OPSYS, and PROTOCOLS are optional fields.
;
; MAKESITE does not allow continuation lines, as described in
; note 2 of the section "GRAMMATICAL HOST TABLE SPECIFICATION"
; in RFC 952. Entries should be specified on a single line of
; up to a maximum of 512 characters per line.
;
; Note: The NET and GATEWAY statements are not used by the TCP/IP for
; MVS applications. However, some socket calls require the NET
; entries. For better performance, if your programs do not need
; the NET and GATEWAY statements, delete them before running
; the MAKESITE program.
;
;
HOST : 9.67.43.100 : NAMESERVER :::
HOST : 9.67.43.126 : RALEIGH :::
HOST : 129.34.128.245, 129.34.128.246 : YORKTOWN, WATSON :::
;
NET : 9.67.43.0 : RALEIGH.IBM.COM :
;
GATEWAY : 129.34.0.0 : YORKTOWN-GATEWAY :::
;
```

## Using MAKESITE

Because many servers and commands allocate *hlq*.HOSTS.SITEINFO and *hlq*.HOSTS.ADDRINFO, it is important not to overwrite or delete these data sets while TCP/IP is running. To avoid disrupting any active users, use an *HLQ*=parm that is different than your active *hlq*. This allows you to swap names (by renaming the old HOSTS data sets and then renaming the new HOSTS data sets) without starting and stopping TCP/IP.

Use MAKESITE as a TSO command or in a batch job to generate new *hlq*.HOSTS.SITEINFO and *hlq*.HOSTS.ADDRINFO data sets. The parameters are the same for either a TSO command or a batch job invocation of MAKESITE. See [z/OS Communications Server: IP System Administrator's Commands](#) for more information.

After you make changes to your *hlq*.HOSTS.LOCAL data set, you must generate and install new *hlq*.HOSTS.SITEINFO and *hlq*.HOSTS.ADDRINFO data sets.

**Guidelines:** Use ETC.IPNODES (in the style of etc/ipnodes) as the preferred alternative to the generated local hosts tables from MAKESITE for the following reasons:

- No imposed 24 character restriction on host names.
- No imposed restriction on the first eight characters of the host names having to be unique. However, there are certain applications that require the first eight characters to be unique, such as Network Job Entry (NJE).
- Closely resembles that of other TCP/IP platforms, and eliminates the MAKESITE requirement of file post-processing.
- Allows configuration of both IPv4 and IPv6 addresses.
- Only one file is managed for the system, and that all the APIs can use the same single file. The COMMONSEARCH statement in the resolver setup file can be used to reduce IPv6 and IPv4 searching to a single search order, as well as to reduce the z/OS UNIX and native MVS environments to a single search order.

For more information on [the use of IPNODES by the resolver to locate IPv4 and IPv6 addresses and sitenames](#), see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

For the search orders used in locating the local host tables, see [“Configuration files for TCP/IP applications” on page 25](#). For a description of the use of IPNODES by the resolver to locate IPv4 and IPv6 addresses and sitenames when the resolver setup statement COMMONSEARCH is specified, see [“IPv6/common search order” on page 806](#) and [“IPv6/common search order” on page 811](#).

## Creating /etc/hosts

The /etc/hosts file can be defined as follows:

- The maximum line length is 256 characters. If a line is greater than 256 characters, it is truncated to 256 characters and processed. If Trace Resolver is active, a warning message is issued.
- The line starts with an IP address, followed by a blank, followed by host names. Host names are separated by one or more blanks. The first host name that follows an IP address is the official host name, or CNAME (canonical name). Any additional host names that follow the CNAME are alias host names.
- Only IPv4 addresses are supported. For z/OS UNIX file /etc/hosts within a container’s filesystem namespace, the IP addresses can be both IPv4 and IPv6.
- Each IP address can have up to 35 host names. A host name can have up to 35 IP addresses.
- The values for the host name must conform to the following rules:
  - Maximum of 128 characters.
  - Must contain one or more tokens that are separated by a period.
  - Each token must be at least one character and less than 64 characters.
  - The first character in each token must be a letter (A-Z or a-z) or number (0-9).
- A comment is indicated by the # or ; character.

For the search orders used in locating /etc/hosts, see [“Configuration files for TCP/IP applications” on page 25](#).

## Creating ETC.IPNODES and /etc/ipnodes

The ETC.IPNODES and /etc/ipnodes file can be defined as follows:

- z/OS UNIX files can be in any directory. The maximum line length that is supported is 256 characters. If a line is greater than 256 characters, it is truncated to 256 characters and processed. If Trace Resolver

is active, a warning message is issued. If you need more than 256 characters for the IP address and the associated host names, you can code more lines with the same IP address as follows:

```
Address1 Hostname1
Address1 Hostname2
Address1 Hostname3
```

- MVS data sets must be partitioned organization (PO) or sequential (PS), RECFM=F or RECFM=FB, a logical record length (LRECL) 56 - 256, and have any valid blocksize (BLKSIZE) for fixed block.
- It can contain IPv4 and IPv6 addresses, but not IPv4 mapped addresses. Each IP address can have up to 35 host names. A host name can have up to 35 IP addresses.
- The line starts with an IP address, followed by a blank, followed by host names. Host names are separated by one or more blanks. The first host name that follows an IP address is the official host name, or CNAME (canonical name). Any additional host names that follow the CNAME are alias host names.
- The values for the host name must conform to the following rules:
  - Maximum of 128 characters.
  - Must contain one or more tokens that are separated by a period.
  - Each token must be at least one character and less than 64 characters.
  - The first character in each token must be a letter (A-Z or a-z) or number (0-9).
- A comment is indicated by the # or ; character.

The sample IPNODES file that is provided by z/OS Communications Server follows. It can be found as member EZBREIPN (alias IPNODES) in SEZAINST.

```
;
; IBM z/OS Communications Server
; SMP/E distribution name: EZBREIPN
;
; 5694-A01 (C) Copyright IBM Corp. 2002.
; Licensed Materials - Property of IBM
;
; Function: Sample ETC.IPNODES file
;
; The file contains the Internet Protocol (IP) host names
; and addresses for the local host and other hosts in the
; Internet network.
; This file is used to resolve a name into an address (that is, to
; translate a host name into its Internet address) or resolve
; an address into a name.
;
; Comments begin with a # or ; character and continue until the
; end of the line.
;
; The following statement defines the Internet Protocol (IP) name
; and address of the local host and specifies the names and
; addresses of remote hosts. The maximum line length support is
; 256 characters
;
; Entries in the hosts file have the following format:
;
; Address HostName
;
; Address HostName1 HostName2 HostName3 HostName35
;
; Address: is an IP address, it can be IPV4 or IPV6 address.
; Note: IPv4-mapped IPv6 address is not allowed.
;
; HostName: the length of the hostname is up to 128 characters,
; and each IP address can have up to 35 hostnames.
;
;
; 9.67.43.100 NAMESERVER
; 9.67.43.126 RALEIGH
; 9.67.43.222 HOSTNAME1.RALEIGH.IBM.COM
; 129.34.128.245 YORKTOWN WATSON
; 1::2 TESTIPV6ADDRESS1
```

```
1:2:3:4:5:6:7:8 TESTIPV6ADDRESS2
;
```

For the search orders used in locating ETC.IPNODES and /etc/ipnodes, see [“Configuration files for TCP/IP applications”](#) on page 25.

## Verifying your configuration

At this point, your configuration files have been updated.

To verify a configuration, start the TCP/IP address space and ensure that you see the following message:

```
EZB6473I TCP/IP STACK FUNCTIONS INITIALIZATION COMPLETE
```

If the message is not displayed, the messages issued by the TCP/IP address space should describe why TCP/IP did not start.

The following message will be generated after EZB6473I above and indicates complete initialization of TCP/IP and extended services:

```
EZD1314I TCP/IP AND EXTENDED SERVICES ARE NOW INITIALIZED FOR STACK: stackname
```

If the message is not displayed, see [Diagnosing TCP/IP stack initialization problems](#) in [z/OS Communications Server: IP Diagnosis Guide](#).

## Verifying TCPIP.DATA statement values in the native MVS environment

To display which TCPIP.DATA statement values are being used and where they are being obtained from, use Trace Resolver output. You can obtain Trace Resolver output at your TSO screen by issuing the following TSO commands:

```
alloc f(systcpt) dsn(*)
READY
netstat up
READY
free f(systcpt)
READY
```

### Tips:

- When you direct Trace Resolver output to a TSO terminal, define the screen size to be only 80 columns wide. Otherwise, trace output is difficult to read.
- You can also use the Resolver CTRACE function to collect Trace Resolver output.

For more information about using the Trace Resolver facility and interpreting its output, or about using the Resolver CTRACE function to collect Trace Resolver output, see [z/OS Communications Server: IP Diagnosis Guide](#).

## Verifying TCPIP.DATA statement values in the z/OS UNIX environment

To display which TCPIP.DATA statement values are being used and where they are being obtained from, use Trace Resolver output. You can obtain Trace Resolver output by issuing the following z/OS UNIX shell commands:

```
export RESOLVER_TRACE=stdout
netstat -u
set -A RESOLVER_TRACE
```

**Tip:** You can also use the Resolver CTRACE function to collect Trace Resolver output.

For more information about using the Trace Resolver facility and interpreting its output, or about using the Resolver CTRACE function to collect Trace Resolver output, see [z/OS Communications Server: IP Diagnosis Guide](#).

## Verifying PROFILE.TCPIP

You can use the following commands to verify many configuration values that are specified in the TCP/IP profile:

- Netstat commands

You can use the Netstat DEvlinks/-d command to verify the physical network and hardware definitions. You can use the Netstat CONFIG/-f command to verify operating characteristics.

- DISPLAY TCPIP,,OSAINFO command

You can use this command to verify that the OSA configuration was successfully accepted by the OSA feature. The command output is a view from the OSA feature of the data subchannel device for the interface.

For information about the syntax and output of these commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Verifying interfaces with Ping and Traceroute

The Ping and Traceroute commands can be used in the TSO and z/OS UNIX environments to verify adapters or interfaces attached to the z/OS host. For information about the syntax and output of the commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

Given that your PROFILE.TCPIP file contains the interfaces of your installation and that the TCPIP.DATA file contains the correct TCPIPJOBNAME, the TCPIP address space is configured and you can go on to configuring routes, servers, and so on.

## Verifying local name resolution with TESTSITE

Use the TESTSITE command to verify that the *hlq*.HOSTS.ADDRINFO and *hlq*.HOSTS.SITEINFO data sets can correctly resolve the name of a host, gateway, or net. For more information on the TESTSITE command, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Verifying PROFILE.TCPIP and TCPIP.DATA using HOMETEST

Use the HOMETEST command to verify the HOSTNAME, DOMAINORIGIN, SEARCH, and NSINTERADDR TCPIP.DATA statements. HOMETEST will use the resolver to obtain the IP addresses assigned to the HOSTNAME and compare them to the HOME list specified in PROFILE.TCPIP. A warning message will be issued if any HOSTNAME IP addresses are missing from the HOME list.

Activate Trace Resolver to obtain detailed information about how the HOSTNAME is resolved to IP addresses. The information will also include what TCPIP.DATA data set names were used. This can be done by issuing the following TSO command before running HOMETEST. The detailed information will be displayed on your TSO screen.

```
allocate dd(systcpt) da(*)
```

Issue the following TSO command after HOMETEST to turn off Trace Resolver output.

```
free dd(systcpt)
```

**Tip:** You can also use the Resolver CTRACE function to collect Trace Resolver output.

If you do not have Trace Resolver turned on before you run HOMETEST, the following information is displayed:

```
hometest

Running IBM MVS TCP/IP CS V1R6 TCP/IP Configuration Tester

FTP.DATA file not found. Using hardcoded default values.

TCP Host Name is: MVS026
```

```
Using Name Server to Resolve MVS026
The following IP addresses correspond to TCP Host Name: MVS026
9.67.113.58
```

```
The following IP addresses are the HOME IP addresses defined in PROFILE.TCPIP:
9.67.113.58
127.0.0.1
```

All IP addresses for MVS026 are in the HOME list!

Hometest was successful - all Tests Passed!

For more information about using the Trace Resolver facility and interpreting its output, or about using the Resolver CTRACE function to collect Trace Resolver output, see [z/OS Communications Server: IP Diagnosis Guide](#).

## Verifying your X Window System installation (Optional)

**Note:** You cannot verify your X Window System until after routing and DNS setup.

Support is provided for two versions of the X Window System and the corresponding Motif. The current support, provided as part of the base IP support in z/OS Communications Server, is for X Window System Version 11 Release 6 and Motif Version 1.2. Support for X Window System Version 11 Release 4 and Motif Version 1.1 is available as feature HIP614X.

### Verifying the X Window X11R4 System installation

X Window X11R4 System is installed with the other target libraries. The macro or headers go into the target library data set SEZACMAC. To verify the installation of the X Window System:

1. Specify your workstation IP address by adding a record (such as the following record) to your XWINDOWS.DISPLAY data set.

```
royal.csc.ibm.com:0.0
```

In this example,

```
royal.csc.ibm.com:0.0
```

is the name of the host running the X Window System server.

**Note:** No leading blanks are allowed in this record.

2. On the workstation running the X Window System server, issue an XHOST command specifying the name of your MVS system.
3. Run the program with the XSAMP1 command.

### Verifying the X Window X11R6 System installation

To verify the installation of the X Window X11R6 System:

1. Ensure that a host (the workstation) with an X Window System server that supports X11R6 is properly configured and reachable by the MVS system. From the workstation, use Telnet to access the MVS system, and open a z/OS UNIX shell on the MVS system.
2. From the z/OS UNIX shell, export the DISPLAY environment variable using either the network name or the qualified IP address of the workstation as shown in the following example:

```
export DISPLAY=royal.csc.ibm.com:0.0
```

In this example, *royal.csc.ibm.com* is the name of the workstation running the X Window System server. The display is indicated by *:0.0*, and is specified this way in almost all cases.

3. Authorize the MVS system to access the workstation by executing the XHOST command, and specify either the name of the MVS system or a plus sign (+) as shown in the following example.

```
xhost +
```

**Note:** The + option turns off security for this workstation and allows any X client to display here.

4. The sample X clients are shipped in the directory `/usr/lpp/tcpip/X11R6/Xamples/demos`. Change into this directory. There are four sample program directories, `xsamp1`, `xsamp2`, `xsamp3`, and `pexsamp`. Change to the `xsamp1` directory. Verify that there are files named `Makefile` and `xsamp1.c`, and then execute the following command:

```
make
```

5. Execute the program using the following command:

```
xsamp1
```

6. The z/OS UNIX shell should block as another window is opened. Verify the workstation is displaying a new window. The `xsamp1` client displays a blank window for 60 seconds and then exits, taking its window with it. The z/OS UNIX shell should no longer be blocked.

## Customizing TCP/IP messages

The messages for every application provided by TCP/IP are compiled and linked with the application and are stored in an internal message repository. Some of the applications also store their messages in message catalogs or message data sets. You can modify these message catalogs or message data sets to translate the messages to another language or to customize them for your installation.

### Customizing message catalogs

Applications in [Table 17 on page 299](#) use message catalogs that are created by using the **gencat** utility. The message catalogs are installed in the `/usr/lpp/tcpip/lib/nls/msg/C/` directory in the z/OS UNIX file system.

| Table 17. TCP/IP message catalogs                                                                               |                               |
|-----------------------------------------------------------------------------------------------------------------|-------------------------------|
| Application                                                                                                     | Message catalogs              |
| Autolog<br>TCP/IP configuration                                                                                 | cfmsg.cat                     |
| <b>certbundle</b> command (z/OS UNIX)                                                                           | certbundlemsg.cat             |
| Communications Server SMTP (CSSMTP) application                                                                 | ezamllcat.cat<br>ezamlrpy.cat |
| Defense Manager daemon (DMD)                                                                                    | dmdmsg.cat                    |
| Digital Certificate Access Server (DCAS)                                                                        | dcasm.cat                     |
| DISPLAY TCPIP,,NETSTAT operator command<br>NETSTAT command (TSO)<br><b>netstat/onetstat</b> command (z/OS UNIX) | netmsg.cat<br>netmsg6.cat     |
| DISPLAY TCPIP,,SYSPLEX command<br>VARY TCPIP,,SYSPLEX command                                                   | spxmsg.cat                    |

| Table 17. TCP/IP message catalogs (continued) |                  |
|-----------------------------------------------|------------------|
| Application                                   | Message catalogs |
| <b>dnsdomainname</b> command (z/OS UNIX)      | ezahomsg.cat     |
| <b>domainname</b> command (z/OS UNIX)         | ezaitmsg.cat     |
| <b>host</b> command (z/OS UNIX)               |                  |
| <b>hostname</b> command (z/OS UNIX)           |                  |
| FTP client                                    | ftpdmsg.cat      |
| FTP server                                    | ftpdreply.cat    |
| IKE daemon(IKED)                              | ike_log.cat      |
| <b>ipsec</b> command (z/OS UNIX)              | ipsecmsg.cat     |
| Load Balancing Advisor (LBA)                  | lcadvm.cat       |
| Automated domain name registration (ADNR)     |                  |
| MODDVIPA utility                              | xfdvpm.cat       |
| Motif V1.1                                    | Mrm12.cat        |
| XWindows X11R4                                | Uil12.cat        |
|                                               | xm12.cat         |
|                                               | X11R6.cat        |
| Motif V1.2                                    | Mrm21.cat        |
| XWindows X11R6                                | xm21.cat         |
|                                               | Uil21.cat        |
|                                               | X11R66.cat       |
| Network security services (NSS) server        | nssdmsg.cat      |
| <b>nssctl</b> command (z/OS UNIX)             | nssctlmsg.cat    |
| Omproute                                      | omprdmsg.cat     |
| <b>orexec/rexec</b> command (z/OS UNIX)       | rexcmmsg.cat     |
| <b>orsh/rsh</b> command (z/OS UNIX)           |                  |
| RExec command (TSO)                           |                  |
| RSH command (TSO)                             |                  |
| <b>pasearch</b> command (z/OS UNIX)           | pagentm.cat      |
| Policy Agent(Pagent)                          |                  |
| PING command (TSO)                            | pingmsg.cat      |
| <b>ping</b> command (z/OS UNIX)               |                  |
| popper (z/OS UNIX)                            | popper_msg.cat   |
| PORTMAP (z/OS UNIX)                           | msrpcbin.cat     |
| RPC                                           | msrpcgen.cat     |
| Rpcbind                                       | msrpplib.cat     |

| Table 17. TCP/IP message catalogs (continued) |                  |
|-----------------------------------------------|------------------|
| Application                                   | Message catalogs |
| REXECD server (z/OS UNIX)                     | rexmsg.cat       |
| RSHD server (z/OS UNIX)                       | rshmsg.cat       |
| Simple Network Time Protocol daemon (SNTPD)   | sntpmsg.cat      |
| SNMP Agent (OSNMPD)                           | snmpmsg.cat      |
| <b>snmp</b> command (z/OS UNIX)               | snmpclim.cat     |
| SNMP Network SLAPM2 subagent (nslapm2)        | pagtsmsg.cat     |
| SNMP TN3270E Telnet subagent                  | ezbtsmsg.cat     |
| Syslog daemon (syslogd)                       | syslogd.cat      |
| TCP/IP SNMP subagent                          | subamsg.cat      |
| Telnet server (z/OS UNIX)                     | tnmsgs.cat       |
| TIMED daemon                                  | timedmsg.cat     |
| TRACERTE command (TSO)                        | trtemsg.cat      |
| <b>tracert</b> command (z/OS UNIX)            |                  |
| Traffic regulation manager daemon (TRMD)      | trmdm.cat        |
| Trap forwarder daemon (TRAPFWD)               | trapfwd.cat      |
| <b>trmdstat</b> command (z/OS UNIX)           | trmdstat.cat     |

## Message format

Use the z/OS UNIX **dspscat** command to display the message text from a message catalog. The messages are in the following format:

```
index_num "message text"
```

The *index\_num* value is the identifier that the application uses to access the message text.

The *message text* value might include conversion characters for the variable fields that are converted when the message is printed or displayed and control characters that affect the message format. The conversion characters start with a percent sign (%) and the control characters start with a backslash (\). These are all standard notations for the C language print function. The messages might also contain comments, which start with /\* and end with \*/.

In the following simulated message, the control character \n forces a new line to print. The string variables %1\$s, %2\$s, and %3\$s are converted in the order that they are passed from the application.

```
1 "EZZ2350I MVS TCP/IP NETSTAT %1$s TCP/IP Name: %2$s %3$s\n"
```

## Rules for modifying messages

The general rule for customizing or translating messages is to change only the text portion of the message.

- Do not change the *index\_num* identifier. This part of the message has a specific meaning. If you change it, the application might not function correctly.
- Do not change the conversion characters for the variables. These characters indicate that the application is passing data, the type of data that the application is passing, and the appropriate way

to display or print this data. For example, do not change or delete %1\$s and %2\$d in the following message:

```
475 "EZA1644I Recfm: %1$s lrecl: %2$d\n"
```

If you change or delete the conversion characters, results are unpredictable.

- You can reorder the sequence of variables within a message when the variables are defined by conversion characters with the format %n\$, where *n* is an integer. For example, you can reverse the conversion characters when translating the following message:

```
Before:
480 "EZY9999I Command %1$s received from user %2$s\n"

After:
480 "EZY9999I Utilisador %2$s envio instruccion %1$s\n"
```

The result would be EZY9999I Utilisador MANNY envio instruccion FTP instead of EZY9999I Command FTP received from user MANNY.

You cannot reorder the sequence of variables in the following message:

```
EZY9999I Command $s received from user $s
```

## Steps for creating a modified message catalog

Some applications store their messages in message catalogs. You can modify these message catalogs to translate the messages to another language or to customize them for your installation.

### Before you begin

Review the following information:

- [“Message format” on page 301](#)
- [“Rules for modifying messages” on page 301](#)

You also must know:

- The commands that are indicated in these steps are z/OS UNIX commands; do all of these steps from the z/OS UNIX shell.
- These steps use a message catalog that is called sample.cat, and assume that the application code and catalog are at the correct levels. If you customize a catalog, IBM Service personnel might require that you use the shipped level of the catalog to re-create and diagnose a reported problem.

## Procedure

Perform the following steps to create a modified message catalog:

1. Copy the current z/OS UNIX catalog to a backup file to ensure that you have a copy of the original catalog.

```
cp /usr/lpp/tcpip/lib/nls/msg/C/sample.cat /usr/lpp/tcpip/lib/nls/msg/C/sample.cat.backup
```

2. Using the z/OS UNIX **dspcat** command, convert the editable backup catalog that you just copied.

```
dspcat -t -g /usr/lpp/tcpip/lib/nls/msg/C/sample.cat.backup > /tmp/sample.cat.copy
```

The file sample.cat.copy is the file that you will update to preserve the timestamp and customize the messages.

3. Change the first line in the catalog from a comment to a z/OS UNIX **gencat** command \$timestamp directive.

This enables the original timestamp to be imbedded in the new catalog when the catalog is built. In some cases, when an application opens a message catalog, it checks the timestamp at the top

of the catalog to ensure that it matches the application timestamp. If the timestamps are different, the application does not use the message catalog. You must ensure that the new message catalog contains the timestamp from the original message catalog by performing the following steps:

- a. Edit the file to be updated.

```
oedit /tmp/sample.cat.copy
```

- b. Change the first line comment to add a **gencat** command \$timestamp directive to preserve the timestamp when the directory is built. The first line in the file is similar to the following line:

```
The time stamp of catalog /usr/lpp/tcpip/lib/nls/msg/C/sample.cat.backup is: 2010 095
20:30 UTC
```

Replace the leading text on the line with the \$timestamp directive as follows:

```
$timestamp 2010 095 20:30 UTC
```

If you omit this step and the original line is left unchanged in the catalog, when you attempt to generate a catalog from this file, you will see a message similar to the following message:

```
FSUM5108 gencat: Invalid message number.
```

- c. Save the file.
4. Update the catalog (/tmp/sample.cat.copy) with any local modifications and save the file.
5. Build a new and customized catalog by using the z/OS UNIX **gencat** command.

```
gencat /tmp/sample.cat /tmp/sample.cat.copy
```

The correct response is the following message:

```
FSUM5105 gencat: Message catalog generated normally.
```

**Tip:** Verify that your changes are correct before invoking the **gencat** command. Some errors cause the **gencat** command to fail, but other errors might not be apparent until the message is displayed.

6. Browse the new catalog and verify that the timestamp from step “3” on [page 302](#) matches what is in the file.

```
obrowse /tmp/sample.cat
```

The first record contains the time stamp (*yyyy ddd hh:mm UTC*). For example:

```
...2010 095 20:30 UTC
```

7. Replace the z/OS UNIX catalog, which is shipped with the release, with the updated catalog that you created in step “5” on [page 303](#).

```
cp /tmp/sample.cat /usr/lpp/tcpip/lib/nls/msg/C/sample.cat
```

## What to do next

For more information about the **dspscat** and **gencat** utilities, see [z/OS UNIX System Services Command Reference](#).

## Customizing message data sets

The following table shows the servers that have external messages, the DD statement used, and the name of the message data set delivered with the system:

| Server            | DD statement | Data set         |
|-------------------|--------------|------------------|
| SNMP Query Engine | //MSSNMPMS   | SEZAINST(MSSNMP) |

| Server      | DD statement | Data set           |
|-------------|--------------|--------------------|
| MISC Server | //MSMISCSR   | SEZAINST(MSMISCSR) |

The procedures for these servers have a special DD statement that point to the external message data set. If you are going to override the internal messages and use external customized messages, you need to remove the comment from the appropriate DD statement and ensure it points to the correct data set.

## Message text

The message text might include conversion characters for the variable fields that are converted when the message is printed or displayed, and control characters that affect the message format. The conversion characters start with a percent sign (%) and the control characters start with a backslash (\). These are all standard notations for the C language print function. The messages might also contain comments which start with /\* and end with \*/.

In the following simulated message, the control character \n forces a new line to print and the string variables, represented by %s, are converted in the order they are passed from the program.

```
9999 I "Command %s received from user %s\n"
```

## Message format

Figure 50 on page 304 explains the syntax for TCP/IP message IDs on the host:

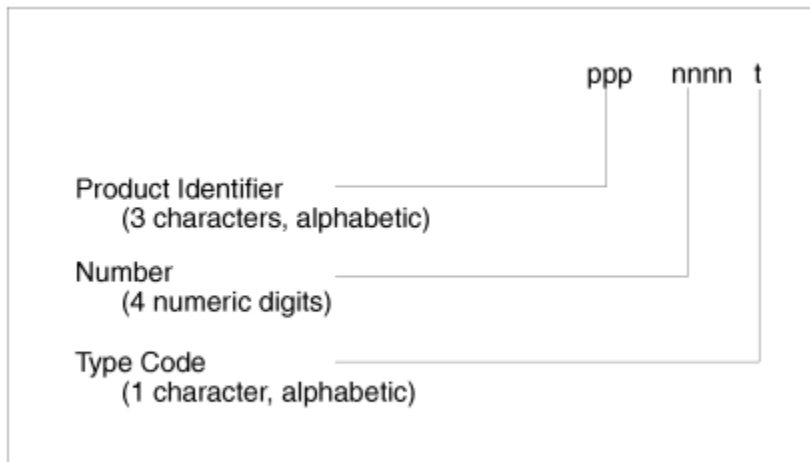

Figure 50. Syntax for TCP/IP message IDs

The *product identifiers* (ppp) for TCP/IP are EZA, EZB, EZD, EZY, EZZ, and SNM. The *number* (nnnn) indicates a unique 4-digit numeric value assigned to the message by product. The *type code* (t) indicates the severity assigned to the message.

## Rules for customizing the messages

The general rule for customizing or translating messages is to change only the text portion of the message.

- Do not change the MARGIN, PRODUCT, and COMPONENT definitions at the top of the data set. These are required definitions for the program. For example, these entries at the top of the MISC server message data set should not be changed:

```
MARGINS(1,72)
PRODUCT EZA
COMPONENT MSC
```

- Do not change the message numbers and the severity code. These parts of the message have specific meaning; if you change them the program may not work correctly.
- Do not change the conversion characters. These indicate that the program is passing data, the type of data it is passing, and the appropriate way to display or print this data. For example, do not change or delete %s and %d in the following message:

```
4059 I "Connecting to agent %s on DPI port %d\n"
```

- You can reorder the variables that are passed in the message. For example, you can reverse the order of the two string variables that are passed when translating a message by specifying the new order of the arguments in parentheses following the message text:

Before: 9999 I "Command %s received from user %s\n"

After: 9999 I "Utilisador %s envio instruccion %s\n"(2, 1)

The result would be EZY9999I Utilisador MANNY envio instruccion FTP instead of EZY9999I Command FTP received from user MANNY.

- Watch for any program parameters or keywords that might be in the message text. In most cases, you should not translate them.

For example, in the following message, 'active' is a keyword used in the gateway definition and should not be translated:

```
3974 E "First two elements must be 'active' for active gateway\n"
```

---

## Chapter 6. Routing

This information explains the steps that are required to configure your TCP/IP stack for dynamic, static, or policy-based routing, and explains how to verify the configuration. If you understand your entire network configuration, after you read this information you can do the following tasks:

- Configure dynamic, static, or policy-based routing
- Use the Ping command to ping a remote host by IP address
- Use the Traceroute command to determine the path that will be taken to reach a particular destination using static or dynamic routing
- Use the Netstat command to display a TCP/IP stack's routing information
- Use DISPLAY commands to display dynamic routing information

**Guideline:** The definition or modification of an installation's routing configuration should not be performed without a complete understanding of the entire network design.

---

### Routing terminology

[“General terms” on page 307](#) describes some of the more common IP routing-related terms and concepts. If you need more detailed information, see *Routing in the Internet* by Christian Huitema.

### General terms

#### **Autonomous system (AS)**

A group of routers that are exchanging routing information through a common routing protocol. A single AS can represent many IP networks.

#### **Dynamic routes**

IP layer routing table entries that are dynamically managed and can automatically change in response to network topology changes. For IPv4, these routes are managed by a routing daemon. For IPv6, these routes can be managed by a routing daemon, and they can also be learned by listening to router advertisement messages received from routers as part of the router discovery protocol.

#### **Exterior Gateway Protocol (EGP)**

A routing protocol that is spoken by routers that belong to different autonomous systems when those routers are configured to share routing information between autonomous systems. This topic does not discuss exterior gateway routing.

#### **Interior Gateway Protocol (IGP)**

A routing protocol that is spoken by routers that belong to the same autonomous system. Each AS has a single IGP. A separate AS within a network can be running a different IGP.

#### **Main route table**

An IPv4 or IPv6 route table that is populated by using static routes and dynamic routes. These route tables have the name EZBMAIN. A TCP/IP stack has one main IPv4 route table and one main IPv6 route table. When policy-based routing is not in use, the main route tables contain all of the routes that a TCP/IP stack uses when it is making routing decisions. When policy-based routing is in use, policies can be configured to use the main route tables in routing decisions when no route is found in a policy-based route table.

#### **Policy-based route table**

A route table that is configured for use by policy-based routing. A TCP/IP stack can have zero or more policy-based route tables. A policy-based route table can be defined by using a flat file that is parsed by the Policy Agent, or by using the IBM Configuration Assistant for z/OS Communications Server. A policy-based route table definition can contain static routes, dynamic routing parameters for controlling the scope of dynamic routes that are added to the table, or both. Policy rules and actions can then be defined to indicate, for given types of traffic, which route tables the TCP/IP stack is to use when it is making routing decisions.

**Policy-based routing (PBR)**

A technique that is used to make routing decisions that are based on policies that are defined by the network administrator. Policy-based routing selects a route for outbound traffic from a set of policy-based route tables, and optionally the main route table, according to the policy defined for the traffic.

**Replaceable static routes**

IPv4 static routes that can be replaced by OMPROUTE, or IPv6 static routes that can be replaced by OMPROUTE or by routes that are learned by listening to router advertisement messages received from routers as part of the router discovery protocol.

**Router**

A device or host that interprets protocols at the IP layer and forwards datagrams on a path towards their correct destination.

**Routing**

The process that is used in an IP network to deliver a datagram to the correct destination.

**Routing daemon**

A server process that manages the IP route table.

**Static routes**

IP layer routing table entries that are manually configured (by using the BEGINROUTES configuration statement) and do not change automatically in response to network topology changes, except when:

- The change is due to an ICMP redirect (if not disabled).
- A dynamic routing protocol learns a route to a destination configured as a replaceable static route.

## Interior Gateway Protocols

An interior gateway protocol (IGP) is a dynamic route update protocol used between routers that run on TCP/IP hosts within a single autonomous system. The routers use this protocol to exchange information about IP routes.

Some of the more common interior gateway protocols are:

**Routing Information Protocol (RIP)**

RIP uses a distance vector algorithm to calculate the best path to a destination based on the number of hops in the path. RIP has several limitations. Some of the limitations which exist in RIP Version 1 are resolved by RIP Version 2.

**RIP Version 2**

RIP Version 2 extends RIP Version 1. Among the improvements are support for multicasting and variable subnetting. Variable subnetting allows the division of networks into variable size subnets. For example, one route can represent addresses from 9.1.1.0 through 9.1.1.255 (the 9.1.1.0/255.255.255.0 subnet) while another can represent addresses from 9.2.0.0 through 9.2.255.255 (the 9.2.0.0/255.255.0.0 subnet).

**IPv6 RIP**

IPv6 RIP uses the same distance vector algorithm used by RIP to calculate the best path to a destination. It is intended to allow routers to exchange information for computing routes through an IPv6-based network.

**Open Shortest Path First (OSPF)**

OSPF uses a link state or shortest path first algorithm. OSPF's most significant advantage compared to RIP is the reduced time needed to converge after a network change. In general, OSPF is more complicated to configure than RIP and might not be suitable for small networks.

**IPv6 OSPF**

IPv6 OSPF also uses a link state or shortest path first algorithm to calculate the best path to a destination. IPv6 OSPF has the same advantages and more complicated configuration compared to IPv6 RIP, like OSPF compared to RIP.

Table 18. Interior Gateway Protocol characteristics

| Feature                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | RIP-1             | RIP-2             | IPv6 RIP          | OSPF                | IPv6 OSPF           |

| Algorithm                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     | Distance vector   | Distance vector   | Distance vector   | Shortest path first | Shortest path first |
| Network load (1)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | High              | High              | High              | Low                 | Low                 |
| CPU processing requirement (1)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | Low               | Low               | Low               | High                | High                |
| IP network design restrictions                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                | Many              | Some              | Some              | Virtually none      | Virtually none      |
| Convergence time                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              | Up to 180 seconds | Up to 180 seconds | Up to 180 seconds | Low                 | Low                 |
| Multicast supported (2)                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | No                | Yes               | Yes               | Yes                 | Yes                 |
| Multiple equal-cost routes                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | No (3)            | No(3)             | No(3)             | Yes                 | Yes                 |
| <b>Notes:</b><br>1. Depends on network size and stability.<br>2. Multicast saves CPU cycles on hosts that are not interested in certain periodic updates, such as OSPF link state advertisements or RIP-2 routing table updates. Multicast frames are filtered out either in the device driver or directly on the interface card if this host has not joined the specific multicast group.<br>3. RIP in OMPROUTE allows multiple equal-cost routes only for directly connected destinations over redundant interfaces. See <a href="#">“Use of static routing with OMPROUTE”</a> on page 385. |                   |                   |                   |                     |                     |

## Route selection algorithm

Whether static, dynamic, or policy-based routing is used, the algorithm used by the IP layer to select a route from a route table is the same. Route selection occurs in the following order:

1. If a route exists to the destination address (a host route), it is chosen.
2. If no host route exists to the destination address, the route chosen depends upon the version of IP being used:
  - For IPv4:
    - a. If subnet, network, or supernet routes exist to the destination, the route with the most specific network mask (the mask with the most bits on) is chosen.
    - b. If the destination is a multicast destination and a multicast default route exists, that route is chosen.
  - For IPv6, if prefix routes exist to the destination, the route with the most specific prefix is chosen.
3. Default routes are chosen when no other route exists to a destination.

Multiple equal-cost routes are allowed for static, dynamic, and policy-based routing. [Table 18 on page 309](#) and [“Multiple equal-cost routes” on page 323](#) provide additional information about the use of multiple equal-cost routes.

In the absence of policy-based routing, the IP layer routes traffic by searching the main route table for the most specific route known, using the selection order described. If policy-based routing is being used, the

IP layer routes traffic according to the policy defined for the traffic. For more information about how the IP layer routes traffic when policy-based routing is being used, see [“Policy-based routing” on page 377](#).

## The sample network

Figure 51 on page 310 and Figure 52 on page 311 show network diagrams that depict a sample network. This sample network is used in the following topics as the configuration of static, dynamic, and policy-based routing is described:

- [“IPv4 static routing” on page 311](#)
- [“IPv6 static routing” on page 313](#)
- [“IPv4 dynamic routing using OMPROUTE” on page 316](#)
- [“IPv6 dynamic routing using OMPROUTE” on page 319](#)
- [“Policy-based routing” on page 377](#)

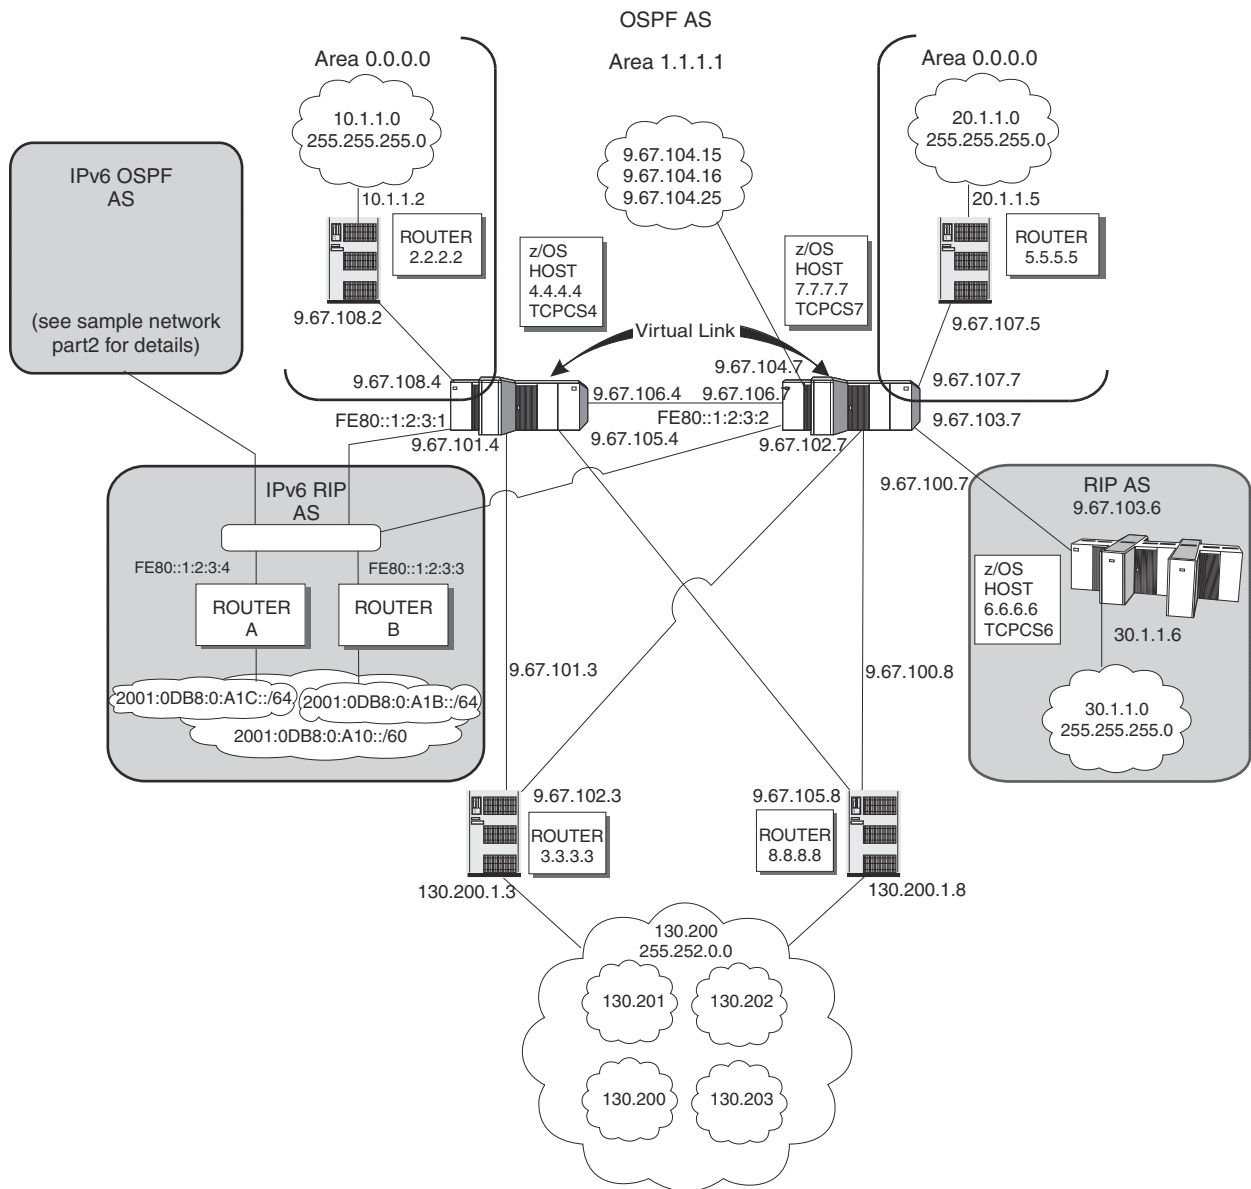

Figure 51. Sample network part 1

Figure 52. Sample network part 2, IPv6 OSPF AS

In this sample network, TCPCS4 and TCPCS7 are both performing as OSPF area border routers between OSPF areas 0.0.0.0 and 1.1.1.1. TCPCS64 and TCPCS67 are both performing as OSPF area border routers between IPv6 OSPF areas 0.0.0.0 and 6.6.6.6. TCPCS7 is performing as an AS boundary router between the OSPF AS and the RIP AS. TCPCS67 is performing as an AS boundary router between the IPv6 OSPF AS and the IPv6 RIP AS. TCPCS4 and TCPCS7 have interfaces to both the IPv4 network and the IPv6 network.

## IPv4 static routing

Static routing requires that routes are configured manually for each router or destination; this is a significant reason system administrators avoid this technique if given a choice. Static routing has the disadvantage that network reachability is not dependent on the state of the network itself. If a destination is down or unreachable over that statically configured route, the static routes remain in the routing table, and traffic continues to be sent toward that destination without success.

To minimize network administrator tasks, configuration of static routes is to be avoided, especially in a large network. However, certain circumstances make static routing more appropriate. For example, static routes can be used:

- To define a default route or a route that is not being advertised within a network using a dynamic routing protocol
- To replace exterior gateway protocols when trying to avoid:

- The cost of routing protocol traffic between ASs
- Complex routing policies
- In conjunction with a routing daemon to provide backup routes when the daemon cannot find a dynamic route to the destination. In this case, the static route must be configured as replaceable.

If static routing is used, only the PROFILE.TCPIP data set has to be updated with the BEGINROUTES statement.

The only ways to modify static routes are:

- Replace the routing table using the VARY TCPIP,,OBEYFILE command
- Use incoming ICMP Redirect packets
- Use ICMP Must Fragment packets
- If a static route is defined on a BEGINROUTES statement as being replaceable, it can be replaced if a dynamic route is discovered by OMROUTE. This is the only way that a static route can be replaced by a dynamic route.

For more information on the VARY TCPIP,,OBEYFILE command, see [z/OS Communications Server: IP System Administrator's Commands](#). For more information on the IPCONFIG statement, and the IGNOREREDIRECTS and PATHMTUDISC parameters for the IPCONFIG statement, see [z/OS Communications Server: IP Configuration Reference](#).

The first BEGINROUTES statement in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command, replaces all static routes in the TCP/IP stack routing table, including those destination addresses specified in the BSDROUTINGPARMS section of the PROFILE.TCPIP. Subsequent statements within the same data set append to the routing table.

Every interface must have an IP address to transmit or receive packets. Along with the IP address, each interface must have a subnet mask associated with it for routing purposes. The combination of the address and mask will yield the subnet that the interface belongs to and also determines the broadcast address for the interfaces. For interfaces not involved in dynamic routing, the subnet mask can be specified in one of the following ways:

- On the BSDROUTINGPARMS statement in PROFILE.TCPIP.
- On the INTERFACE statement in the OMROUTE configuration file, if running OMROUTE. Also, if running OMROUTE, OMROUTE will always override the stack's BSDROUTINGPARMS and set the subnet mask for every interface it is aware of, even if you did not code the interface to OMROUTE. Therefore, it is highly recommended that you either specify every interface to OMROUTE with the correct subnet mask, or configure OMROUTE to ignore undefined interfaces.

If you do not specify the subnet mask by one of these methods, the subnet mask is determined by the stack using the stack routing table. Specifying the subnet mask rather than letting it default is highly recommended.

For point-to-point links, such as CTC, a destination address is used to document the other end of a point-to-point connection. For interfaces not involved in dynamic routing, this can be specified in one of the following ways:

- On the BSDROUTINGPARMS statement in PROFILE.TCPIP.
- On the INTERFACE statement in the OMROUTE configuration file, if running OMROUTE. Also, if running OMROUTE, OMROUTE will always override the stack's BSDROUTINGPARMS and set the destination address for every point-to-point link it is aware of, even if you did not code the interface to OMROUTE. Therefore, it is highly recommended that you either specify every interface to OMROUTE with the correct destination address, or configure OMROUTE to ignore undefined interfaces.

If you do not specify the destination address by one of these methods, the stack determines the address by using the stack routing table. Specifying the destination address rather than letting it default is highly recommended.

**Tip:** You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMROUTE

and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see [z/OS Communications Server: IP Diagnosis Guide](#) and [IBM Health Checker for z/OS User's Guide](#).

## Replaceable static routes

Because replaceable static routes are intended to be last-resort routes, TCP/IP attempts to use them only if no dynamic routes to the destination are available.

If a non-replaceable static route fails validation, even if the reason for the failure is transient like gateway unreachable, the definition for the non-replaceable static route is discarded. However, if a replaceable static route fails validation for a transient reason, the definition of the route is retained. When there are no dynamic routes to the destination, TCP/IP periodically tries to add the replaceable static route to the routing table. Because of these periodic attempts, multiple EZZ4333I messages might be seen. Retries are performed no more often than every 30 seconds, and only as long as there are no active routes to the destination in the routing table, and only if at least one new route has been added to the routing table since the last retry. Retries are terminated as soon as a valid route to the destination is installed into the routing table, whether it is dynamic, static, or replaceable static.

For a discussion of things to consider when using IPv4 static routing and OMROUTE together on the same TCP/IP stack, see [“Use of static routing with OMROUTE” on page 385](#).

## IPv6 static routing

---

Static routing requires that routes are configured manually for each router or destination; this is a significant reason system administrators avoid this technique if given a choice. Static routing has the disadvantage that network reachability is not dependent on the state of the network itself. If a destination is down, or unreachable through a statically configured route, the static routes remain in the routing table and traffic continues to be sent toward that destination without success.

To minimize network administrator tasks, configuration of static routes is to be avoided, especially in a large network. However, certain circumstances make static routing more appropriate. For example, static routes can be used:

- To define a route that will not be learned dynamically from OMROUTE or from router advertisements received from routers as part of the router discovery protocol
- In conjunction with dynamic routes to provide backup routes when a dynamic route to the destination cannot be found. In this case, the static route must be configured as replaceable.

If static routing is used, only the PROFILE.TCPIP data set has to be updated with BEGINROUTES statements. The only ways to modify static routes are:

- Replace the routing table using the VARY TCPIP,,OBEYFILE command
- Use incoming ICMPv6 redirect packets
- If a static route is defined on a BEGINROUTES statement as being replaceable, it can be replaced by a dynamic route

Note that the first BEGINROUTES statement in PROFILE.TCPIP, or in the data set referenced by a VARY TCPIP,,OBEYFILE command, replaces all static routes in the TCP/IP stack routing table. Subsequent statements within the same data set append to the routing table.

**Rule:** If you use static routes and want to honor ICMPv6 redirect messages (that is, you do not code IPCONFIG6 IGNOREREDIRECTS), then you must code the first hop address using the link-local address of the router. This is required because all redirect messages are sent using the router's link-local address, and if the source address of the redirect message does not match the address of the first hop in the routing table, the redirect message will be ignored.

For more information on the VARY TCPIP,,OBEYFILE command, see [z/OS Communications Server: IP System Administrator's Commands](#). For more information on the IPCONFIG6, and the IGNOREREDIRECTS parameter on the IPCONFIG6, see [z/OS Communications Server: IP Configuration Reference](#).

**Tip:** You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see [z/OS Communications Server: IP Diagnosis Guide](#) and [IBM Health Checker for z/OS User's Guide](#).

## Replaceable static routes

Because replaceable static routes are intended to be last-resort routes, TCP/IP attempts to use them only if no dynamic routes to a destination are available. If a non-replaceable static route fails validation, even if the reason for the failure is transient (for example, gateway unreachable), the definition for the non-replaceable static route is discarded. However, if a replaceable static route fails validation for a transient reason, the definition of the route is retained. When there are no dynamic routes to the destination, TCP/IP periodically tries to add the replaceable static route to the routing table. Because of these periodic attempts, multiple EZZ4348I messages might be seen. Attempts occur every 30 seconds at the most, if there are no active routes to the destination in the routing table and at least one new route was added to the routing table since the last attempt. Attempts end when a valid route to the destination is installed into the routing table, whether it is a dynamic, static, or replaceable static route.

For a discussion of things to consider when using IPv6 static routing and IPv6 router advertisements together on the same TCP/IP stack, see [“Use of IPv6 static routing with router advertisements” on page 385](#). For a discussion of things to consider when using IPv6 static routing and OMROUTE together on the same TCP/IP stack, see [“Use of static routing with OMROUTE” on page 385](#).

## Static routing configuration examples

The following topics illustrate static routing configuration examples.

### z/OS TCPCS4

Static route statements for z/OS TCPCS4:

```
BEGINRoutes ;first BEGINRoutes in the profile
;
;Network/mask FirstHop LinkName PacketSize
Route 9.67.106.0/24 = CTC4T07 MTU 1500 ;route1
Route 9.67.105.0/24 = CTC4T08 MTU 1500 ;route2
Route 9.67.101.0/24 = CTC4T03 MTU 1500 ;route3
Route 9.67.108.0/24 = CTC4T02 MTU 1500 ;route4
Route 9.67.107.0/24 9.67.106.7 CTC4T07 MTU 1500 ;route5
Route 7.7.7.7/32 9.67.106.7 CTC4T07 MTU 1500 ;route6
Route 9.67.103.0/24 9.67.101.3 CTC4T03 MTU 1500 ;route7
Route 9.67.103.0/24 9.67.106.7 CTC4T07 MTU 1500 ;route8
Route 30.1.1.0/24 9.67.106.7 CTC4T07 MTU 1500 ;route9
Route 10.1.1.0/24 9.67.108.2 CTC4T02 MTU 1500 ;route10
Route 130.200.0.0/14 9.67.101.3 CTC4T03 MTU 1500 ;route11
Route 130.200.0.0/14 9.67.105.8 CTC4T08 MTU 1500 ;route12
Route 130.203.0.0/16 9.67.105.8 CTC4T08 MTU 1500 ;route13
Route DEFAULT 9.67.106.7 CTC4T07 MTU 1500 ;route14
;
;Destination/PrefixLen FirstHop Interface PacketSize
Route FE80::1:2:3:3/128 = OSAQDI046 MTU 5000 REPL ;route15
Route FE80::1:2:3:4/128 = OSAQDI046 MTU 5000 REPL ;route16
Route 2001:0DB8:0:A1B::/64 FE80::1:2:3:3 OSAQDI046 MTU 5000 REPL ;route17
Route 2001:0DB8:0:A1C::/64 FE80::1:2:3:4 OSAQDI046 MTU 5000 REPL ;route18
Route DEFAULT6 FE80::1:2:3:4 OSAQDI046 MTU 5000 REPL ;route19
EndRoutes
;
```

#### Notes:

1. In the BEGINROUTES block, the netmask can be specified by a /xx. This number, denoted by xx, represents the number of significant bits in the netmask. For example:

```
/16 = 16 significant bits = 11111111 11111111 00000000 00000000 = 255.255.0.0
```

For IPv6, you must specify the prefix length of the route using the /xxx notation.

2. For direct routes, use an equals symbol (=) for the first hop.

BSDROUTINGPARMS statements for z/OS TCPCS4:

```
BSDRoutingParms TRUE ; Shown only for completeness
; Linkname MTU Metric Subnet Mask Dest Address
CTC4T08 1500 0 255.255.255.0 0
CTC4T07 1500 0 255.255.255.0 0
CTC4T03 1500 0 255.255.255.0 0
CTC4T02 1500 0 255.255.255.0 0
VIPA1A 1500 0 255.255.255.252 0
EndBSDRoutingParms
;
```

## z/OS TCPCS7

Static route statements for z/OS TCPCS7:

```
BEGINRoutes
;
;Network/mask FirstHop LinkName PacketSize
Route 9.67.106.0/24 = CTC7T04 MTU 1500 ;route1
Route 9.67.100.0/24 = CTC7T08 MTU 1500 ;route2
Route 9.67.102.0/24 = CTC7T03 MTU 1500 ;route3
Route 9.67.103.0/24 = CTC7T06 MTU 1500 ;route4
Route 9.67.107.0/24 = CTC7T05 MTU 1500 ;route5
Route 4.4.4.4/32 9.67.106.4 CTC7T04 MTU 1500 ;route6
Route 10.1.1.0/24 9.67.106.4 CTC7T04 MTU 1500 ;route7
Route 20.1.1.0/24 9.67.107.5 CTC7T05 MTU 1500 ;route8
Route 30.1.1.0/24 9.67.103.6 CTC7T06 MTU 1500 ;route9
Route 130.200.0.0/14 9.67.100.8 CTC7T08 MTU 1500 ;route10
Route 130.200.0.0/14 9.67.102.8 CTC7T03 MTU 1500 ;route11
Route 130.203.0.0/16 9.67.102.3 CTC7T03 MTU 1500 ;route12
Route DEFAULT 9.67.107.5 CTC7T05 MTU 1500 ;route13
;
;Destination/PrefixLen FirstHop Interface PacketSize
Route FE80::1:2:3:3/128 = OSAQDI076 MTU 5000 REPL ;route14
Route FE80::1:2:3:4/128 = OSAQDI076 MTU 5000 REPL ;route15
Route 2001:0DB8:0:A1B::/64 FE80::1:2:3:3 OSAQDI076 MTU 5000 REPL ;route16
Route 2001:0DB8:0:A1C::/64 FE80::1:2:3:4 OSAQDI076 MTU 5000 REPL ;route17
Route DEFAULT6 FE80::1:2:3:4 OSAQDI076 MTU 5000 REPL ;route18
EndRoutes
```

BSDROUTINGPARMS statements for z/OS TCPCS7:

```
BSDRoutingParms TRUE
; Linkname MTU Metric Subnet Mask Dest Address
CTC7T08 1500 0 255.255.255.0 0
CTC7T03 1500 0 255.255.255.0 0
CTC7T06 1500 0 255.255.255.0 0
CTC7T04 1500 0 255.255.255.0 0
CTC7T05 1500 0 255.255.255.0 0
VIPA1A 1500 0 255.255.255.252 0
EndBSDRoutingParms
;
```

The sample configuration has an IPv4 supernet route for 130.200.0.0. An IPv4 supernet route means that the netmask for the route is smaller than the class netmask. In this case, 130.200.0.0 is a class B address. The default netmask for class B is 255.255.0.0. The netmask used for this sample is 255.252.0.0, which is less than 255.255.0.0, hence making this a supernet route. In routing, the stack prefers a route that has the most bits in common. Therefore, the stack chooses a route in the following order:

1. If a route exists to the destination address (a host route), it is chosen.
2. At this point, the route chosen depends upon the version of IP being used:
  - For IPv4:
    - a. If subnet, network, or supernet routes exist to the destination, the route with the most specific network mask (the mask with the most bits on) is chosen.

b. If the destination is a multicast destination and a multicast default route exists, that route is chosen.

- For IPv6, if prefix routes exist to the destination, the route with the most specific prefix is chosen.

3. Default routes are chosen when no other route exists to a destination.

For example, for TCPCS4 (and when trying to reach 130.200.0.0), route12 in the list is used, which is the supernet route 130.200.0.0 with mask 255.252.0.0. If applying the mask of that route, 255.252.0.0, to the destination IP address, 130.200.0.0, the result is 130.200.0.0, which is the IP address of this route. Now, when trying to reach destination 130.203.5.2, the stack would use route13 in the list, which is a network route for 130.203.00 with mask 255.255.0.0. If applying the mask of that route, 255.255.0.0, to the destination IP address, 130.203.5.2, the result is 130.203.00, which is the IP address of this route.

For TCPCS4, route7 and route8 are examples of equal cost multipath routes to get to 9.67.103.0 subnet. This means that TCPCS4 has two different routes to get to this destination. If IPCONFIG MULTIPATH is not enabled, then only route7 will be used as long as it is active. This is because the stack chooses the first route and ignores route8. If route7 becomes inactive, then the stack will switch and use route8. If MULTIPATH is enabled, then the stack will use both routes according to the MULTIPATH specification.

In the preceding example, all of the IPv4 links have a subnet mask of 255.255.255.0 because this is what is specified for the links in the BSDROUTINGPARMS. Therefore, to determine the broadcast addresses for link CTC4TO3, AND the IP Address, 9.67.101.4, and the subnet mask, 255.255.255.0, to yield the subnet for this link, 9.67.101.0. Then, OR the subnet, 9.67.101.0, with the complement of the subnet mask, 0.0.0.255. This determines that the broadcast address for this link is 9.67.101.255.

For TCPCS4, route15 and route16 would be selected to reach host FE80::1:2:3:3 and host FE80::1:2:3:4 respectively. Route17 and route18 would be selected to reach any IPv6 address that had the first 64 bits of 2001:0DB8:0:A1B and 2001:0DB8:0:A1C respectively. Route19 would be selected for any other IPv6 destination.

#### Rules:

1. All IPv4 IP addresses must follow Classless Inter-Domain Routing (CIDR) convention that requires the actual mask to be one or more on-bits followed by zero or more off-bits. On-bits cannot be followed by off-bits followed by on-bits. Therefore, a mask of 255.255.254.0 is valid (an actual mask of FFFFE00), but a mask of 255.255.253.0 is not valid (an actual mask of FFFFD00) because 253 is 11111101.
2. VIPA links or VIPA interfaces are not allowed on BEGINROUTES statements.
3. DEFAULT and DEFAULT6 routes are always indirect routes and therefore must always have a first hop address specified.

## IPv4 dynamic routing using OMROUTE

Daemon is a UNIX term for a background server process, and daemons are used for dynamic routing. For z/OS Communications Server IP, there is a multiprotocol routing daemon available. For IPv4, OMROUTE supports the RIP Version 1, RIP Version 2, and OSPF routing protocols. You can send RIP Version 1 or RIP Version 2, but not both at the same time on a single interface. However, you can configure a RIP interface to receive both versions.

**Guideline:** If OROUTED was used in a prior release and the RIP protocol is still the preferred dynamic routing method in your host configuration, use OMROUTE to provide RIP support.

For IPv4, OMROUTE implements the OSPF protocol described in RFC 1583 (*OSPF Version 2*), the OSPF subagent protocol described in RFC 1850 (*OSPF Version 2 Management Information Base*), and the RIP protocols described in RFC 1058 (*Routing Information Protocol*) and in RFC 1723 (*RIP Version 2 - Carrying Additional Information*). It provides an alternative to the static TCP/IP gateway definitions. The MVS host running with OMROUTE becomes an active OSPF or RIP router in an IP network. Either or both of these routing protocols can be used to dynamically maintain the host routing table. For example, OMROUTE can detect when a route is created, is temporarily unavailable, or if a more efficient route exists. If both OSPF and RIP protocols are used simultaneously, OSPF routes are preferred over RIP routes to the same destination.

**Tip:** You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see [z/OS Communications Server: IP Diagnosis Guide](#) and [IBM Health Checker for z/OS User's Guide](#).

## Open Shortest Path First

Open Shortest Path First (OSPF) is classified as an Interior Gateway Protocol (IGP). This means that it distributes routing information between routers belonging to a single autonomous system (AS), a group of routers all using a common routing protocol. The OSPF protocol is based on link-state or shortest path first (SPF) technology. It has been designed expressly for the TCP/IP Internet environment, including explicit support for IP subnetting and the tagging of externally derived routing information.

OSPF performs the following tasks:

### **Multiple routes**

Provides support for up to 16 equal-cost routes.

### **Authentication**

Provides for the authentication of routing updates.

### **IP multicast**

Uses IP multicast when sending or receiving the updates.

### **Allows network grouping**

Allows sets of networks to be grouped together. Such a grouping is called an area. The topology of an area is hidden from the rest of the autonomous system. This method of hiding information enables a significant reduction in routing traffic. Also, routing within the area is determined only by the area's own topology, lending the area protection from bad routing data. An area is a generalization of an IP subnetted network.

### **IP subnet configuration**

Enables the flexible configuration of IP subnets. Each route distributed by OSPF has a destination and mask. Two different subnets of the same IP network number may have different sizes (that is, different masks). This is commonly referred to as variable length subnetting. A packet is routed to the best (longest or most specific) match. Host routes are considered to be subnets whose masks are all ones (0xFFFFFFFF).

### **Authenticate OSPF protocol exchanges**

Can be configured such that all OSPF protocol exchanges are authenticated. This means that only trusted routers can participate in the autonomous system's routing. A single authentication scheme is configured for each physical link. This enables some links to use authentication while others do not.

OSPF is a dynamic routing protocol. It quickly detects topological changes in the AS (such as router interface failures) and calculates new loop-free routes after a period of convergence. This period of convergence is short and involves a minimum of routing traffic as compared to the RIP protocol.

In a link-state routing protocol, each router maintains a database describing the autonomous system's topology. Each individual piece of this database is a particular router's local state (for example, the router's usable interfaces and reachable neighbors). The router distributes its local state throughout the autonomous system by flooding.

To generate routes, all routers run the exact same algorithm, in parallel. From the topological database, each router constructs a tree of shortest paths with itself as root. This shortest-path tree gives the route to each destination in the autonomous system. Externally derived routing information (for example, routes learned from the RIP protocol) appears on the tree as leaves. When multiple equal-cost routes to a destination exist, the routes (up to 16) are added to the TCP/IP stack's route table. The TCP/IP stack uses these equal-cost routes according to the multipath setting configured for the route table. [“Multiple equal-cost routes” on page 323](#) provides additional information about the multipath setting configured for a route table and the use of multiple equal-cost routes.

Externally derived routing data (for example, routes learned from the RIP protocol) is passed transparently throughout the autonomous system. This externally derived data is kept separate from

the OSPF protocol's link state data. Each external route can also be tagged by the advertising router, but not by OMPROUTE, enabling the passing of additional information between routers on the boundaries of the autonomous system. OMPROUTE does pass tags created by others. For information on configuring OSPF, see [“Steps for configuring OSPF and RIP \(IPv4 and IPv6\)”](#) on page 333.

## Routing Information Protocol

Routing Information Protocol (RIP) is an Interior Gateway Protocol (IGP) designed to manage a relatively small network. RIP is based on the Bellman-Ford or the distance-vector algorithm. RIP has many limitations and is not suitable for every TCP/IP environment. Before using the RIP function in OMPROUTE, read RFCs 1058 and 1723 to decide if RIP can be used to manage the routing tables of your network. For more information about RFCs 1058 and 1723, see [Appendix G, “Related protocol specifications,”](#) on page 1439.

RIP uses the number of hops, or hop count, to determine the best possible route to a host or network. The term hop count is also referred to as the metric. In RIP, a hop count of 16 means infinity, or that the destination cannot be reached. This limits the longest path in the network that can be managed by RIP to 15 gateways.

A RIP router broadcasts routing information to its directly connected networks every 30 seconds. It receives updates from neighboring RIP routers every 30 seconds and uses the information contained in these updates to maintain the routing table. If an update has not been received from a neighboring RIP router in 180 seconds, a RIP router assumes that the neighboring RIP router is down, sets all routes through that router to a metric of 16 (infinity), and stops using those routes when routing IP packets. If an update has still not been received from the neighboring RIP router after another 120 seconds, the RIP router deletes from the routing table all of the routes through that neighboring RIP router.

RIP Version 2 is an extension of RIP Version 1 and provides the following features:

### Route Tags

The route tags are used to separate *internal* RIP routes (routes for networks within the RIP routing domain) from *external* RIP routes, which may have been imported from an EGP (external gateway protocol) or another IGP. OMPROUTE does not generate route tags, but preserves them in received routes and readvertises them when necessary.

### Variable subnetting support

Variable length subnet masks are included in routing information so that dynamically added routes to destinations outside subnetworks or networks can be reached.

### Immediate next hop for shorter paths

Next hop IP addresses, whenever applicable, are included in the routing information to eliminate packets being routed through extra hops in the network.

### Multicasting to reduce load on hosts

IP multicast address 224.0.0.9, reserved for RIP Version 2 packets, is used to reduce unnecessary load on hosts which are not listening for RIP Version 2 messages. This support is dependent on interfaces that are multicast-capable.

### Authentication for routing update security

Authentication keys can be configured for inclusion in outgoing RIP Version 2 packets. Incoming RIP Version 2 packets are checked against the configured keys.

### Configuration switches for RIP Version 1 and RIP Version 2 packets

Configuration parameters allow for controlling which version of RIP packets are to be sent or received over each interface.

### Supernetting support

The supernetting feature is part of Classless InterDomain Routing (CIDR). Supernetting provides a way to combine multiple network routes into fewer supernet routes, thus reducing the number of routes in the routing table and in advertisements.

For configuration information for RIP, see [“Steps for configuring OSPF and RIP \(IPv4 and IPv6\)”](#) on page 333.

## IPv6 dynamic routing using router discovery

---

Enabling IPv6 router discovery in z/OS Communications Server requires no additional z/OS Communications Server configuration. All that is needed is at least one IPv6 interface that is defined and started, and at least one adjacent router through that interface that is configured for IPv6 router discovery. If these things exist, then z/OS Communications Server begins receiving router advertisements from the adjacent routers. Depending on the configuration in the adjacent routers, the following types of routes can be learned from the received router advertisements:

- Default route for which the originator of the router advertisement is the next hop
- Indirect routes to prefixes for which the originator of the router advertisement is the next hop
- Direct routes (no next hop) to prefixes that are on the link that is shared by z/OS Communications Server and the originator of the router advertisement

If a stack routing table contains non-replaceable static routes to a destination, any route to that destination that is learned from a router advertisement is not added to the stack routing table.

### Multiple routes from router advertisements

Multiple default routes and multiple prefix routes to a single prefix might be learned through router advertisements. If an adjacent router is on a link onto which z/OS Communications Server TCP/IP has multiple IPv6 interfaces, multiple routes are learned for each route in the router advertisement from the adjacent router (one route through each interface onto the link). Default routes and indirect routes to a prefix might be learned from the router advertisements that are originated by multiple adjacent routers.

When multiple direct prefix routes to a single prefix are learned, all of the routes are installed in the stack main route table. The subset of the routes that are installed in a stack policy-based route table is controlled by the `DynamicRoutingParms` parameter on the `RouteTable` statement for that route table.

When multiple default routes or multiple indirect prefix routes to a single prefix are learned, the stack uses the following information to determine the subset of the routes that are installed in the stack route tables:

- The reachability of the advertising routers.
- The status (active or inactive) of the associated interfaces.
- The preference values (high, medium, or low) that are advertised for the routes in the router advertisements. This value enables the originator of the router advertisement to indicate whether it is to be preferred over other routers as the next hop for the route.
- For a policy-based route table, the dynamic routing parameters that are defined for the route table by using the `DynamicRoutingParms` parameter on the `RouteTable` statement.

The routes with the highest preference value are installed in the route table; however, routes that are learned from routers that are reachable over active interfaces take priority, regardless of preference value.

When multiple default routes or multiple prefix routes to a single prefix are installed in the stack main route table, TCP/IP uses those routes according to the setting of the `MULTIPATH` parameter on the `IPCONFIG6` statement. When multiple default routes or multiple prefix routes to a single prefix are installed in a stack policy-based route table, TCP/IP uses those routes according to the setting of the `Multipath6` parameter on the `RouteTable` statement for that route table.

## IPv6 dynamic routing using OMPROUTE

---

For IPv6, OMPROUTE implements the IPv6 RIP protocol described in RFC 2080 (*RIPng for IPv6*) and the IPv6 OSPF protocol described in RFC 2740 (*OSPF for IPv6*). It provides an alternative to the static TCP/IP gateway definitions. The MVS host running with OMPROUTE becomes an active OSPF or RIP router in an IP network. Either or both of these routing protocols can be used to dynamically maintain the host IPv6 routing table. For example, OMPROUTE can detect when a route is created, is temporarily unavailable, or if a more efficient route exists. If both IPv6 OSPF and IPv6 RIP protocols are used simultaneously, IPv6 OSPF routes will be preferred over IPv6 RIP routes to the same destination.

**Tip:** You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMPROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see [z/OS Communications Server: IP Diagnosis Guide](#) and [IBM Health Checker for z/OS User's Guide](#).

## IPv6 OSPF protocol

IPv6 OSPF is classified as an Interior Gateway Protocol (IGP). This means that it distributes routing information between routers belonging to a single autonomous system (AS), a group of routers all using a common routing protocol. The IPv6 OSPF protocol is based on link-state or shortest path first (SPF) technology.

IPv6 OSPF is a dynamic routing protocol. It quickly detects topological changes in the AS (such as router interface failures) and calculates new loop-free routes after a period of convergence. This period of convergence is short and involves a minimum of routing traffic as compared to the IPv6 RIP protocol. However, it does generally require more CPU resources on participating routers.

In IPv6 OSPF, sets of networks can be placed together in groups called areas. The topology of an area is hidden from the rest of the AS. This method of hiding information enables a significant reduction in routing traffic. Also, routing within the area is determined only by the area's own topology, lending the area protection from bad routing data.

Each IPv6 OSPF router maintains a database describing the autonomous system's topology. Each individual piece of this database is a particular router's local state (for example, the router's usable interfaces and reachable neighbors). The router distributes its local state information by flooding. The routing information in an area is summarized and advertised into adjacent areas, allowing for the generation of interarea routes. This summarization and advertising of routing information between areas is the responsibility of the routers that are on the border between areas (called area border routers).

To generate routes, all routers run the exact same algorithm, in parallel. From the topological database, each router constructs a tree of shortest paths with itself as root. This shortest-path tree gives the route to each destination in the autonomous system. Externally derived routing information (for example, routes learned from the IPv6 RIP protocol) appears on the tree as leaves. When multiple equal-cost routes to a destination exist, the routes (up to 16) are added to the TCP/IP stack's route table. The TCP/IP stack uses these equal-cost routes according to the multipath setting configured for the route table. [“Multiple equal-cost routes” on page 323](#) provides additional information about the multipath setting configured for a route table and the use of multiple equal-cost routes.

Externally derived routing data is passed transparently throughout the autonomous system. This externally derived data is kept separate from the IPv6 OSPF protocol's link state data. Each external route can also be tagged by the advertising router, but not by OMPROUTE, enabling the passing of additional information between routers on the boundaries of the autonomous system. OMPROUTE does pass tags created by others. For information on configuring IPv6 OSPF, see [“Steps for configuring OSPF and RIP \(IPv4 and IPv6\)” on page 333](#).

## IPv6 RIP protocol

IPv6 RIP is an Interior Gateway Protocol (IGP) designed to manage a relatively small network. IPv6 RIP is based on the Bellman-Ford or the distance-vector algorithm. IPv6 RIP has limitations and is not suited for every TCP/IP environment. Before using the IPv6 RIP function in OMPROUTE, read RFC 2080 to decide if RIP can be used to manage the IPv6 routing tables of your network. For more information about RFC 2080, see [Appendix G, “Related protocol specifications,” on page 1439](#).

IPv6 RIP uses the number of hops, or hop count, to determine the best possible route to a host or network. The term hop count is also referred to as the metric. In IPv6 RIP, a hop count of 16 means infinity, or that the destination cannot be reached. This limits the longest path in the network that can be managed by IPv6 RIP to 15 gateways.

A IPv6 RIP router broadcasts routing information to its directly connected networks every 30 seconds. It receives updates from neighboring IPv6 RIP routers every 30 seconds and uses the information contained

in these updates to maintain the IPv6 routing table. If an IPv6 RIP update has not been received from a neighboring router in 180 seconds, an IPv6 RIP router assumes that the neighboring router is down, sets all IPv6 RIP routes through that router to a metric of 16 (infinity), and stops using those routes when routing IP packets. If an update has still not been received from the neighboring router after another 120 seconds, the IPv6 RIP router deletes from the IPv6 routing table all of the IPv6 RIP routes through that neighboring router.

Next hop IP addresses, whenever applicable, are included in IPv6 RIP updates to eliminate packets being routed through extra hops in the network. IPv6 multicast address FF02::9, reserved for IPv6 RIP packets, is used to reduce unnecessary load on hosts that are not listening for IPv6 RIP messages.

For configuration information for IPv6 RIP, see [“Steps for configuring OSPF and RIP \(IPv4 and IPv6\)”](#) on page 333.

## OMPROUTE configuration

---

This topic includes items to consider when configuring OMPROUTE, and the steps to use to configure OMPROUTE.

### Run-time environment

OMPROUTE is a z/OS UNIX application, and it requires a z/OS UNIX file system to operate. It can be started from an MVS started procedure, from the z/OS shell, or from AUTOLOG (see step “2” on page 325 for restrictions on using AUTOLOG to start OMPROUTE). OMPROUTE must be started by a RACF-authorized user ID, and it must be in an APF authorized library.

OMPROUTE uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and syslogd are used for major events such as initialization, termination, and error conditions. CTRACE is used for tracing the receipt and transmission of OSPF/RIP packets and communications between OMPROUTE and the TCP/IP stack. In addition, OMPROUTE can be configured to use CTRACE for detailed tracing and debugging. STDOUT is used for detailed tracing and debugging.

When syslogd is active and /dev/console is defined in the syslog.conf file, OMPROUTE logging messages are directed to syslogd and to the MVS console. If syslogd is active and /dev/console is not defined, OMPROUTE logging messages are directed to syslogd only.

When syslogd is inactive, OMPROUTE logging messages are directed to the OMPROUTE JES joblog and to the MVS console.

If OMPROUTE tracing or debugging is enabled, the output can be directed to STDOUT, the JES joblog, or OMPROUTE CTRACE. Additionally, the logging messages (that is, interface initialization messages) can be found in syslogd, provided it is active at the time of tracing or debugging. Syslogd directs urgent OMPROUTE messages to the MVS console.

**Tip:** If you enable OMPROUTE tracing without syslogd active, large amounts of data can be written to the console.

OMPROUTE uses a standard message catalog. The message catalog must be in the z/OS UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

Configuration of OMPROUTE is accomplished using an OMPROUTE configuration file. For details on the statements in the [OMPROUTE configuration file](#), see [z/OS Communications Server: IP Configuration Reference](#).

Display of OMPROUTE information is performed using the DISPLAY or MODIFY command. Modification of OMPROUTE information is performed using the MODIFY command. For details on OMPROUTE's DISPLAY and MODIFY command for OMPROUTE commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Language Environment run-time considerations

When starting OMPROUTE from a started or cataloged procedure, it is usually recommended that OMPROUTE be started directly from the SEZALOAD data set using PGM=OMPROUTE. However, there is a situation where it might be desirable to start OMPROUTE using BPXBATCH.

When OMPROUTE is started using PGM=OMPROUTE, the STDENV DD card, if used, is passed directly to the OMPROUTE program. The Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the \_CEE\_RUNOPTS= environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM= parameter and the options must be specified before any OMPROUTE options. However, the PARM= statement allows a maximum of 100 characters. If the wanted Language Environment run-time options plus OMPROUTE parameters exceeds 100 characters, consideration should be given to using BPXBATCH to start OMPROUTE. When PGM=BPXBATCH is used, the Language Environment environment variable \_CEE\_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

## OMPROUTE tuning considerations

It might be desirable to tune OMPROUTE's storage usage when running in complex network environments or when running with traces enabled for long periods of time. To determine if tuning is necessary, use the Language Environment run-time options RPTSTG and RPTOPTS. For information on these options and the reports they generate, see z/OS Language Environment documentation.

## Multiple TCP/IP stacks

A one-to-one relationship exists between an instance of OMPROUTE and a stack. OSPF, RIP, IPv6 OSPF, and IPv6 RIP support on multiple stacks requires multiple instances of OMPROUTE.

## TCP/IP stack routing table management

OMPROUTE's job is limited to the management of the TCP/IP stack routing table. OMPROUTE is not involved in the actual routing decisions made by the TCP/IP stack when routing a packet to its destination.

If IPv4 interfaces are defined in the OMPROUTE configuration file as OSPF or RIP interfaces, all IPv4 dynamic routes are deleted from the stack's IPv4 routing table upon initialization of OMPROUTE. If IPv6 interfaces are defined in the OMPROUTE configuration file as OSPF or RIP interfaces, all IPv6 dynamic routes, excluding those dynamic routes learned through IPv6 router discovery, are deleted from the stack's IPv6 routing table upon initialization of OMPROUTE. OMPROUTE then repopulates the stack routing tables that it cleared, using information learned through the routing protocols.

IPv4 Internet Control Message Protocol (ICMP) redirects are ignored when OMPROUTE is active and there are IPv4 interfaces configured to OMPROUTE as RIP or OSPF interfaces. IPv6 ICMP redirects are ignored when OMPROUTE is active and there are IPv6 interfaces configured to OMPROUTE as RIP or OSPF interfaces.

OMPROUTE does not make use of the BSDROUTINGPARMS statement. Instead, the IPv4 Maximum Transmission Unit (MTU), subnet mask, and destination address parameters are configured using the OSPF\_INTERFACE, RIP\_INTERFACE, and INTERFACE statements in the OMPROUTE configuration file. The MTU for IPv6 interfaces is learned from the TCP/IP stack and therefore is not a parameter on the IPV6\_OSPF\_INTERFACE, IPV6\_RIP\_INTERFACE, and IPV6\_INTERFACE statements.

**Result:** The Netstat DEvlinks/-d report displays these parameters under the heading Routing Parameters, even though the BSDROUTINGPARMS statement is not defined.

## Using RIP, IPv6 RIP, OSPF, and IPv6 OSPF with OMPROUTE

When OMPROUTE is initialized, it uses the OMPROUTE configuration file to determine which routing protocols will be enabled. If at least one OSPF interface is configured, the OSPF protocol is enabled. If at least one RIP interface is configured, RIP is enabled. If at least one IPv6 RIP interface is configured, IPv6 RIP is enabled. If at least one IPv6 OSPF interface is configured, IPv6 OSPF is enabled. If OMPROUTE

is started with no interfaces defined for a particular protocol, that protocol is disabled until one of the following events occur:

- OMPROUTE is stopped and restarted with a configuration file containing at least one interface of the specific type.
- OMPROUTE is dynamically reconfigured using the MODIFY command with a configuration file containing at least one interface of the specific type.

When OMPROUTE is configured for both the OSPF and RIP protocols (either IPv4 or IPv6), routes that are learned through the OSPF protocol take precedence over routes learned through the RIP protocol.

The OSPF and RIP protocols are communicated over IPv4 interfaces that are defined with the `OSPF_INTERFACE` and `RIP_INTERFACE` configuration statements, respectively. An IPv4 interface involved in the communication of neither the RIP nor the OSPF protocol should be configured to OMPROUTE with the `INTERFACE` configuration statement, unless `Ignore_Undefined_Interfaces=YES` is coded on the `Global_Options` configuration statement. OMPROUTE supports a maximum of 255 real, physical, IPv4 interfaces (that is, interfaces on which data can actually be sent and received). There is no theoretical limit on how many VIPAs can be configured, though there are practical limits imposed by network design. For special VIPA considerations, see step “5” on page 337.

The IPv6 OSPF and IPv6 RIP protocols are communicated over IPv6 interfaces that are defined with the `IPV6_OSPF_INTERFACE` and `IPV6_RIP_INTERFACE` configuration statements, respectively. An IPv6 interface not involved in the communication of the IPv6 OSPF or IPv6 RIP protocol can be configured to OMPROUTE with the `IPV6_INTERFACE` configuration statement. If default values are acceptable and you do not need to define additional prefixes to an IPv6 interface not involved in the communication of the IPv6 OSPF or IPv6 RIP protocol, it is not necessary to configure the interface to OMPROUTE at all. OMPROUTE will learn about the interface and its MTU value from the stack and use default values for other parameters. This is different from IPv4, where all interfaces should be configured to prevent OMPROUTE from using default values for MTU size and subnet mask, unless `Global_Options` is coded with `Ignore_Undefined_Interfaces=YES`.

OMPROUTE allows for the generation of multiple, equal-cost routes to a destination. For OSPF and IPv6 OSPF, up to 16 multiple equal-cost routes are allowed. For RIP and IPv6 RIP, multiple equal-cost routes are supported only to directly connected destinations over redundant interfaces.

## Virtual IP addresses

OMPROUTE is enhanced with virtual IP addressing (VIPA) to handle network interface failures by switching to alternate paths. The VIPA routes are included in the OSPF, RIP, IPv6 OSPF, and IPv6 RIP advertisements to adjacent routers. Adjacent routers learn about VIPA routes from the advertisements and can use them to reach the destinations at the MVS host.

## Service policy

If service policy is going to be used to restrict access to neighbors on point-to-multipoint interfaces (for example MPCPTP interfaces including XCF and IUTSAMEH connections) for temporary intervals, those neighbors must be explicitly defined on the `OSPF_INTERFACE` or `RIP_INTERFACE` statement. Otherwise, OMPROUTE might not be able to communicate with those neighbors when the access restriction expires.

## Multiple equal-cost routes

When the TCP/IP main route table is used to route traffic, multiple routes exist in the TCP/IP main route table for a destination, and the `IPCONFIG MULTIPATH` or `IPCONFIG6 MULTIPATH` statement is specified in `PROFILE.TCPIP`, outbound traffic for that destination is distributed across all of the routes. The same is true when a policy-based route table is used to route traffic, multiple routes exist in the policy-based route table for a destination, and the `Multipath` parameter on the `RouteTable` policy statement indicates that multipath support should be provided for the policy-based route table. This traffic distribution is done on either a packet-basis or connection-basis, depending on the type of multipath support configured. For information on configuring different types of multipath support using the `IPCONFIG` statement and

IPCONFIG6 statements, and the [RouteTable](#) policy statement, see [z/OS Communications Server: IP Configuration Reference](#).

When OMPROUTE is being used to provide dynamic routing for a TCP/IP stack, multiple routes to the same destination can be dynamically added to a TCP/IP stack route table, based upon the routing information learned from other routers. These multiple routes will be added when the route calculation for each has resulted in the same route cost value. No more than 16 equal-cost routes will be added for each destination. For RIP and IPv6 RIP, multiple equal-cost routes will be added only to directly-connected destinations over redundant interfaces. The RIP and IPv6 RIP protocols will generate no more than one indirect route to a destination.

| <i>Table 19. Multipath route limitations</i> |                                                |                                      |                                         |
|----------------------------------------------|------------------------------------------------|--------------------------------------|-----------------------------------------|
| <b>Multipath route type</b>                  | <b>Static (BEGINROUTES and policy-defined)</b> | <b>OMPROUTE (OSPF and IPv6 OSPF)</b> | <b>OMPROUTE (RIP and IPv6 RIP)</b>      |
| Direct host                                  | Yes (no limit)                                 | Yes (up to 16)                       | No                                      |
| Indirect host                                | Yes (no limit)                                 | Yes (up to 16)                       | No                                      |
| Direct network                               | Yes (no limit)                                 | Yes (up to 16)                       | Yes (up to 16 for redundant interfaces) |
| Indirect network                             | Yes (no limit)                                 | Yes (up to 16)                       | No                                      |
| Default (indirect)                           | Yes (no limit)                                 | Yes (up to 16)                       | No                                      |

**Guidelines:**

- If more equal-cost multipath routes are needed in the main IPv4 route table than can be provided by an IPv4 dynamic routing protocol, you can configure static routes using the BEGINROUTES statement.
- If more equal-cost multipath routes are needed in the main IPv6 route table than can be provided by an IPv6 dynamic routing protocol, you can configure static routes using the BEGINROUTES statement.
- If more equal-cost multipath routes are needed in a policy-based route table than can be provided by a dynamic routing protocol, you can configure static routes using the RouteTable policy statement.

## Sysplex autonomics

If you enable sysplex autonomics, it is important that you ensure that the WLM policy for the OMPROUTE address space receives sufficient resources in relationship to other work that is being managed on the system. Under high load conditions, if not properly classified it is possible that OMPROUTE can trigger an autonomic response from the TCP/IP stack it has an affinity with, resulting in the TCP/IP address space removing itself from the sysplex group. Place the TCP/IP and OMPROUTE address spaces in the SYSSTC service classification. Classification in another service class leaves the system vulnerable to a sysplex distributor outage. For more information about sysplex autonomics, see [“Sysplex problem detection and recovery”](#) on page 480.

## Steps for configuring OMPROUTE

OMPROUTE is a multiprotocol routing daemon capable of handling both OSPF and RIP interfaces concurrently.

### Before you begin

You can configure OMPROUTE by using the following general steps. Details follow the general steps.

1. Create the OMPROUTE configuration file.
2. Reserve the ports, and ensure loopback availability.
3. Update the resolver configuration file.
4. Update the OMPROUTE cataloged procedure.

5. Specify the RIP UDP port numbers in the SERVICES file or data set (if using the RIP or IPv6 RIP protocol).
6. RACF authorize user IDs for starting OMPROUTE.
7. Start syslogd.
8. Update the OMPROUTE environment variables (optional).
9. Create static routes (optional).
10. Configure OSPF authentication (optional, if using the IPv4 OSPF protocol).

If policy-based routing is used on the TCP/IP stack and the routing policy is configured with dynamic routing parameters, you do not need to provide additional configuration to OMPROUTE for dynamic routing support to be provided for the policy-based route tables. The dynamic routing parameters specified in the routing policy are provided to OMPROUTE by the TCP/IP stack to control the scope of dynamic routes computed by OMPROUTE. For a description of this function, see [“Policy-based routing” on page 377](#).

If policy-based routing is used on the TCP/IP stack and a route table is configured to the Policy Agent with no dynamic routing parameters, OMPROUTE has no knowledge of that route table. For example, the route table does not appear in the display of OMPROUTE route tables.

## Procedure

Perform the following steps to configure OMPROUTE:

1. Create the OMPROUTE configuration file.

The OMPROUTE configuration file provides information about the host's routing capabilities and TCP/IP interfaces. For more detail about the contents of this file, see [“Steps for configuring OSPF and RIP \(IPv4 and IPv6\)” on page 333](#). The following search order is used by OMPROUTE to locate the configuration data set or file:

- a. The MVS data set or z/OS UNIX file that is specified on the OMPCFG DD statement in the OMPROUTE started procedure.
- b. If the environment variable, OMPROUTE\_FILE, is defined, OMPROUTE uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data. The syntax for an MVS data set name is `//'mvs.dataset.name'`. The syntax for a z/OS UNIX file name is `/dir/subdir/file.name`.
- c. `/etc/omproute.conf`
- d. `hlq.ETC.OMPROUTE.CONF`

**Tip:** If you are configuring a complex environment, you can use the following OMPROUTE configuration file features:

- Group related statements into separate files and use the INCLUDE statement to include them in your OMPROUTE configuration.
- Use MVS system symbols (such as &SYSCONE, &SYSNAME, and &SYSPLEX). This feature reduces the number of OMPROUTE configuration files that must be maintained in a multisystem environment.

A sample configuration file is provided in SEZAINST(EZAORCFG). The configuration files for TCP4S4, TCP4S6, TCP4S7, and TCP4S64 in the sample network are shown in [“Sample OMPROUTE configuration files” on page 375](#). For a description of the syntax rules for the OMPROUTE configuration file and details on each of the configuration statements, see [z/OS Communications Server: IP Configuration Reference](#).

2. Reserve the ports.

- RIP protocol

If the RIP protocol of OMPROUTE is going to be used, UDP port 520 should be reserved for OMPROUTE. If the IPv6 RIP protocol of OMPROUTE is going to be used, UDP port 521 should be reserved for OMPROUTE. This is done by adding the name of the member containing the OMPROUTE cataloged procedure to the PORT statement in PROFILE.TCPIP:

```
PORT
 520 UDP OMPROUTE
 521 UDP OMPROUTE
```

If you want to be able to start OMPROUTE from the z/OS shell, use the special name OMVS as follows:

```
PORT
 520 UDP OMVS
 521 UDP OMVS
```

- Autolog considerations for OMPROUTE when using the OSPF protocol

If a procedure in the AUTOLOG list also has a PORT statement reserving a TCP or UDP port but does not have a listening connection on that port, TCP/IP periodically attempts to cancel that procedure and start it again.

Therefore, if OMPROUTE is being started with AUTOLOG and only the OSPF or IPv6 OSPF protocol is being used (no RIP or IPv6 RIP protocol, so no listening connection on the RIP or IPv6 RIP UDP port), it is important to take one of the following actions:

- Ensure that the RIP UDP port (520) and the IPv6 RIP UDP port (521) are not reserved by the PORT statement in the PROFILE.TCPIP.
- Add the NOAUTOLOG parameter to the PORT statement in the PROFILE.TCPIP. For example,

```
PORT
 520 UDP OMPROUTE NOAUTOLOG
 521 UDP OMPROUTE NOAUTOLOG
```

**Tip:** When using only the OSPF or IPv6 OSPF protocol, the auto-start feature of AUTOLOG can be used as described. However, the monitoring and auto-restart features of AUTOLOG are unavailable due to AUTOLOG's dependence on listening to a TCP or UDP connection, which does not exist with OSPF and IPv6 OSPF.

If you fail to take one of these actions, OMPROUTE will be periodically canceled and restarted by TCP/IP.

### 3. Update the resolver configuration file.

The resolver configuration file contains keywords (DATASETPREFIX and TCPIPjobname) used by OMPROUTE. The value assigned to DATASETPREFIX will determine the high-level qualifier (*hlq*). The *hlq* is used in the search order for the OMPROUTE configuration file. If no DATASETPREFIX keyword is found, a default of TCPIP is used. The value assigned to TCPIPjobname will be used as the name of the TCP/IP stack with which OMPROUTE establishes a connection.

For a description of the search order used by the resolver to locate the resolver configuration file, see [“Resolver configuration files” on page 796](#).

### 4. Update the OMPROUTE cataloged procedure.

If OMPROUTE is to be started by a procedure, create the cataloged procedure by copying the sample in SEZAINST(OMPROUTE) to your system or recognized PROCLIB. Specify OMPROUTE parameters and change the data set names to suit your local configuration.

// PARM=('ENVAR("_CEE_ENVFILE_S=DD:STDENV")')
/**
/** Example of start parameters to OMROUTE:
/**
/** PARM=('ENVAR("_CEE_ENVFILE_S=DD:STDENV")/-t1 -6t1')
/**
/** Provide environment variables to run with the desired
/** stack and configuration. As an example, the file
/** specified by STDENV could have these lines in it:
/**
/** RESOLVER_CONFIG=/'SYS1.TCPPARMS(TCPDATA2)'
/** OMROUTE_FILE=/u/usernnn/config.tcpcs2
/** OMROUTE_DEBUG_FILE=/tmp/logs/omproute.debug
/** OMROUTE_IPV6_DEBUG_FILE=/tmp/logs/omprout6.debug
/** OMROUTE_DEBUG_FILE_CONTROL=1000,5
/**
/** For information on the above environment variables,
/** refer to the IP CONFIGURATION GUIDE.
/**
/** When using _CEE_ENVFILE with an MVS data set, the data set must
be allocated with RECFM=V. To use a RECFM=F data set, _CEE_ENVFILE_S
should be used to prevent the environment variable values from being padded
with blanks.
/**
/** If you want to include comments in the data set or
/** z/OS UNIX file, specify the _CEE_ENVFILE_COMMENT
/** environment variable as the first environment variable
/** in the data set or file. The value specified for the
/** _CEE_ENVFILE_COMMENT variable is the comment character.
/** For example, if you want to use the semicolon sign, ;,
/** as the comment character, specify this as the first
/** statement:
/** _CEE_ENVFILE_COMMENT=;
/**
/**STDENV DD PATH='/u/usernnn/envcs2',
/** PATHOPTS=(ORDONLY)
/**
/** The stdout stream may be redirected to a HFS file as
/** shown below.
/** The PATHOPTS OTRUNC option will clear the stdout file
/** every time OMROUTE is started. If you want to retain
/** previous stdout information, change it to OAPPEND.
/**
/**SYSPRINT DD SYSOUT=*
/**SYSPRINT DD PATH='/tmp/omproute.stdout',
/** PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
/** PATHMODE=(SIRUSR,SIWUSR,SIRGRP,SIWGRP)
/**
/** The stderr stream may be redirected to a HFS file as
/** shown below.
/** The PATHOPTS OTRUNC option will clear the stderr file
/** every time OMROUTE is started. If you want to retain
/** previous stderr information, change it to OAPPEND.
/**
/**SYSOUT DD SYSOUT=*
/**SYSOUT DD PATH='/tmp/omproute.stderr',
/** PATHOPTS=(OWRONLY,OCREAT,OTRUNC),
/** PATHMODE=(SIRUSR,SIWUSR,SIRGRP,SIWGRP)
/**
/**CEEDUMP DD SYSOUT=*,DCB=(RECFM=FB,LRECL=132,BLKSIZE=132)

```

5. Specify the RIP UDP port numbers in the SERVICES file or data set (if using the RIP or IPv6 RIP protocol).

The [services file](#) contains the relationship between services and port numbers as described in [z/OS Communications Server: IP Configuration Reference](#). The portion of the services file relevant to OMROUTE is:

|       |         |                 |
|-------|---------|-----------------|
| route | 520/udp | router omproute |
| route | 521/udp | ipv6rip ripng   |

The file must exist for the RIP and IPv6 RIP protocols of OMROUTE to operate.

For a description of the search order used to locate the services file, see [“Configuration files for TCP/IP applications” on page 25](#).

6. RACF authorize user IDs for starting OMROUTE.

To reduce risk of an unauthorized user starting OMPROUTE and affecting the contents of the routing table, users who start OMPROUTE must be RACF-authorized to the entity MVS.ROUTEGR.OMPROUTE. To RACF-authorize, the following commands must be entered from a RACF user ID, substituting the authorized user ID on the ID(userid) parameter. The commands in this example are taken from SEZAINST(EZARACF).

```
RDEFINE OPERCMDS (MVS.ROUTEGR.OMPROUTE) UACC(NONE)
PERMIT MVS.ROUTEGR.OMPROUTE ACCESS(CONTROL) CLASS(OPERCMDS) ID(userid)
SETROPTS RACLIST(OPERCMDS) REFRESH
```

**Rule:** The user ID specified for OMPROUTE must have read/write permission to the directories where OMPROUTE reads and writes files. To determine the files that OMPROUTE reads and writes, see [OMPROUTE environment variables in z/OS Communications Server: IP Configuration Reference](#).

7. Start syslogd.

To write only the urgent OMPROUTE messages to the z/OS console, syslogd should be running while OMPROUTE is running. Syslogd sends the non-urgent messages to the z/OS UNIX file system message log.

8. Update the OMPROUTE environment variables (optional).

The following environment variables are used by OMPROUTE and can be tailored to a particular installation:

**RESOLVER\_CONFIG**

The RESOLVER\_CONFIG variable is used by OMPROUTE to locate the resolver configuration file. For more information on OMPROUTE's use of the resolver configuration file, see step “3” on page 326. For more information about the RESOLVER\_CONFIG environment variable, see “[z/OS XL C/C++ environment variables for configuration files](#)” on page 801.

**OMPROUTE\_FILE**

The OMPROUTE\_FILE variable is used by OMPROUTE in the search order for the OMPROUTE configuration file. For details on the search order used for locating this configuration file, see step “1” on page 325.

**OMPROUTE\_DEBUG\_FILE**

The OMPROUTE\_DEBUG\_FILE variable is used by OMPROUTE to override the debug output destination for IPv4 dynamic routing protocols and for processing common to both IPv4 and IPv6 routing protocols.

**Tip:** When the OMPROUTE CTRACE with option DEBUGTRC (or option ALL) is active, debug output is written to CTRACE and not to the destination specified by this variable.

For more information on using this environment variable, see “[OMPROUTE parameters](#)” on page 330.

**OMPROUTE\_DEBUG\_FILE\_CONTROL**

The OMPROUTE\_DEBUG\_FILE\_CONTROL variable is used by OMPROUTE to control the size and quantity of trace files created when the OMPROUTE\_DEBUG\_FILE or OMPROUTE\_IPV6\_DEBUG\_FILE variable is specified. The syntax of this variable is:

```
OMPROUTE_DEBUG_FILE_CONTROL=<size of file>,<num of files>
```

The default values for <size of file> and <num of files> are 200 (KB) and 5 respectively. In general, these values are sufficient for most installations.

If OMPROUTE\_DEBUG\_FILE and OMPROUTE\_IPV6\_DEBUG\_FILE are both specified with different output destinations, the values specified on the OMPROUTE\_DEBUG\_FILE\_CONTROL variable will apply to both the IPv4 debug files and the IPv6 debug files. The total number of files created in this environment would be <num of files> multiplied by 2.

**OMPROUTE\_IPV6\_DEBUG\_FILE**

The OMPROUTE\_IPV6\_DEBUG\_FILE variable is used by OMPROUTE to override the debug output destination for IPv6 dynamic routing protocols.

**Tip:** When the OMPROUTE CTRACE with option DEBUGTRC (or option ALL) is active, debug output is written to CTRACE and not to the destination specified by this variable.

For more information on using this environment variable, see [“OMPROUTE parameters” on page 330](#).

#### **OMPROUTE\_CTRACE\_MEMBER**

The OMPROUTE\_CTRACE\_MEMBER variable is used by OMPROUTE to specify the name of the parmlib member containing CTRACE default settings. If not specified, the default value is CTIORA00. Use this environment variable to set different CTRACE options and buffer sizes for multiple OMPROUTE instances.

#### **9. Create static routes (optional).**

To create IPv4 or IPv6 static routes, use the BEGINROUTES statement in PROFILE.TCPIP. For information about the syntax of the [BEGINROUTES statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

During initialization, OMPROUTE learns of static routes by reading the internal routing table set up by TCP/IP. If static routes are changed during execution by VARY TCPIP,,OBEYFILE command processing, OMPROUTE is dynamically notified of the changes by TCP/IP. OMPROUTE will advertise active static routes to other routers if allowed by configuration (for example, the IMPORT\_STATIC\_ROUTES parameter of the AS\_BOUNDARY\_ROUTING or IPV6\_AS\_BOUNDARY\_ROUTING configuration statements).

Static routes can be defined as replaceable or nonreplaceable, with nonreplaceable being the default.

A nonreplaceable static route cannot be replaced or modified by OMPROUTE, even if a better dynamic route can be learned and even if the static route is not actually available (but a static route that is not available will not be advertised by OMPROUTE). Because of this, the use of nonreplaceable static routes with OMPROUTE is not recommended unless it is to provide routing over an interface over which no routing protocol is being communicated.

A replaceable static route will be replaced by OMPROUTE if it dynamically learns a route to the destination. Any dynamically learned route will be considered more desirable than a replaceable static route. A replaceable static route should be considered as a last resort route, to be used by TCP/IP when no dynamic route to a destination can be found.

For detailed information, see [“Use of static routing with OMPROUTE” on page 385](#).

#### **10. Configure OSPF authentication (optional, if using the IPv4 OSPF protocol).**

OMPROUTE supports defining the IPv4 OSPF authentication type by area or by interface. By default, all interfaces attached to an area use the type of authentication defined for that area on the AREA configuration statement, unless overridden on the OSPF\_INTERFACE configuration statement. The values of authentication keys must be defined on OSPF\_INTERFACE statements in any case. All routers which could become neighbors of each other must use the same authentication type and key, or OSPF communication between the routers will not be possible.

Virtual links behave similarly to interfaces for authentication purposes. By default, a virtual link uses the same type of authentication that is specified for the backbone area unless overridden on the VIRTUAL\_LINK configuration statement. When the authentication type is not NONE, the value of the authentication key must be specified on the VIRTUAL\_LINK configuration statement. There is no requirement for a virtual link to have the same authentication key value as its underlying real interface.

OSPF authentication does not protect the contents of an OSPF packet. These packets are not encrypted. However, it does provide verification that the packet is genuine.

**Tip:** Unlike IPv4 OSPF, IPv6 OSPF does not provide its own, protocol-layer authentication. It relies instead on authentication provided by IPv6 IPSec.

There are two methods of IPv4 OSPF authentication, password and MD5 cryptographic.

Password authentication is very basic: an 8-byte password is appended to all OSPF packets and sent in the clear with the rest of the packet. If the sent password matches that defined by the packet receiver, the packet is accepted.

MD5 authentication is more sophisticated. The combination of the OSPF packet and the MD5 key is summarized into a 16-byte message digest, which is appended to the packet and sent. The keys are never sent, only the message digests. The receiver then attempts to re-create the message digest from the combination of its defined key and the OSPF packet. If the digest is successfully re-created, the packet is accepted; otherwise it is rejected. MD5 authentication also contains a monotonic increasing counter to protect against replay attacks.

If MD5 cryptographic authentication is being used, a 16-byte MD5 key must be defined on the OSPF\_INTERFACE configuration statement. This key is defined as a hexadecimal string and may be obtained in several ways. One method for obtaining MD5 keys is provided in the pwtokey utility, which converts a password into an MD5 key. This UNIX System Services utility implements the algorithm defined in RFC 3414, *User-based Security Model (USM) for version 3 of the Simple Network Management Protocol (SNMPv3)*. Because OSPF does not support localization of keys, it is necessary only to provide a password to this utility to generate a single, 16-byte key. If multiple sites have this utility, MD5 keys can easily be generated from passwords, which are easier to remember and communicate than 16-byte hexadecimal strings.

## Starting and controlling OMPROUTE

After the necessary RACF authorization has been defined (see step “6” on page 327), OMPROUTE can be started from an MVS procedure, from the z/OS shell, or from AUTOLOG.

- You can start OMPROUTE from the MVS operators console by starting the OMPROUTE start procedure. A sample start procedure is provided with the product in SEZAINST(OMPROUTE).
- You can start OMPROUTE from the z/OS shell by starting OMVS and then issuing the OMPROUTE command and, optionally, any parameters. For information on parameters, see “[OMPROUTE parameters](#)” on page 330.
- You can use the AUTOLOG statement to start OMPROUTE automatically during TCP/IP initialization. Insert the name of the OMPROUTE start procedure in the AUTOLOG statement of the PROFILE.TCPIP data set.

```
AUTOLOG
OMPROUTE
ENDAUTOLOG
```

**Note:** For special considerations when using AUTOLOG to start OMPROUTE with the OSPF or IPv6 OSPF protocol, see step “2” on page 325.

In a Common INET environment, OMPROUTE will attempt to connect to a stack whose name is determined by the TCPIPjobname keyword from the resolver configuration data set or file. In configurations with multiple stacks, a copy of OMPROUTE must be started for each stack that requires OMPROUTE services. To associate OMPROUTE with a particular stack, use the environment variable RESOLVER\_CONFIG to point to the data set or file that defines the unique TCPIPjobname.

When running from an MVS procedure, the environment variables can be set by using the STDENV DD statement in the OMPROUTE procedure. For information concerning the environment variables used by OMPROUTE, see step “8” on page 328.

## OMPROUTE parameters

OMPROUTE accepts five command line parameters, which govern tracing and debug information. OMPROUTE's trace and debug information is written to stdout with three exceptions:

- When OMPROUTE is started with no tracing, and then a MODIFY command is issued to enable tracing. In this case, by default, the output destination is the file omproute\_debug in the current temporary directory (the default is /tmp).
- When the debug output destination has been overridden with the use of an environment variable (OMPROUTE\_DEBUG\_FILE or OMPROUTE\_IPV6\_DEBUG\_FILE).

**Rule:** OMPROUTE\_DEBUG\_FILE and OMPROUTE\_IPV6\_DEBUG\_FILE can specify only a z/OS UNIX file. To have debug information go into an MVS data set, instead of coding these environment variables, use the SYSPRINT DD card to redirect stdout to the wanted MVS data set.

- When the OMPROUTE CTRACE with option DEBUGTRC (or option ALL) is enabled. In this case, the output is sent to the CTRACE facility.

If OMPROUTE is to be started from an MVS procedure, add your parameters to PARM=() in the OMPROUTE cataloged procedure. For example:

```
//* PARM=('POSIX(ON) ',
//* 'ENVAR("_CEE_ENVFILE=DD:STDENV")') -t1 -6t1'
/*
```

If OMPROUTE is to be started from a z/OS shell command line, enter the parameters on the command line.

For either method of starting OMPROUTE, parameters can be specified in mixed case.

**Note:** The -tn, -dn, -6tn, -6dn, and -sn parameters affect OMPROUTE performance. If you use these parameters, you might need to increase the Dead\_Router\_Interval value on OSPF interfaces to prevent neighbor adjacencies from collapsing. If this becomes necessary, you will also need to modify other routers because the Dead\_Router\_Interval value must be the same for all routers attached to a common network.

## The -tn and -6tn command line parameters

The -tn parameter specifies the external tracing level for OMPROUTE initialization and IPv4 routing protocols, where *n* is a supported trace level. The -6tn parameter specifies the external tracing level for IPv6 routing protocols, where *n* is a supported trace level. The -tn and -6tn traces are intended for customers, testers, service, or developers, and provide information on the operation of the routing application. These options can be used for many purposes, such as debugging a configuration, education on the operation of the routing application, verification of test cases, and so on. The following levels are supported:

- 1  
Informational messages
- 2  
Formatted packet trace

These option levels are cumulative—level 2 includes level 1. For example, -t2 provides formatted packet trace and informational messages.

## The -dn, -6dn, and -sn command line parameters

These options specify the internal debugging levels. They are intended for service and provide internal debugging information needed for debugging problems. Use of these parameters can significantly impact performance and are not recommended unless needed to debug a problem. For more information about the use of these [parameters](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

## Controlling OMPROUTE

You can control OMPROUTE from the operator's console using the MODIFY command. The syntax of the MODIFY command for OMPROUTE can be found in [z/OS Communications Server: IP System Administrator's Commands](#). MODIFY commands are available to perform the following functions:

- [“Stopping OMPROUTE” on page 332](#)
- [“Rereading the configuration file” on page 332](#)
- [“Enabling or disabling the OMPROUTE subagent” on page 332](#)
- [“Changing the cost of OSPF links” on page 333](#)
- [“Controlling OMPROUTE tracing and debugging” on page 333](#)

## Stopping OMPROUTE

OMPROUTE can be stopped in several ways:

- From MVS, issue STOP <procname> or MODIFY <procname>,KILL.

If OMPROUTE was started from a cataloged procedure, *procname* is the member name of that procedure. If OMPROUTE was started from the z/OS shell, *procname* is based on the *userid*. If the *userid* is 8 characters long, the *procname* is the *userid*. If the *userid* is less than 8 characters long, the *procname* is *useridX*, where X is the sequence number set by the system. To determine the sequence number, from the SDSF LOG window on TSO, issue /D OMVS,U=*userid*. This will show the programs running under this user ID. The *procname* can also be set using the environment variable \_BPX\_JOBNAME and then starting OMPROUTE in the shell background.

- From a z/OS shell superuser ID, issue the kill command to the process ID (PID) associated with OMPROUTE. To determine the PID, use one of the following methods:
  - From the MVS console, issue D OMVS,U=*userid*, or issue /D OMVS,U=*userid* at the SDSF LOG window on TSO (where *userid* is the user ID that started omproute from the shell).
  - Issue the **ps -ef** command from the z/OS shell.
  - Record the PID when you start OMPROUTE.

For information on the environment variable [Commonly used environment variables](#), see [z/OS UNIX System Services Planning](#). For information on the [D OMVS,U=\*userid\*](#) command, see [z/OS MVS System Commands](#).

**Tip:** When OMPROUTE is taken down, it should be kept down for at least 3 times the largest dead router interval of any IPv4 OSPF interfaces using MD5 authentication. The same applies to routers adjacent to interfaces using MD5 authentication. Do not stop and start OMPROUTE without waiting for this required time interval.

## Rereading the configuration file

The MODIFY *procname*,RECONFIG command is used to reread the OMPROUTE configuration file. This command accepts and applies only statements of the following types that have been added to the configuration file since the last time the file was read:

- OSPF\_INTERFACE
- RIP\_INTERFACE
- INTERFACE
- IPV6\_OSPF\_INTERFACE
- IPV6\_OSPF (ROUTERID parameter only)
- IPV6\_RIP\_INTERFACE
- IPV6\_INTERFACE

These configuration statements must be reread from the configuration file using the MODIFY *procname*,RECONFIG command before the interfaces to which they refer are defined to the TCP/IP stack. If you have coded GLOBAL\_OPTIONS IGNORE\_UNDEFINED\_INTERFACES=YES in your OMPROUTE configuration file, you can use OMPROUTE reconfiguration to add a definition for an interface that has already been configured in the stack but ignored by OMPROUTE. However, OMPROUTE does not associate the interface with the new definition until the interface has been deleted from the stack and re-added.

**Restriction:** The IPV6\_OSPF statement (ROUTERID parameter only) is recognized by this command only if there is no existing IPv6 OSPF router ID value set in OMPROUTE. This command cannot be used to change the value of an existing IPv6 OSPF router ID.

## Enabling or disabling the OMPROUTE subagent

Use the MODIFY <procname>,ROUTESA=ENABLE command or the MODIFY <procname>,ROUTESA=DISABLE command to enable or disable the OMPROUTE subagent.

**Rule:** To change any other value on the ROUTESA\_CONFIG statement, the OMPROUTE application must be recycled.

The OMPROUTE subagent implements RFC 1850, *OSPF Version 2 Management Information Base*, for the OSPF protocol. The ROUTESA\_CONFIG statement is used in the OMPROUTE configuration file to configure the OMPROUTE subagent. For details on ROUTESA\_CONFIG, see [z/OS Communications Server: IP Configuration Reference](#).

## Changing the cost of OSPF links

The cost of an OSPF interface can be dynamically changed using the MODIFY <procname>,OSPF,WEIGHT,NAME=<if\_name>,COST=<cost> command. The cost of an IPv6 OSPF interface can be dynamically changed using the MODIFY <procname>,IPV6OSPF,WEIGHT,NAME=<if\_name>,COST=<cost> command. This new cost is flooded quickly throughout the OSPF routing domain, and modifies the routing immediately.

The cost of the interface reverts to its configured value whenever OMPROUTE is restarted. To make the cost change permanent, you must change the appropriate OSPF\_INTERFACE or IPV6\_OSPF\_INTERFACE statement in the configuration file.

## Controlling OMPROUTE tracing and debugging

The following commands are used to start, stop, or change the level of OMPROUTE tracing and debugging:

- MODIFY <procname>,TRACE=n : for OMPROUTE tracing for initialization and IPv4 routing protocols; n can be 0–2.
- MODIFY <procname>,DEBUG=n : for OMPROUTE debugging for initialization and IPv4 routing protocols; n can be 0–4.
- MODIFY <procname>,SADEBUG=n : for OMPROUTE subagent debugging; n can be 0 or 1.
- MODIFY <procname>,TRACE6=n : for OMPROUTE tracing for IPv6 routing protocols; n can be 0–2.
- MODIFY <procname>,DEBUG6=n : for OMPROUTE debugging for IPv6 routing protocols; n can be 0–4.

**Tip:** Use of OMPROUTE tracing and debugging affects OMPROUTE performance and might require increasing the Dead\_Router\_Interval on OSPF interfaces to keep neighbor adjacencies from collapsing.

## Steps for configuring OSPF and RIP (IPv4 and IPv6)

---

RIP uses a distance vector algorithm to calculate the best path to a destination based on the number of hops in the path. OSPF uses a link state or shortest path first algorithm.

### Before you begin

The following steps are the general steps to configure OSPF and RIP. Details follow the general steps.

1. Set the global configuration options.
2. Set the OSPF router ID, if the OSPF protocol is used.
3. Define OSPF areas, if the OSPF protocol is used.
4. Limit information exchange between OSPF areas, if the OSPF protocol is used.
5. Define IPv4 interfaces, if the IPv4 OSPF or IPv4 RIP protocol is used.
6. Define IPv6 interfaces, if the IPv6 OSPF or IPv6 RIP protocol is used.
7. Define interface costs (OSPF\_INTERFACE, RIP\_INTERFACE, IPV6\_OSPF\_INTERFACE, and IPV6\_RIP\_INTERFACE).
8. Configure virtual links, if the OSPF protocol is used.
9. Manage high-cost links, if the OSPF protocol is used.
10. Define RIP filters, if the RIP protocol is used.
11. Define route precedence in a multiprotocol environment, if the OSPF protocol is used.

If policy-based routing is used on the TCP/IP stack and the routing policy is configured with dynamic routing parameters, additional configuration to OMPROUTE is not needed for dynamic routing support to be provided for the policy-based route tables. The dynamic routing parameters that are specified in the routing policy are provided to OMPROUTE by the TCP/IP stack to control the scope of dynamic routes that are computed by OMPROUTE. For a description of this function, see [“Policy-based routing” on page 377](#).

## Procedure

Perform the following steps to configure OSPF and RIP (IPv4 and IPv6):

1. Set the global configuration options.

Use the GLOBAL\_OPTIONS statement to set the Ignore\_Undefined\_Interfaces parameter for OMPROUTE processing. Undefined interfaces are stack interfaces that are not configured by using OMPROUTE interface definitions, either explicit definitions or wildcard definitions. If you specify the value YES on the Ignore\_Undefined\_Interfaces parameter (Ignore\_Undefined\_Interfaces=YES), OMPROUTE does not configure undefined interfaces with default values. When Ignore\_Undefined\_Interfaces is set to the value NO, OMPROUTE configures undefined interfaces with default values that can override the stack definition values. The default value for Ignore\_Undefined\_Interfaces is NO.

**Tip:** Specify Ignore\_Undefined\_Interfaces=YES to ensure that undefined interfaces are not configured with default values that might affect network connectivity.

2. Set the OSPF router ID, if the OSPF protocol is used.

Every router in an OSPF autonomous system must be assigned a unique router ID.

- IPv4 OSPF

Code the ROUTERID parameter of the OSPF configuration statement within the OMPROUTE configuration file to assign the router ID. The value must be the IP address of one of the OSPF\_INTERFACES defined in the OMPROUTE configuration file. If the ROUTERID parameter of the OSPF configuration statement is not coded, OMPROUTE chooses the IP address from one of the OSPF\_INTERFACE statements as the router ID. Because dynamic VIPAs (DVIPAs) can move between z/OS hosts within a sysplex, the router ID should be the IP address of a physical interface or a static VIPA, but not a dynamic VIPA. For more information about the rules and guidelines for the ROUTERID parameter of the [OSPF statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

In the example network that is shown in [Figure 51 on page 310](#), the router ID is set to the static VIPA address that represents each OMPROUTE router. TCPCS4 has ROUTERID=4.4.4.4, and TCPCS7 has ROUTERID=7.7.7.7.

- IPv6 OSPF

The ROUTERID parameter of the IPV6\_OSPF configuration statement is coded within the OMPROUTE configuration file to assign the IPv6 OSPF router ID. This router ID is any IPv4-style dotted decimal value except for 0.0.0.0, with care taken to assure its uniqueness across routers within the IPv6 autonomous system. If the ROUTERID parameter of the IPV6\_OSPF configuration statement is not coded and the IPv4 OSPF protocol is also being used, OMPROUTE uses the IPv4 OSPF router ID as the IPv6 OSPF router ID. If the IPv4 OSPF protocol is not being used, the ROUTERID parameter of the IPV6\_OSPF statement must be specified. For more information about the rules and guidelines for the ROUTERID parameter of the [IPV6\\_OSPF statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

In the example network that is shown in [Figure 52 on page 311](#), the ROUTERID parameter of the IPV6\_OSPF statement on TCPCS64 is to be explicitly configured by using ROUTERID=64.64.64.64.

3. Define OSPF areas, if the OSPF protocol is used.

The sample network that is shown in [Figure 51 on page 310](#) and [Figure 52 on page 311](#) depicts an IPv4 network and an IPv6 network, both divided by using two methods. The first division is between IP subnetworks within the OSPF autonomous system (AS) and IP subnetworks external to the OSPF AS (within the RIP AS). The subnetworks included within each OSPF AS are further subdivided into regions called areas. OSPF areas are collections of contiguous IP subnetworks. The function of areas

is to reduce the OSPF overhead that is required to compute routes to destinations in different areas. Overhead is reduced because less information is exchanged and stored by routers and because fewer processor cycles are required for a less complex route table calculation.

Every OSPF AS with multiple areas must have at least a backbone area. The backbone is always identified by area number 0.0.0.0. For networks with multiple areas, the backbone provides a core that connects the areas. Unlike other areas, the backbone subnets can be physically separate. In this case, logical connectivity of the backbone is maintained by configuring virtual links between backbone routers across intervening non-backbone areas. For more information, see step “8” on page 348.

Routers that attach to more than one area function as area border routers. All area border routers are part of the backbone, so they must either attach directly to a backbone IP subnet or be connected to another backbone router over a virtual link.

The information and algorithms that are used by OSPF to calculate routes vary according to whether the destination is within the same area, in a different area within the OSPF AS, or external to the OSPF AS. Every router maintains a database of all links within its area. A shortest path first algorithm is used to calculate the best routes to destinations within the area from this database. Routes between areas are calculated from summary advertisements that are originated by area border routers for destinations that are located in other areas of the OSPF AS. External routes (for example, routes to destinations that lie within a RIP AS) are calculated from AS external advertisements that are originated by AS boundary routers and flooded throughout the OSPF AS.

- IPv4 OSPF

Use the AREA configuration statement to define the areas to which a router attaches. If you do not use the AREA statement, the default is that all OSPF interfaces attach to the backbone area. In the sample network, TCPCS4 and TCPCS7 are both area border routers that belong to both the backbone area (0.0.0.0) and area 1.1.1.1.

```
AREA
 Area_Number=0.0.0.0;

AREA
 Area_Number=1.1.1.1;
```

- IPv6 OSPF

Use the IPV6\_AREA configuration statement to define the areas to which a router attaches. If you do not use the IPV6\_AREA statement, the default is that all IPv6 OSPF interfaces attach to the backbone area. In the sample network, TCPCS64 and TCPCS67 are area border routers that belong to both the backbone area (0.0.0.0) and area 6.6.6.6.

```
IPV6_AREA
 Area_Number=0.0.0.0;
IPV6_AREA
 Area_Number=6.6.6.6;
```

#### 4. Limit information exchange between OSPF areas, if the OSPF protocol is used.

When area border routers are configured, the OSPF route information that crosses the area boundary can be controlled with configuration statements. For information about the usefulness of multiple areas in the z/OS CS environment, see [“Minimizing the routing responsibility of z/OS Communications Server” on page 352.](#)

One option is to define an area as a stub area. AS external advertisements are never flooded into stub areas. In addition, the origination into the stub area of summary advertisements for interarea routes can be suppressed, creating what is commonly known as a *totally stubby* area.

Destinations external to the stub area are still reachable since the area border routers advertise default routes into stub areas. Traffic within the stub area for unknown destinations is forwarded to the area border router (by using the default route). It is acceptable for routers within the area to use a default route for traffic that is destined outside the AS. The border router uses its more complete routing information to forward the traffic on an appropriate path toward its destination.

The following requirements must be met for an area to be defined as a stub area:

- No virtual links are configured through the area to maintain backbone connectivity.
- No routers within the area are AS boundary routers (OSPF routers that advertise routes from external sources as AS external advertisements).

**Tip:** Static routes and RIP routes are AS external.

Another option is to use IP address ranges to limit the number of summary advertisements that are originated out of an area. In IPv4, a range is defined by an IP address and an address mask. Destinations are considered to fall within the range when the destination address and the range IP address match after the range mask is applied to both addresses. In IPv6, a range is defined by an IP address prefix and a prefix length, and destinations are considered to fall within the range if a destination address and a range IP address match for the length of the range prefix.

When a range is configured for an area at an area border router, the border router suppresses summary advertisements for destinations within that area that fall within the range. The suppressed advertisements would have been originated into the other areas to which the border router attaches. Instead, the area border router originates a single summary advertisement for the range or no advertisement at all, depending on the option that is chosen with the configuration statement.

**Rules:**

- a. If the range is not advertised, there will be no interarea routes for any destination that falls within the range.
  - b. Ranges cannot be used for areas through which virtual links are configured to maintain backbone connectivity.
- IPv4 OSPF

The following statement configures an OSPF area as a stub area. The `Import_Summaries=No` parameter results in the suppression of summary advertisements for interarea routes into the stub area, creating a totally stubby area:

```
AREA
 Area_Number=2.2.2.2
 Stub_area=Yes
 Import_Summaries=No;
```

In the sample network that is shown in [Figure 51 on page 310](#), the following `RANGE` statement could be configured on TCPCS7 to prevent TCPCS7 from advertising destinations in the 9.67.101.0 subnet into the backbone area (Area 0.0.0.0):

```
RANGE
 IP_Address=9.67.101.0
 Subnet_Mask=255.255.255.0
 Area_Number=1.1.1.1
 Advertise=No;
```

- IPv6 OSPF

The following statement configures an IPv6 OSPF area as a stub area. The `Import_Summaries=No` parameter results in the suppression of summary advertisements for interarea routes into the stub area, creating a totally stubby area:

```
IPV6_AREA
 Area_Number=1.1.1.1
 Stub_area=Yes
 Import_Prefixes=No;
```

In the sample network, the following IPV6\_RANGE statement could be configured on TCPCS67 to cause TCPCS67 to advertise all destinations in the 2001:0DB8:0:31::/64 prefix into the backbone area (Area 0.0.0.0) as a single route to the 2001:0DB8:0:31::/64 prefix:

```
IPV6_RANGE
 Prefix=2001:0DB8:0:31::/64
 Area_Number=6.6.6.6
 Advertise=Yes;
```

5. Define IPv4 interfaces, if the IPv4 OSPF or IPv4 RIP protocol is used.

Define each interface in use by the stack to OMPROUTE by using an OSPF\_INTERFACE, RIP\_INTERFACE, or INTERFACE statement. This topic describes the differences between interface types for your consideration when you are configuring interfaces to OMPROUTE. In general, use the following guidelines:

- An interface over which the OSPF protocol is communicated with other routers must be configured with the OSPF\_INTERFACE statement.
- An interface over which the RIP protocol is communicated with other routers must be configured with the RIP\_INTERFACE statement.
- Either configure all other interfaces with the INTERFACE statement, or configure OMPROUTE to ignore undefined interfaces by using the IGNORE\_UNDEFINED\_INTERFACES parameter of the GLOBAL\_OPTIONS statement in the OMPROUTE configuration file. It is important that one or the other is done.

If OMPROUTE is not configured to ignore undefined interfaces, it configures stack interfaces that are not defined to OMPROUTE with default values. These values might not be desirable. For example, the class mask is used as the subnet mask and 576 is used as the MTU value. Furthermore, OMPROUTE overrides stack values with its default values. To prevent this situation from happening, either configure every interface, even those interfaces that are not using RIP or OSPF, or configure OMPROUTE to ignore undefined interfaces.

A VIPA interface is an exception to these guidelines and is described in more detail in this step.

z/OS Communications Server enforces RFC rules against using either a subnetwork broadcast or network address as a host address. (An address that has all ones in the host portion is a subnet broadcast address. An address that has all zeros in the host portion is the subnet network address.) Therefore, the subnet\_mask on an OSPF\_INTERFACE, RIP\_INTERFACE, or INTERFACE statement should have enough zero bits such that no home address in that subnet has all zeros or all ones in the host portion of the address. For example, if a subnet has two home addresses 10.1.1.1 and 10.1.1.2, the subnet mask must have zeros in at least 2 bits; for example, 255.255.255.252. However, if a subnet has four home addresses 10.1.1.1, 10.1.1.2, 10.1.1.3, and 10.1.1.4, the subnet mask must have zeros in at least 3 bits; for example, 255.255.255.248. In this case, there can be up to six home addresses in that subnet (10.1.1.1 through 10.1.1.6). In general, if a subnet mask has  $n$  zero bits, then there can be up to  $((2^n)-2)$  home addresses in that subnet. This limit applies even if the home addresses are configured on different TCP/IP stacks.

**Rules:**

- a. OMPROUTE supports a maximum of 255 real, physical, IPv4 interfaces (that is, interfaces on which data can actually be sent and received). There is no theoretical limit on how many VIPAs can be configured, though there are practical limits that are imposed by network design.
- b. RIP version 1 uses broadcast and RIP version 2 uses multicast. RIP version 1 cannot run on a medium that supports multicast but not broadcast, which is the default OSA configuration. To configure an OSA feature to send and receive broadcast packets, use the IPBCAST parameter on the INTERFACE statement in your TCP/IP profile.

• Configuring multi-access parallel interfaces

Whenever configuring multi-access parallel interfaces (primary and backup redundant interfaces with IP addresses in the same network) for OMPROUTE (OSPF), use the Parallel\_OSPF parameter on the OSPF\_INTERFACE statement to designate whether each OSPF interface is primary or

backup. If the IP\_address parameter on an OSPF\_INTERFACE statement is using wildcards (\*), also include the Name parameter for the interface to distinguish the primary from the backups. For more information about the `OSPF_INTERFACE` statement and its parameters, see [z/OS Communications Server: IP Configuration Reference](#).

- Point-to-point (For example, CTC)

For point-to-point interfaces, the destination IP address must be known to OMROUTE. If OSPF or RIP is run on the interface, the destination IP address is learned when the router at the other end comes up and shares information with OMROUTE. Additionally, defining a destination address on an interface that is running OSPF or RIP allows OMROUTE to learn and advertise a route to that destination address before a neighboring router becomes fully adjacent. This can be beneficial if the neighboring router takes a long time to come up, or is otherwise not expected to be promptly and reliably available.

**Tip:** For a point-to-point interface that is running OSPF, OMROUTE does not advertise a host route to its own home address on the point-to-point interface. By default, OMROUTE advertises a host route to the link destination, and relies on the router at the other end to advertise a host route to the OMROUTE home address. This behavior is described by the OSPF architecture, RFC 1583 (OSPF version 2), section 12.4.1. This means that the OMROUTE home address on the point-to-point link cannot be advertised as reachable unless there is a neighboring router available to advertise it. OMROUTE implements an extension that is described in RFC 2328 to overcome this limitation. If a neighboring router will not be reliably available over the point-to-point link, you might want to code the parameter `SUBNET=YES` on the `OSPF_INTERFACE` statement for the point-to-point interface. This parameter causes OMROUTE to implement option 2 described in RFC 2328, section 12.4.1.1, and advertise a route to the point-to-point link subnet address, which makes both endpoints reachable regardless of the status of a neighboring router.

If the interface is only an `INTERFACE` (not running OSPF or RIP), specify the `DESTINATION_ADDR` parameter to allow for the creation of a host route to the address at the remote end of the interface.

Sample `OSPF_INTERFACE`:

```
OSPF_INTERFACE
 IP_Address=9.67.106.7
 Name=CTC7T04
 Subnet_mask=255.255.255.0
 Attaches_to_Area=1.1.1.1
 Destination_Addr=9.67.106.4;
```

Sample `RIP_INTERFACE`:

```
RIP_INTERFACE
 IP_Address=9.67.103.7
 Name= CTC7T06
 Subnet_mask=255.255.255.0
 Destination_Addr=9.67.103.6
 RIPV2=Yes;
```

### Sample INTERFACE:

```
INTERFACE
 IP_Address=9.67.111.1
 Name=CTCX
 Subnet_mask=255.255.255.0
 Destination_addr=9.67.111.2;
```

- Point-to-multipoint

For point-to-multipoint capable interfaces (for example MPCPTP interfaces including XCF and IUTSAMEH connections), OMPROUTE must know the IP addresses of the other routers (neighbors) with which it must communicate the OSPF or RIP packets. However, because of underlying signaling that takes place when a host connects to these network types, the stack is able to learn the required addresses. In turn, OMPROUTE learns those IP addresses from the stack. As a result, it is not necessary to configure the IP addresses of the other routers on the interface statements.

### Sample OSPF\_INTERFACE:

```
OSPF_INTERFACE
 IP_Address=9.27.13.81
 Name=XCFD00
 Attaches_to_Area=1.1.1.1
 Subnet_mask=255.255.255.0;
```

### Sample RIP\_INTERFACE:

```
RIP_INTERFACE
 IP_Address=9.27.23.81
 Name=MPCA01
 Subnet_mask=255.255.255.0
 RIPV2=Yes;
```

### Sample INTERFACE:

```
INTERFACE
 IP_Address=9.27.33.81
 Name=XCFB00
 Subnet_mask=255.255.255.0;
```

- Broadcast network interfaces (For example, Ethernet)

When the OSPF or RIP protocol is communicated over a broadcast medium such as Ethernet, these networks allow for broadcasting and multicasting. Therefore, it is not necessary for OMPROUTE to know the IP addresses of the other routers on the network for OSPF or RIP packets to be communicated with those routers. OMPROUTE sends packets to the other routers on the network by using appropriate broadcast or multicast addresses. The IP addresses of the other routers are learned as OSPF/RIP packets are received from them. The OSPF\_INTERFACE must include the ROUTER\_PRIORITY parameter to help elect a designated router for the network.

### Sample OSPF\_INTERFACE:

```
OSPF_INTERFACE
 IP_Address=9.59.101.5
 Name=ETH1
 Subnet_mask=255.255.255.0
 Attaches_to_Area=1.1.1.1
 Cost0=2
 Router_Priority=1;
```

#### Sample RIP\_INTERFACE:

```
RIP_INTERFACE
 IP_Address=9.29.107.3
 Name=ETH2
 Subnet_mask=255.255.255.0
 RIPV2=Yes;
```

#### Sample INTERFACE:

```
INTERFACE
 IP_Address=9.77.14.49
 Name=ETHB00
 Subnet_mask=255.255.255.0;
```

For interfaces into broadcast media which contain routers that do not support multicast, it is possible to configure the interfaces as non-broadcast network interfaces, which would cause OMPROUTE to unicast to the neighbor addresses rather than using a multicast address. However, it would also be necessary to configure all the routers on the network to unicast. Otherwise, their multicast packets would never be received.

Note that it is possible to define neighbors by using DR\_NEIGHBOR and/or NO\_DR\_NEIGHBOR parameters for OSPF\_INTERFACES and by using NEIGHBOR parameters for RIP\_INTERFACES that are broadcast capable, but it is not required or advised. If you define neighbors on these interfaces, you must define all of them, as OMPROUTE does not communicate RIP or OSPF to undefined neighbors if any are defined on an interface.

- VIPA interfaces (Static VIPA and Dynamic VIPA)

If only the RIP protocol is used by OMPROUTE, define VIPA interfaces with the INTERFACE statement. If only OSPF or if both OSPF and RIP are used by OMPROUTE, define VIPA interfaces with the OSPF\_INTERFACE statement.

#### Sample OSPF\_INTERFACE:

##### OSPF example:

```
OSPF_INTERFACE
 IP_Address=4.4.4.4
 Name=VIPA1
 Subnet_mask=255.255.255.252;
```

#### Sample INTERFACE:

##### non-OSPF example:

```
INTERFACE
 IP_Address=6.6.6.6
 Name=VIPA1
 Subnet_mask=255.255.255.252;
```

**Rule:** The most specific subnet mask you can specify is 255.255.255.252.

If the name in an OSPF\_INTERFACE or INTERFACE statement refers to a link of type VIRTUAL, then OMPROUTE generates and advertises the following routes whenever applicable:

- A network route to the network specified in that statement
- A subnet route to the subnet specified in that statement
- A host route to the IP\_address specified in that statement

The following conditions apply for advertising these routes on a physical network interface to a network:

- Network route - if VIPA is not in the same network as the physical network interface and is allowed by filters or RANGE.

- Subnet route - VIPA subnet routes are advertised in OMPROUTE in all conditions, except for RIP when filters prevent it.
- Host route - as allowed by filters or RANGE. Advertisement of the host route for a VIPA defined on an OSPF\_INTERFACE statement can be controlled by the SUBNET parameter on the OSPF\_INTERFACE statement that defines that VIPA. If SUBNET=YES, then the host route is not advertised. If SUBNET=NO (the default), the host route is advertised. Take care in using this parameter. Do not suppress VIPA host routes for dynamic VIPAs or for VIPAs whose subnet might exist on multiple hosts. It is up to the user to ensure that these restrictions are enforced, as they are not and cannot be enforced by OMPROUTE.

On the RIP\_INTERFACE statement for a physical network interface, the VIPA routes are allowed to be advertised by the following filter parameters:

- Send\_Net\_Routes
- Send\_Subnet\_Routes
- Send\_Host\_Routes, and Send\_Only

In addition, the global FILTER and Send\_Only statements for RIP can be used to specify which routes are advertised or not.

For OSPF, the RANGE statement can be used to advertise or not to advertise the VIPA routes external to an area in terms of address range based on a subnet mask.

**Note:** For RIP, the Send\_Only = (VIRTUAL) filter with the Send\_Net\_Routes, Send\_Subnet\_Routes, and Send\_Host\_Routes filters, or the FILTER statement with VIPA routes, indicates whether VIPA routes can be advertised over a RIP interface. Unlike RIP, there are no routing filters for OSPF. For OSPF, the RANGE statement can be used to control which address range of routes can be advertised or not advertised external to an area; however, it is not granular enough for use as a routing filter. In area-border router configurations, if there are multiple VIPA addresses that are uniquely subnetted, the RANGE statement can be used to specify which VIPA subnet address range of routes can be advertised or not advertised external to an area.

For Dynamic VIPA (DVIPA), link names are assigned programmatically by the stack when the DVIPA is created. Therefore, the name field that is set on the INTERFACE or OSPF\_INTERFACE statement is ignored by OMPROUTE for DVIPAs.

Because a stack can have many DVIPAs defined, and DVIPA ranges, more wildcard capabilities exist on the OSPF\_INTERFACE and INTERFACE statements for use only with DVIPAs.

Ranges of DVIPA interfaces can be defined by using the Subnet\_Mask parameter on the OSPF\_INTERFACE or INTERFACE statement. The range that is defined in this way includes all the IP addresses that fall within the subnet that is defined by the mask and the IP address. The IP address parameter must be the subnet number of the range that is being defined, not a host address within that range. Further information about the Subnet\_Mask parameter is available earlier in this step.

In the following example, DVIPA interfaces in the range of 10.138.65.81 through 10.138.65.94 are defined:

Sample OSPF\_INTERFACE:

OSPF example:

```
OSPF_INTERFACE
IP_Address=10.138.65.80
Name=DVIPAs
Subnet_mask=255.255.255.240;
```

Sample INTERFACE:

non-OSPF example:

```
INTERFACE
IP_Address=10.138.65.80
```

```
Name=DVIPAs
Subnet_mask=255.255.255.240;
```

In the following example, only an interface with home address 10.138.65.98 is being defined, because the subnet number (obtained by using a binary file AND operation of the IP\_Address parameter and the Subnet\_mask parameter) for this definition is 10.138.65.96. Because the IP\_Address parameter does not equal that subnet number, this definition cannot be treated as a DVIPA wildcard.

```
OSPF_INTERFACE
IP_Address=10.138.65.98
Name=DVIPA
Subnet_mask = 255.255.255.240;
```

In the following example, DVIPAs with IP addresses 10.138.120.x and 10.138.121.x with a 24-bit mask (255.255.255.0) result in two subnets 10.138.120.0/24 and 10.138.121.0/24. The 10.138.120.0/24 subnet ranges from 10.138.120.1 through 10.138.120.254 and the 10.138.121.0/24 subnet ranges from 10.138.121.1 through 10.138.121.254. Two OSPF\_INTERFACE statements with the extended wildcard capabilities are defined.

```
OSPF_INTERFACE
IP_Address=10.138.120.0
Name=DVIPAs
Subnet_mask=255.255.255.0;
IP_Address=10.138.121.0
Name=DVIPAs
Subnet_mask=255.255.255.0;
```

In the following example, DVIPAs with IP addresses 10.138.120.x and 10.138.121.x with a 23-bit mask (255.255.254.0) result in a collapsed subnet 10.138.120.0/23. The 10.138.120.0/23 subnet ranges from 10.138.120.1 through 10.138.121.254.

```
OSPF_INTERFACE
IP_Address=10.138.120.0
Name=DVIPAs
Subnet_mask=255.255.254.0;
```

#### Notes:

- If the conventional wildcard IP\_Address=10.138.120.\* is coded, OMPROUTE does not match the 10.138.121.x addresses for the DVIPAs because the subnet mask is not taken into account. Therefore, these DVIPAs might not be added to the OSPF domain.
- If DVIPAs across multiple networks are collapsed into one supernet, the same principle with the mask applies to the extended wildcard capability. For example, a supernet address 192.168.100.0 with a 23-bit mask (255.255.254.0) covers the range 192.168.100.1 through 192.168.101.254.

You must consider an additional issue when VIPAs are being moved between TCP/IP stacks and dynamic routing is provided for those stacks by OMPROUTE. This movement of VIPAs can be done manually or automatically with Dynamic VIPAs. For the VIPAs to be correctly processed and advertised by the routing protocols, they (like all other interfaces) must be configured to OMPROUTE at the time that they become active on the TCP/IP stack. This configuration of VIPAs to OMPROUTE can be accomplished by:

- Explicitly configuring each VIPA with its own OSPF\_INTERFACE or INTERFACE statement
- Configuring a range of DVIPAs with a single OSPF\_INTERFACE or INTERFACE statement
- Configuring a group of VIPAs with a single OSPF\_INTERFACE or INTERFACE statement, by using the wildcard feature available on the interface statements

The advised approach for configuring OMPROUTE for VIPAs that might move is to preconfigure the OMPROUTE on each TCP/IP stack with all VIPAs that can potentially exist on that stack at some time. Preconfiguring in this way prepares each OMPROUTE for the possible addition of the

VIPAs to its stack. During times when the VIPAs do not exist on a particular OMPROUTE stack, the configuration information will not be used. However, during periods when the VIPAs do exist on that OMPROUTE stack, the configuration information is available for use by OMPROUTE. This method is advised because of its ability to respond to movement of the VIPAs between TCP/IP stacks without modification of the OMPROUTE configuration with each move.

If the pre-configuration of VIPAs described in this topic is not done, it is still possible to define a VIPA to OMPROUTE such that it is properly processed and advertised when it becomes active on the corresponding TCP/IP stack. To do this configuration, add the appropriate OSPF\_INTERFACE or INTERFACE statement to the OMPROUTE configuration file and then cause OMPROUTE to reread the configuration file by issuing the MODIFY *procname*,RECONFIG command.

**Rule:** If you did not code GLOBAL\_OPTIONS IGNORE\_UNDEFINED\_INTERFACES=YES in your OMPROUTE configuration file, you must modify the OMPROUTE configuration file and issue the RECONFIG command before the first time that the VIPA moves to the corresponding TCP/IP stack.

**Guideline:**

If you did code GLOBAL\_OPTIONS IGNORE\_UNDEFINED\_INTERFACES=YES in your OMPROUTE configuration file, you can use OMPROUTE reconfiguration to add a definition for a VIPA interface that is or was active in the stack but ignored by OMPROUTE.

However, OMPROUTE does not associate the VIPA with the new definition until the interface is deleted from the stack and readded, either by DVIPA movement or by some other method.

Method of assigning interface definitions to stack interfaces (wildcard and explicit):

Wildcard interface definitions can be a convenient way of making your interface definitions easier. However, to avoid unintended results, be sure to understand how they are parsed, and how different types of interface definitions interact with each other. The following outline shows the algorithm that OMPROUTE uses to find the matching definitions in the OMPROUTE configuration file for an IPv4 stack interface.

a. Search for a RIP\_Interface definition for the interface as follows:

- i) Search for an explicit matching RIP\_Interface definition (IP address matches exactly if a dynamic VIPA, otherwise name and IP address match exactly). If found, use that definition and go to step b.
- ii) If the interface is a dynamic VIPA, search for a RIP\_Interface definition that matches as a dynamic VIPA wildcard. A matching dynamic VIPA wildcard definition is one where the definition IP address matches the value that is obtained by ANDing the definition subnet mask with the interface home address. The definition name parameter is ignored during a search for a dynamic VIPA wildcard definition. If a matching dynamic VIPA wildcard definition is found, use that definition and go to step b.
- iii) Search for a one-octet wildcard RIP\_Interface definition (n.n.n.\*), where the first three octets match the first three octets of the interface home address and the name matches the interface link name. If found, use that definition and go to step b.
- iv) Search for a two-octet wildcard RIP\_Interface definition (n.n.\*\*), where the first two octets match the first two octets of the interface home address and the name matches the interface link name. If found, use that definition and go to step b.
- v) Search for a three-octet wildcard RIP\_Interface definition (n.\*\*\*), where the first octet matches the first octet of the interface home address and the name matches the interface link name. If found, use that definition and go to step b.
- vi) Search for a one-octet wildcard RIP\_Interface definition (n.n.n.\*), where the first three octets match the first three octets of the interface home address, ignoring the name parameter when coded. If found, use that definition and go to step b.
- vii) Search for a two-octet wildcard RIP\_Interface definition (n.n.\*\*), where the first two octets match the first two octets of the interface home address, ignoring the name parameter when coded. If found, use that definition and go to step b.

- viii) Search for a three-octet wildcard RIP\_Interface definition (n.\*\*\*), where the first octet matches the first octet of the interface home address, ignoring the name parameter when coded. If found, use that definition and go to step b.
- ix) If there is a four-octet wildcard RIP\_Interface definition (\*\*\*\* or ALL), use that definition and go to step b.

**Restriction:** Only 1 four-octet wildcard of each type (OSPF\_INTERFACE or RIP\_INTERFACE) is allowed.

- b. Search for an OSPF\_Interface definition for the interface. This step is done regardless of the outcome of step a. The steps for searching OSPF\_Interface definitions are the same as the steps for searching RIP\_Interface definitions, except that OSPF\_Interface definitions are searched.
- c. If either a RIP\_Interface or an OSPF\_Interface definition, or both, are found, the algorithm is complete. In this case, Interface definitions are not searched. If neither a RIP\_Interface or an OSPF\_Interface definition was found, go to step d.
- d. Search for an Interface definition for the interface. The steps for searching Interface definitions are the same as the steps for searching RIP\_Interface statements, except that Interface definitions are searched.
- e. If no definitions are found, check the value of Global\_Options Ignore\_Undefined\_Interfaces. If this option is turned on, the interface is ignored. If it is not turned on, the interface is treated as if it were defined with an Interface statement, with an MTU value of 576 and a subnet mask of the class mask.

The algorithm is complete. Key conclusions of this algorithm are as follows:

- A wildcard interface definition with a matching name is preferred over a wildcard interface definition of the same type without a matching name, regardless of which definition is a more specific wildcard.
  - If the interface is not a dynamic VIPA, the subnet mask that is coded on the definition statement has no influence on which definition, wildcard or otherwise, is selected for an interface. The subnet mask is a characteristic of the definition, not a selection criterion.
  - If a RIP\_Interface or an OSPF\_Interface definition, or both, are found, Interface definitions are not considered. This means that any matching RIP\_Interface or OSPF\_Interface definition supersedes all Interface definitions, even if the Interface definitions are explicit or are more specific wildcard matches. For example, a three-octet wildcard OSPF\_Interface definition supersedes an explicit Interface definition.
  - An interface can be both a RIP\_Interface and an OSPF\_Interface. OMPROUTE supports running both protocols over the same interface. However, an interface cannot be both an interface that runs no routing protocol (that is, defined with the Interface statement) and one that runs RIP, OSPF, or both.
6. Define IPv6 interfaces, if the IPv6 OSPF or IPv6 RIP protocol is used.

Each IPv6 interface in use by the stack can be defined to OMPROUTE by using an IPV6\_OSPF\_INTERFACE, IPV6\_RIP\_INTERFACE, or IPV6\_INTERFACE statement. Defining IPv6 interfaces to OMPROUTE is much simpler than defining IPv4 interfaces because you do not specify IP addresses or MTU sizes to OMPROUTE. Instead, you define interfaces by their names and OMPROUTE learns IP addresses and MTU sizes from the TCP/IP stack. Also, because multicast support is a basic requirement of IPv6, there are no non-broadcast multiaccess considerations or other considerations that might require definitions of neighbors or destination addresses.

Use the following guidelines when you are configuring IPv6 interfaces to OMPROUTE:

- An interface over which the IPv6 OSPF protocol is communicated with other routers must be configured with the IPV6\_OSPF\_INTERFACE statement.
- An interface over which the IPv6 RIP protocol is communicated with other routers must be configured with the IPV6\_RIP\_INTERFACE statement.

- All other interfaces can be configured with the IPV6\_INTERFACE statement when OMPROUTE default values are not acceptable or you want to define more prefixes on the interface.
- The interface name must be coded on the IPV6\_INTERFACE, IPV6\_OSPF\_INTERFACE, and IPV6\_RIP\_INTERFACE statements. The value of the NAME parameter must match the interface name that is coded on the INTERFACE statement in the TCP/IP profile. Wildcard names that end with an asterisk (\*) can be coded. For example, OSAQDIO\* would match stack interfaces named OSAQDIO1, OSAQDIO2, OSAQDIOABC, and so on.

If the interface is dynamically generated by the TCP/IP stack, its name parameter must match what is generated by the TCP/IP stack. Interfaces that are dynamically generated by the TCP/IP stack are named as follows:

- An IPv6 dynamic XCF interface that is generated to attach to other TCP/IP stacks within the same z/OS host is always named EZ6SAMEMVS.
- An IPv6 dynamic XCF interface that is generated to attach to TCP/IP stacks in another z/OS image is always named EZ6XCFxx, where xx is the SYSCONE value of the other z/OS host.

If the routing parameters for your dynamic XCF interfaces are all to be the same, you can use wildcard definitions to avoid having to know and build definitions for every possible dynamic XCF interface on your system. For example, a wildcard definition for name EZ6\* would match all dynamic XCF interfaces that can be generated on a TCP/IP stack. A wildcard definition for EZ6XCF\* would match all dynamic XCF interfaces that can be generated to attach to other z/OS images.

The following definition would define all IPv6 dynamic XCF interfaces to OMPROUTE, with the hello and dead router intervals changed from the default values:

```
IPV6_OSPF_INTERFACE
 NAME=EZ6*
 HELLO_INTERVAL = 30
 DEAD_ROUTER_INTERVAL = 120;
```

If the default values of 10 and 40 for the hello and dead router intervals are acceptable, this definition can be simplified even more:

```
IPV6_OSPF_INTERFACE
 NAME=EZ6*;
```

- To define one or more prefixes on an interface, use the PREFIX parameter on the IPV6\_OSPF\_INTERFACE, IPV6\_RIP\_INTERFACE, and IPV6\_INTERFACE statements. You must use the PREFIX parameter only for prefixes that you must define to an interface, which cannot be learned using IPv6 router discovery. Also note that prefixes defined to OMPROUTE in this manner are not used by TCP/IP to autoconfigure home addresses on the interface.

The following sample shows an IPv6 OSPF interface with prefixes defined:

```
IPV6_OSPF_INTERFACE
 NAME=OSAQDIO4L6
 PREFIX=2001:0DB8:1::/48
 PREFIX=2001:0DB8:2::/48;
```

The prefixes defined in this manner on an IPv6 OSPF interface are advertised as reachable, and are also included in the link LSA generated by OMPROUTE, so all IPv6 OSPF routers on the link will know they are local prefixes. If OMPROUTE is also running IPv6 RIP, they are also advertised into the IPv6 RIP autonomous system as reachable, if IPv6 RIP filters permit it.

The following sample shows an IPv6 RIP interface with prefixes defined:

```
IPV6_RIP_INTERFACE
 NAME=OSAQDIO3L6
 PREFIX=2001:0DB8:3::/48
 PREFIX=2001:0DB8:4::/48;
```

The prefixes defined in this manner on an IPv6 RIP interface are advertised into the IPv6 RIP autonomous system as reachable if IPv6 RIP filters permit it. They are also advertised into the IPv6

OSPF autonomous system as reachable, if OMPROUTE is running IPv6 OSPF and is configured as an IPv6 AS boundary router importing RIP routes.

The following sample shows an IPv6 generic interface with prefixes defined:

```
IPv6_INTERFACE
 NAME=OSAQDIO2L6
 PREFIX=2001:0DB8:5::/48
 PREFIX=2001:0DB8:6::/48;
```

The prefixes defined in this manner on an IPv6 generic interface are advertised into the RIP autonomous system as reachable, if OMPROUTE is running IPv6 RIP and IPv6 RIP filters permit it. They are also advertised into the IPv6 OSPF autonomous system as reachable, if OMPROUTE is running IPv6 OSPF and is configured as an IPv6 AS boundary router importing direct routes.

Method of assigning interface definitions to stack interfaces (wildcard and explicit):

For IPv6 interfaces, interface-name wildcards can be used to simplify definitions. However, be sure to understand how they are parsed, and how different types of interface definitions interact with each other, to avoid unintended results. The following outline shows the algorithm OMPROUTE uses to find the matching definitions in the OMPROUTE configuration file for an IPv6 stack interface.

- a. Search for an IPv6\_RIP\_Interface definition for the interface as follows:
  - i) Search for an explicit matching IPv6\_RIP\_Interface statement for the interface. This match is one where the name parameter exactly matches the interface name. If one is found, use that definition and go to step b.
  - ii) Search for the best IPv6\_RIP\_Interface wildcard match for the name. The IPv6\_RIP\_Interface wildcard definitions are searched, starting with the most specific (longest wildcard name string) and checking each in order of declining specificity until a match is found. As soon as a match is found, use that definition and go to step b.
- b. Search for an IPv6\_OSPF\_Interface definition for the interface. This step is done regardless of the outcome of step a. The steps for searching IPv6\_OSPF\_Interface definitions are the same as the steps for searching IPv6\_RIP\_Interface definitions, except that IPv6\_OSPF\_Interface definitions are searched.
- c. If either an IPv6\_RIP\_Interface or an IPv6\_OSPF\_Interface definition, or both, are found, the algorithm is complete. In this case, IPv6\_Interface definitions are not searched. If neither an IPv6\_RIP\_Interface or an IPv6\_OSPF\_Interface definition was found, go to step d.
- d. Search for an IPv6\_Interface definition for the interface. The steps for searching IPv6\_Interface definitions are the same as the steps for searching IPv6\_RIP\_Interface statements, except that IPv6\_Interface definitions are searched.
- e. If no definitions are found, check the value of Global\_Options Ignore\_Undefined\_Interfaces. If this option is turned on, the interface is ignored. If it is not turned on, the interface is treated as if it were defined with an IPv6\_Interface statement. Default values are used for all parameters.

The algorithm is complete. Key conclusions of this algorithm are as follows:

- If an IPv6\_RIP\_Interface definition, an IPv6\_OSPF\_Interface definition, or both, are found, IPv6\_Interface definitions are not considered. This means that any matching IPv6\_RIP\_Interface or IPv6\_OSPF\_Interface definition supersedes all IPv6\_Interface definitions, even if the IPv6\_Interface definitions are explicit or more specific wildcard matches. For example, an IPv6\_OSPF\_Interface definition with a name parameter of V\* supersedes any IPv6\_Interface, explicit or wildcard, with a name parameter that begins with V. In this case, the IPv6\_Interface definition is redundant and can never be used. If OMPROUTE detects this case, it issues message EZZ8068I and deletes the redundant IPv6\_Interface definition.

**Note:** If an IPv6\_Interface definition was already selected for an interface that is installed in the stack, and then an IPv6\_OSPF\_Interface or IPv6\_RIP\_Interface definition that would make that IPv6\_Interface definition redundant is added by using RECONFIG, OMPROUTE issues message EZZ8069I and retains the IPv6\_Interface definition.

- An interface can be both an IPv6\_RIP\_Interface and an IPv6\_OSPF\_Interface. OMPROUTE supports running both protocols over the same interface. However, an interface cannot be both an interface that runs no routing protocol (that is, defined with the IPv6\_Interface statement) and one that runs IPv6 RIP, IPv6 OSPF, or both.

7. Define interface costs (OSPF\_INTERFACE, RIP\_INTERFACE, IPV6\_OSPF\_INTERFACE, and IPV6\_RIP\_INTERFACE).

Both the OSPF and RIP protocols have a cost value that is associated with interfaces. With both protocols, the cost of a route to reach a destination is the sum of the costs of each link to be traversed on the way to the destination. In the sample network that is shown in [Figure 51 on page 310](#), the cost of a route to get from TCP7 to router 3.3.3 through TCP4 is the cost of the link from TCP7 to TCP4 plus the cost of the link from TCP4 to router 3.3.3.

The method for configuring cost values differs between the OSPF and RIP protocols. Configure the cost values of OSPF links to ensure that preferred routes to destinations have a lower cost than less preferable routes. The less preferable routes, with the higher cost, are not used except upon failure of the preferred routes.

For the following examples, the sample network that is shown in [Figure 51 on page 310](#) is used and the convention stack (interface) is used to refer to the cost configured for a particular interface on a stack. For instance, TCP7(9.67.106.7) refers to the cost configured for interface 9.67.106.7 on TCP7. While these examples use the IPv4 portion of the sample network, the same methods for computing route costs would also be used by the IPv6 portion.

The following three routes are possible from TCP7 to router 3.3.3:

- Direct (TCP7 to 3.3.3)
- Through TCP4 (TCP7 to TCP4 to 3.3.3)
- Through router 8.8.8 and TCP4 (TCP7 to 8.8.8 to TCP4 to 3.3.3)

If the preferred route from TCP7 to router 3.3.3 is through TCP4, then interface costs must be configured such that the following conditions are true:

```
TCP7(9.67.106.7) + TCP4(9.67.101.4) < TCP7(9.67.102.7)
TCP7(9.67.106.7) + TCP4(9.67.101.4) < TCP7(9.67.100.7) +
8.8.8(9.67.105.8) + TCP4(9.67.101.4)
```

The reasons for preferring one route over another are numerous. One approach for assigning OSPF link costs would be to set the costs to values inversely proportional to the bandwidth of the physical media. This would result in higher bandwidth routes with lower costs, thus becoming the preferred routes.

The cost values of RIP links are generally set to a value of 1. This results in the cost of a route to a destination being the number of hops to reach the destination. In the sample network, this would result in the three possible RIP routes from TCP7 to router 3.3.3 having the following costs:

- Direct (TCP7 to 3.3.3), cost = 1
- Through TCP4 (TCP7 to TCP4 to 3.3.3), cost = 2
- Through router 8.8.8 and TCP4 (TCP7 to 8.8.8 to TCP4 to 3.3.3), cost = 3

If it was desirable that the route through TCP4 be the preferred route, this can be accomplished by increasing the cost of getting directly from TCP7 to router 3.3.3. This can be done by increasing either the out metric for 9.67.102.3 on router 3.3.3 or the in metric for 9.67.102.7 on TCP7. Take care when you are increasing in metric and out metric values to be sure that the cost to reach any destination does not exceed the RIP maximum of 15.

- IPv4 OSPF and RIP

The cost value of an OSPF interface is set with the COST0 parameter of the OSPF\_INTERFACE statement. The in metric and out metric of a RIP interface are set with the IN\_METRIC and OUT\_METRIC parameters of the RIP\_INTERFACE statement.

- IPv6 OSPF and RIP

The cost value of an IPv6 OSPF interface is set with the COST parameter of the IPV6\_OSPF\_INTERFACE statement. The in metric and out metric of an IPv6 RIP interface are set with the IN\_METRIC and OUT\_METRIC parameters of the IPV6\_RIP\_INTERFACE statement.

8. Configure virtual links, if the OSPF protocol is used.

The OSPF protocol is dependent upon complete connectivity of the backbone area. To maintain backbone connectivity, each backbone router must be interconnected. If the configuration of an OSPF autonomous system is such that the backbone area becomes separated into two or more disconnected sections, connectivity must be restored for the protocol to work correctly. This can be done by using a virtual link. Do not confuse an OSPF virtual link with a VIPA link. Virtual links can be configured between any two backbone routers that have an interface to a common non-backbone area.

- IPv4 OSPF

The VIRTUAL\_LINK statements specify the router ID of the link endpoint and must be configured at both endpoints. In the sample network that is shown in [Figure 51 on page 310](#), a virtual link is configured between TCPCS4 and TCPCS7 to restore backbone connectivity through area 1.1.1.1.

TCPCS4:

```
VIRTUAL_LINK
 Virtual_Endpoint_RouterID=7.7.7.7
 Links_Transit_Area=1.1.1.1;
```

TCPCS7:

```
VIRTUAL_LINK
 Virtual_Endpoint_RouterID=4.4.4.4
 Links_Transit_Area=1.1.1.1;
```

- IPv6 OSPF

The IPV6\_VIRTUAL\_LINK statements specify the router ID of the link endpoint and must be configured at both endpoints. In the sample network, a virtual link is configured between TCPCS64 and TCPCS67 to restore backbone connectivity through area 6.6.6.6.

TCPCS64:

```
IPV6_VIRTUAL_LINK
 Virtual_Endpoint_RouterID=67.67.67.67
 Links_Transit_Area=6.6.6.6;
```

TCPCS67:

```
IPV6_VIRTUAL_LINK
 Virtual_Endpoint_RouterID=64.64.64.64
 Links_Transit_Area=6.6.6.6;
```

9. Manage high-cost links, if the OSPF protocol is used.

The periodic nature of OSPF routing traffic requires a link's underlying data-link connection to be constantly open. This can result in unwanted usage charges on network segments whose costs are high. There are two configuration steps that can be taken to inhibit the periodic nature of the protocol.

The first step that can be taken is to define the link as a demand circuit. When this is done, link state advertisements (LSAs) sent over the interface are not periodically refreshed. Only LSAs with real changes are readvertised. In addition, aging of these LSAs is disabled such that they will not age out of the link state database.

Another step that can be taken is to define hello suppression for the link. Hello suppression is meaningful only if the link is a demand circuit and is either point-to-point or point-to-multipoint. Hello suppression inhibits the periodic transmission of OSPF hello packets.

- IPv4 OSPF

To define OSPF interfaces as demand circuits, the Demand\_Circuit=YES parameter must first be specified on the global OSPF configuration statement. Then, the OSPF\_INTERFACE statement for each interface to be configured as a demand circuit must be specified with the Demand\_Circuit=YES parameter. Use the Hello\_Suppression parameter of the OSPF\_INTERFACE statement to configure hello suppression. For more information about configuring the Hello\_Suppression parameter on the OSPF\_INTERFACE statement, see [z/OS Communications Server: IP Configuration Reference](#). If hello suppression is implemented, the PP\_Poll\_Interval parameter of the OSPF\_INTERFACE statement can be used to specify the interval at which OMPROUTE attempts to contact a neighbor to reestablish a neighbor relationship when the relationship failed, but the interface is still available.

- IPv6 OSPF

To define IPv6 OSPF interfaces as demand circuits, the Demand\_Circuit=YES parameter must first be specified on the global IPV6\_OSPF configuration statement. Then, the IPV6\_OSPF\_INTERFACE statement for each interface to be configured as a demand circuit must be specified with the Demand\_Circuit=YES parameter. Use the Hello\_Suppression parameter of the IPV6\_OSPF\_INTERFACE statement to configure hello suppression. For more information about configuring the Hello\_Suppression parameter on the IPV6\_OSPF\_INTERFACE statement, see [z/OS Communications Server: IP Configuration Reference](#). If hello suppression is implemented, the PP\_Poll\_Interval parameter of the IPV6\_OSPF\_INTERFACE statement can be used to specify the interval at which OMPROUTE attempts to contact a neighbor to reestablish a neighbor relationship when the relationship failed, but the interface is still available.

10. Define RIP filters, if the RIP protocol is used.

RIP Filters can be configured to OMPROUTE such that certain RIP routing information is not broadcast out to other routers and/or accepted from other routers. The filters can be applied to individual RIP interfaces or to all RIP interfaces. When you are defining a filter, a filter type (sending or receiving) is specified along with values that identify the route information to be filtered. By using filters, an installation can limit the amount of RIP routing information broadcast into the network and/or the amount of RIP routing information that is maintained by OMPROUTE. In addition, filters can be used to hide destination addresses from portions of the network.

- IPv4 RIP

To configure a filter for an individual RIP interface, use the FILTER parameter of the RIP\_INTERFACE statement. To configure a filter that applies to all IPv4 RIP interfaces, use the global FILTER statement. In the sample network that is shown in [Figure 51 on page 310](#), if you wanted to hide the 10.1.1.0 subnet from TCP6S6 (and all routers and hosts on the remote side of TCP6S6), you can define the following filter on TCP6S7:

```
Filter=(nosend,10.1.1.0,255.255.255.0);
```

- IPv6 RIP

To configure a filter for an individual IPv6 RIP interface, use the FILTER parameter of the IPV6\_RIP\_INTERFACE statement. To configure a filter that applies to all IPv6 RIP interfaces, use the global IPV6\_RIP\_FILTER statement. In the sample network that is shown in [Figure 51 on page 310](#), for example, if you wanted to hide the 2001:0DB8:0:A1B/64 prefix from TCP6S4, you can define the following filter on TCP6S4:

```
IPv6_RIP_Filter=(noreceive,2001:0DB8:0:A1B/64);
```

11. Define route precedence in a multiprotocol environment, if the OSPF protocol is used.

This discussion of route precedence is complicated. If only the OSPF or IPv6 OSPF routing protocol, or both, are used in your network, route precedence is less of a concern. If, in addition, none of your OSPF or IPv6 OSPF routers are configured as AS boundary routers, the route precedence concern is

entirely eliminated. For environments with multiple protocols or AS boundary routers, the following information is provided. In this discussion, RIP is meant to apply to both RIP and IPv6 RIP, OSPF is meant to apply to both OSPF and IPv6 OSPF, and the OSPF configuration statement is meant to apply to both the OSPF statement and the IPV6\_OSPF statement.

OMPROUTE applies an order of precedence in choosing between two routes to the same destination that were learned through different routing protocols or by using information that is provided by an OSPF AS boundary router. To describe this order of precedence that is applied by OMPROUTE, a few terms must first be defined.

#### **RIP route**

A route learned through the RIP protocol. A RIP route is generated by using information that is provided in a RIP packet from a neighboring router. For example, in the sample network that is shown in [Figure 51 on page 310](#), the route from TCPCS7 to destination subnet 30.1.1.0 is a RIP route.

#### **OSPF internal route**

A route learned through the OSPF protocol where the entire path traversed to reach the destination lies within the OSPF autonomous system. For example, in the sample network that is shown in [Figure 51 on page 310](#), the route from TCPCS7 to destination 9.67.108.2 on Router 2.2.2.2 is an OSPF internal route.

#### **OSPF external route**

A route learned through the OSPF protocol where part of the path traversed to reach the destination does not lie within the OSPF autonomous system. The path leaves the autonomous system when it uses information brought into the OSPF autonomous system by an AS boundary router. This information that is brought into the OSPF AS can be information that is imported from a different autonomous system (for example, RIP) or information about destinations that are statically configured on or directly connected to the AS boundary router. For example, in the sample network that is shown in [Figure 51 on page 310](#), the route from TCPCS4 to destination 9.67.103.6 on TCPCS6 is an OSPF external route. TCPCS7, configured as an AS boundary router, imported information about that destination into the OSPF AS from the RIP AS.

OSPF external routes fall into two categories that are based upon the setting of the multiprotocol comparison value. If the comparison value is set to Type1 on the AS boundary router that imports the external information into the OSPF AS, then OSPF external routes that are generated by using this information are OSPF type 1 external routes. If the comparison value is set to Type2 on the AS boundary router, then the generated routes are OSPF type 2 external routes. For example, in the sample network that is shown in [Figure 51 on page 310](#), if the comparison value on TCPCS7 (an AS boundary router) is set to Type1, the route from TCPCS4 to destination 9.67.103.6 on TCPCS6 is an OSPF type 1 external route. If the comparison value on TCPCS7 is set to Type2, the route is an OSPF type 2 external route.

#### **Multiprotocol comparison**

You can configure this comparison value to allow for the specification of how route costs from different autonomous systems are treated when they coexist. In OMPROUTE, you can configure this value by using the COMPARISON parameter on the OSPF or IPV6\_OSPF configuration statements. When COMPARISON=Type1 is configured, the route cost values used within different autonomous systems (for example, the OSPF AS and the RIP AS) are considered comparable. With COMPARISON=Type2 configured, the route cost values used with the different autonomous systems are considered non-comparable.

The comparison value can be used in several different ways, depending on the function that is being provided by a router:

- As an AS boundary router, OMPROUTE uses the comparison value to determine the type of external routes (type 1 or type 2) that are generated by routers in the OSPF AS by using routing information that the AS boundary router imports into the OSPF AS.
- As an AS boundary router, OMPROUTE also uses the comparison value in determining how route cost values are assigned when routes are imported from the OSPF AS into the RIP AS.

- When COMPARISON=Type1 is configured (indicating that cost values are comparable), an OSPF route that is imported into the RIP AS is advertised with the actual cost of the OSPF route. For example, in the sample network, if TCPCS7 is configured with COMPARISON=Type1 and the OSPF route from TCPCS7 to destination 9.67.108.2 on TCPCS2 has a cost of 7, then TCPCS7 advertises into the RIP AS a RIP route to that destination with a cost of 7.

**Notes:**

- An exception to this rule (defining how OSPF routes are advertised into the RIP AS when COMPARISON=Type1) occurs when the OSPF route to be imported is an OSPF type 2 external route. In this case, the route is not advertised into the RIP AS at all.
  - It is important to remember the requirement that all destinations in the RIP AS must be reachable with a cost no greater than 15. Using COMPARISON=Type1 requires that the cost values of OSPF routes be low. Any destinations in the OSPF AS that can be reached only from the RIP AS with a cost greater than 15 become unreachable.
- When COMPARISON=Type2 is configured (indicating that cost values are non-comparable), an OSPF route that is imported into the RIP AS is advertised with a cost of 1. If a router in the RIP AS has two possible routes to a destination, one internal to the RIP AS and another that was imported from OSPF, this approach results in the route that is imported from OSPF being favored. For example, in the sample network that is shown in [Figure 51 on page 310](#), if TCPCS7 is configured with COMPARISON=Type2 and TCPCS7 can somehow reach a destination in the 30.1.1.0 subnet without passing through TCPCS6 (by using links that are not shown in the sample), then TCPCS7 advertises into the RIP AS a RIP route to the destination with a cost of 1. As a result, TCPCS6 determines that the destination can be reached through TCPCS7 with a cost of 2. If the cost of the route for TCPCS6 to reach the destination internal to the RIP AS is greater than 2, then the route through TCPCS7 is chosen.

**Note:** An exception to this rule (defining how OSPF routes are advertised into the RIP AS when COMPARISON=Type2) occurs when the OSPF route to be imported is an OSPF type 2 external route. In this case, the route is advertised into the RIP AS with the actual cost of the OSPF type 2 external route.

- As any router that has routing information from different autonomous systems, OMPROUTE uses the comparison value while it is choosing between the routes generated by using the information from the different autonomous systems. How the comparison value is used in this case is shown in [Table 20 on page 351](#).

Given these definitions, the order of precedence that is used in choosing between multiple routes to the same destination, which were learned through the different protocols or by using information that is provided by an OSPF AS boundary router, can be shown in [Table 20 on page 351](#). In [Table 20 on page 351](#), *Source comparison* refers to the setting of the comparison value (by using the COMPARISON parameter on the OSPF configuration statement) on the router that is using the order of precedence to choose between the multiple routes. Route 1 and Route 2 are the two possible routes that are being chosen between.

| <i>Table 20. Route precedence</i> |                      |                      |                      |
|-----------------------------------|----------------------|----------------------|----------------------|
| Source comparison                 | Route 1 type         | Route 2 type         | Route chosen         |
| Type 1                            | OSPF internal        | RIP                  | OSPF internal        |
| Type 1                            | OSPF internal        | OSPF type 1 external | OSPF internal        |
| Type 1                            | OSPF internal        | OSPF type 2 external | OSPF internal        |
| Type 1                            | RIP                  | OSPF type 1 external | Lowest cost route    |
| Type 1                            | RIP                  | OSPF type 2 external | RIP route            |
| Type 1                            | OSPF type 1 external | OSPF type 2 external | OSPF type 1 external |
| Type 2                            | OSPF internal        | RIP                  | OSPF internal        |

| <i>Table 20. Route precedence (continued)</i> |                      |                      |                      |
|-----------------------------------------------|----------------------|----------------------|----------------------|
| Source comparison                             | Route 1 type         | Route 2 type         | Route chosen         |
| Type 2                                        | OSPF internal        | OSPF type 1 external | OSPF internal        |
| Type 2                                        | OSPF internal        | OSPF type 2 external | OSPF internal        |
| Type 2                                        | RIP                  | OSPF type 1 external | OSPF type 1 external |
| Type 2                                        | RIP                  | OSPF type 2 external | Lowest cost route    |
| Type 2                                        | OSPF type 1 external | OSPF type 2 external | OSPF type 1 external |

## Minimizing the routing responsibility of z/OS Communications Server

OMPROUTE may be run on z/OS Communications Server for a variety of reasons. If the z/OS Communications Server host is being used as an application or server host and the routing daemon is being run primarily to provide access to network resources, or to provide network resources access to the z/OS Communications Server host, then care must be taken to ensure that the z/OS Communications Server host is not overly burdened with routing work. Unlike routers or other network boxes whose sole purpose is routing, an application host z/OS Communications Server will be doing many things other than routing, and it is not desirable for a large percentage of machine resources (memory and CPU) to be used for routing tasks, as can happen in very complex or unstable networks. In this case the z/OS Communications Server should not be configured as a backbone router, either intentionally or inadvertently. Careful network design can minimize the routing burdens on the z/OS Communications Server application host without compromising the accessibility of z/OS Communications Server resources to the network and vice versa. If care is not taken to minimize the routing work required by the z/OS Communications Server host, OMPROUTE may consume excessive cycles or memory processing huge numbers of routing updates from the network. Or the burden of routing updates may become so large that the z/OS Communications Server cannot keep up because of other workloads on the machine. Because OSPF is heavily timer-driven, this could cause loss of adjacencies and routing problems.

The primary way to reduce the routing burdens on the z/OS Communications Server host is by use of OSPF areas. See step “3” on page 334 for more information. A z/OS Communications Server application host or sysplex can be placed into a non-backbone area with dedicated routers acting as area-border routers. The area-border routers would advertise the z/OS Communications Server resources to other attached areas (for example the backbone) and would summarize the network outside the local area to the z/OS Communications Server hosts. If possible, this can be further refined to reduce routing protocol traffic by use of interarea route summarization, accomplished in OMPROUTE area-border routers by the [RANGE](#) and [IPV6\\_RANGE](#) statements, and in Cisco routers with the `area range` command. For more information, see [z/OS Communications Server: IP Configuration Reference](#) and step “4” on page 335.

An even further, and ideal, optimization would be to make the area containing the z/OS Communications Server application host or sysplex a stub area. A stub area can be configured such that route summaries (IPv4) or prefixes (IPv6) from other areas are not flooded into the stub area by the area border routers. When this is done, only routes to destinations within the stub area are shared among the hosts. Default routes are used to represent all destinations outside the stub area. The stub area's resources are still advertised to the network at large by the area-border routers. You can use this optimization, sometimes referred to as a totally stubby area, if the following conditions apply to your network:

- It is acceptable to use default routes to reach destinations outside the stub area. This means that either there is only one area-border router connecting the stub area to the rest of the network, or if there are multiple such connections they are redundant, so that it does not matter which one is used to get outside the stub area.
- You have no non-OSPF destinations to advertise to the network at large. Stub areas do not permit importation of OSPF external routes. This means for example that you do not have a RIP network attached to the stub area, or if you do, you do not want its destinations reachable from the stub area. Other types of routes that cannot be imported into stub areas include direct routes (for example,

for networks attached to interfaces that are not running the OSPF protocol) and static routes. RIP or static routes can be used by the z/OS Communications Server that learns them, they just cannot be advertised.

**Tip:** If you define your VIPAs as OSPF interfaces in your OMPROUTE configuration file, routes to their addresses will be considered OSPF routes, and therefore importable into the stub area and able to be advertised by the area-border routers to the network at large.

It is highly recommended to put z/OS Communications Server application hosts or sysplexes into stub areas if at all possible.

A further optimization is to prevent z/OS Communications Server from becoming the designated router on multiaccess media, when pure routers that can perform this function are present. On a multiaccess medium, the designated router and the backup designated router will carry the majority of the routing protocol load for all hosts on the medium. While z/OS Communications Server is capable of performing this role, it does impose additional routing overhead on the system. It would be preferable to allow pure routers to perform this role, if they are available. This is accomplished by ensuring that the pure routers' interfaces onto the medium have higher ROUTER\_PRIORITY values than the z/OS Communications Server interfaces on the same medium. However, if the only hosts on a medium are z/OS Communications Server, such as in HiperSockets communications, then one or two of them will have to be designated router or backup designated router.

**Tip:** You can use the IBM Health Checker for z/OS to check whether the total number of indirect routes in a TCP/IP stack routing table exceeds a maximum threshold. When this threshold is exceeded, OMPROUTE and the TCP/IP stack can experience high CPU consumption from routing changes. For more information about IBM Health Checker for z/OS, see [z/OS Communications Server: IP Diagnosis Guide](#) and [IBM Health Checker for z/OS User's Guide](#).

## Preventing futile neighbor state loops during adjacency formation

---

In OSPF environments in which there might be a problem with some remote hardware (for example, router, switch, or network cable) that is beyond detection by z/OS hardware or software, OMPROUTE can get into an infinite (or futile) neighbor state loop over one of its interfaces with a neighbor. This loop might contribute to increased workload. In LAN configurations in which there are parallel OSPF interfaces that can reach the same neighbor for adjacency formation, unless you are using OMPROUTE futile neighbor state loop detection or unless you manually fix the problem, the backup interfaces are not used until after an outage occurs for the OSPF interface that was initially involved in an adjacency formation attempt with a designated router. For information about parallel OSPF interfaces, see step “5” on page 337.

Futile neighbor state loops can occur during adjacency formation with a neighboring designated router before full adjacency has been reached. According to OSPF protocol, all routers on a multiaccess network attempt to establish adjacency with the designated router (DR) and backup designated router (BDR) after two-way communication has been established. When a problem occurs during the adjacency formation process, the adjacency formation attempt is restarted. Repeated adjacency attempts can continue until full adjacency has been established or an interruption occurs. Interruption occurs from an interface outage to the neighbor or from a neighbor outage. Whether or not parallel interfaces are used, OMPROUTE repeatedly attempts to establish full adjacency with the neighbor, and if the problem is due to a cabling error or failure or some other non-transient condition, it is highly unlikely that the problem will be resolved and the loop will become futile.

To stop a futile neighbor state loop, you can either manually deactivate the interface or suspend the OSPF interface within OMPROUTE so that OMPROUTE will stop attempting to form the adjacency over the interface. If the OSPF interface is suspended, any active sessions using static routes over the interface will not be disrupted. If the interface is deactivated, all active sessions over the interface will be disrupted. If a parallel OSPF interface is available, OMPROUTE will then attempt to form adjacency with the neighbor over the parallel interface.

OMPROUTE futile neighbor state loop detection removes the need for manual detection of futile neighbor state loops, manual intervention to resolve the loops, and the disruption of existing sessions due to deactivating the interface. Code the DR\_MAX\_ADJ\_ATTEMPT parameter on the OSPF or IPV6\_OSPF statement, or both, in your OMPROUTE configuration file to enable this function. OMPROUTE will then

report and control futile neighbor state loops during the adjacency formation process. For a list of interfaces that support the futile neighbor state loop detection function, see [z/OS Communications Server: IP Configuration Reference](#)

If you use the DR\_MAX\_ADJ\_ATTEMPT parameter, futile neighbor state loops are automatically detected and reported using message EZZ8157I. If a parallel OSPF interface is not available, adjacency formation attempts continue to be tried over the same interface. If parallel OSPF interfaces are available, an interface change is reported using message EZZ8158I and adjacency formation attempts are tried again over a parallel OSPF interface. The problematic interface is suspended within OMPROUTE, but the interface is not deactivated and active sessions over the interface are not disrupted.

After a problematic OSPF interface is suspended in OMPROUTE and adjacencies are formed on a parallel OSPF interface, you might want to switch back to the original interface after you have fixed the problem that caused the futile neighbor state loop. To accomplish this, activate the repaired interface and then suspend the parallel interface. After OSPF adjacencies are established over the repaired interface, the parallel interface can be reactivated so it is again available as a backup for the repaired interface. Use the ACTIVATE function of the OMPROUTE MODIFY command to activate a suspended OSPF interface. Use the SUSPEND function of the OMPROUTE MODIFY command to manually suspend an OSPF interface. For more information about these functions of the MODIFY command for OMPROUTE, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Verification of OMPROUTE IPv4 configuration and state

The following topics show sample output from each of the commands that can be used to display OMPROUTE IPv4 information. The syntax of these [DISPLAY](#) commands, as well as detailed information about the data displayed, can be found in [z/OS Communications Server: IP System Administrator's Commands](#).

**Note:** All commands that include the LIST subparameter indicate that the information being displayed is configured information only and does not necessarily mean that the information is currently being used by OMPROUTE. To display information in current use, use related commands to display current, run-time statistics, and parameters. There are cases when the configured information will not match the in-use information due to some undefined or unresolved information in the OMPROUTE configuration. For example, undefined interfaces or parameters in the OMPROUTE configuration or an incorrect sequence of dynamic reconfiguration with the MODIFY OMPROUTE, RECONFIG command can result in no update of the in-use information at all. Information defined on wildcard interfaces is not displayed in the LIST commands; it is displayed only in the corresponding non-LIST commands when wildcard information is resolved to actual physical interfaces.

## Displaying all OSPF configuration information

To display all of the OSPF configuration information, enter the following command:

```
D TCPIP,TCPCS7,OMP,OSPF,LIST,ALL
EZZ7831I GLOBAL CONFIGURATION 735
TRACE: 0, DEBUG: 0, SADEBUG LEVEL: 0
STACK AFFINITY: TCPCS7

DYNAMIC ROUTING PARAMETERS
INTERFACE: CTC7T03 NEXT HOP: ANY

```

**Result:** If a policy-based route table is configured with no IPv4 dynamic routing parameters, OMPROUTE has no knowledge of that route table for IPv4. The route table is not included in this display. If no policy-based route tables are configured with IPv4 dynamic routing parameters, message EZZ8150I is issued.

## Displaying the routes in an OMPROUTE IPv4 policy-based routing table

To display all of the routes in an OMPROUTE policy-based routing table, enter the following command:

```

D TCP,IP,TCPCS7,OMP,RTTABLE,PR=SECHIGH

DYNAMIC ROUTING PARAMETERS
INTERFACE: CTC7T08 NEXT HOP: ANY

```

**Result:** If the policy-based route table is configured with no IPv4 dynamic routing parameters, OMPROUTE has no knowledge of the route table for IPv4. If no policy-based route tables are configured with IPv4 dynamic routing parameters, message EZZ8150I is issued.

## Displaying the routes to a specific destination in an IPv4 policy-based routing table

To display information about the routes to a specific destination that are in a policy-based routing table, enter the following command:

```
D TCPIP,TCPCS7,OMP,RTTABLE,PR=SECHIGH,DEST=130.201.0.0
EZZ7874I ROUTE EXPANSION 165
TABLE NAME: SECHIGH
DESTINATION: 130.201.0.0
MASK: 255.255.0.0
ROUTE TYPE: SPE2
DISTANCE: 0
AGE: 548
NEXT HOP(S): 9.67.100.8 (CTC7T08)
```

**Result:** If the policy-based route table is configured with no IPv4 dynamic routing parameters, OMPROUTE has no knowledge of the route table for IPv4. If no policy-based route tables are configured with IPv4 dynamic routing parameters, message EZZ8150I is issued.

## Displaying all of the generic configuration information

To display all of the IPv4 configuration information that is not related to any routing protocol, enter the following command:

```
D TCPIP,TCPCS3,OMP,GENERIC,LIST,ALL
EZZ8053I IPV4 GENERIC CONFIGURATION
TRACE: 2, DEBUG: 3, SADEBUG LEVEL: 0
IPV4 TRACE DESTINATION: /TMP/AMPROUT3.DBG
STACK AFFINITY: TCPCS3

EZZ8056I IPV4 GEN INT CONFIGURATION
IFC NAME IFC ADDRESS SUBNET MASK MTU DESTADDR
NSQDI03L 9.67.120.3 255.255.255.0 576 N/A
CTC3T04 9.67.101.3 255.255.255.0 10000 9.67.101.4
```

## Displaying information about configured generic interfaces

To display information about configured generic interfaces (that is, interfaces defined to OMPROUTE with the INTERFACE statement, or not defined to OMPROUTE but learned from the stack), enter the following command:

```
D TCPIP,TCPCS3,OMP,GENERIC,LIST,IFS
EZZ8056I IPV4 GEN INT CONFIGURATION
IFC NAME IFC ADDRESS SUBNET MASK MTU DESTADDR
NSQDI03L 9.67.120.3 255.255.255.0 576 N/A
CTC3T04 9.67.101.3 255.255.255.0 10000 9.67.101.4
```

## Displaying current run-time information about generic interfaces

To display current run-time information about generic interfaces, enter the following command:

```
D TCPIP,TCPCS3,OMP,GENERIC,IFS
EZZ8060I IPV4 GENERIC INTERFACES
IFC NAME IFC ADDRESS SUBNET MASK MTU CFG IGN
NSQDI03L 9.67.120.3 255.255.255.0 576 YES NO
CTC3T01 130.200.1.3 N/A N/A NO YES
VIPAO3 3.3.3.103 N/A N/A NO YES
CTC3T04 9.67.101.3 255.255.255.0 10000 YES NO
```

## Verification of OMPROUTE IPv6 configuration and state

The following topics show sample output from each of the commands that can be used to display OMPROUTE IPv6 information. The syntax of these `DISPLAY` commands, as well as detailed information about the data displayed, can be found in [z/OS Communications Server: IP System Administrator's Commands](#).

### Displaying all IPv6 OSPF information

To display a comprehensive list of IPv6 OSPF information, enter the following command:

```
D TCP/IP,TCPCS67,OMP,IPV6OSPF,ALL
EZZ7970I IPV6 OSPF INFORMATION 322
TRACE6: 0, DEBUG6: 0

--AREA RANGES--
AREA ID ADVERTISE PREFIX
6.6.6.6 NO 2001:DB8:0:101::/64
```

## Displaying IPv6 OSPF interface statistics and parameters

To display current, run-time statistics and parameters related to IPv6 OSPF interfaces, enter the following command:

```
D TCP/IP,TCPCS67,OMP,IPV6OSPF,IFS
EZZ7958I IPV6 OSPF INTERFACES 575
NAME AREA TYPE STATE COST HELLO DEAD NBRS ADJS

DEMAND CIRCUIT: ON HELLO SUPPRESS: OFF SUPPRESS REQ: ON
```

```
NEIGHBORS: 1 # ADJACENCIES: 1 # FULL ADJS.: 1
```

## Displaying IPv6 OSPF neighbor statistics and parameters

To display the statistics and parameters related to IPv6 OSPF neighbors, enter the following command:

```
D TCPIP,TCPCS67,OMP,IPV6OSPF,NBRS
EZZ8129I IPV6 OSPF NEIGHBORS 715
ROUTER ID STATE LSRXL DBSUM LSREQ HSUP RTR-PRI IFC
65.65.65.65 128 0 0 0 OFF 1 MPCPTP7T05
63.63.63.63 8 0 0 0 OFF 1 NSQDI01L6
64.64.64.64 128 0 0 0 OFF 1 NSQDI01L6
68.68.68.68 128 0 0 0 OFF 1 NSQDI01L6
64.64.64.64 128 0 0 0 OFF 1 *
```

**Tip:** On multiaccess media (LANs), attached routers become adjacent only with the designated router and the backup designated router. Routers that are not performing a designated router role do not become adjacent to each other on LAN networks. Therefore, in this example, the state of 8 for 63.63.63.63 does not necessarily represent a problem or an incomplete adjacency. You can conclude that 64.64.64.64 and 68.68.68.68 are the designated routers, and 63.63.63.63 is simply another router on the network. State 8 is the final state in this case.

## Displaying statistics and parameters for a specific IPv6 OSPF neighbor

To display current, run-time statistics and parameters for a specific IPv6 OSPF neighbor, enter the following command:

```
D TCPIP,TCPCS67,OMP,IPV6OSPF,NBR,ID=64.64.64.64,IFNAME=NSQDI01L6
EZZ8130I IPV6 OSPF NEIGHBOR DETAILS 737

## Policy-based routing

Policy-based routing enables the TCP/IP stack to make routing decisions that take into account criteria other than just the destination IP address. The additional criteria can include job name, source port, destination port, protocol type (TCP or UDP), source IP address, NetAccess security zone, and multilevel secure environment security label. Policy-based routing might be useful in the following sample scenarios:

- You might want to favor high-bandwidth links for batch traffic, but for interactive traffic you prefer low-latency links. If so, you could define policies such that Telnet traffic is routed over the low-latency links, and FTP traffic is routed over the high-bandwidth links.
- You could define a policy to ensure that traffic that is tagged with a security label and zone is routed to a secured network over an appropriate outbound interface.
- You might want to control the links that are used by Enterprise Extender traffic to keep that traffic from being impacted by other IP traffic loads.

#### **Restrictions:**

- Policy-based routing applies only to TCP and UDP traffic that originates at the TCP/IP stack. The following types of traffic are routed always by using the main route table, even when policy-based routing is in use:
  - Traffic that uses protocols other than TCP and UDP
  - Traffic that the TCP/IP stack uses
  - Traffic for the Ping and Traceroute commands
- If Common INET (CINET) is used to run multiple z/OS Communications Server TCP/IP stacks concurrently, CINET has no knowledge of the policy-based route tables that are used by those TCP/IP stacks. CINET has knowledge only of the routes in the main route table of each TCP/IP stack. Avoid use of policy-based routing in a CINET environment, unless at least one of the following conditions is true:
  - All applications establish affinity with a particular TCP/IP stack.
  - The route destinations in each TCP/IP stack route table are mutually exclusive with the route destinations on the other TCP/IP stacks, including the default route.

## **Options for configuring policy-based routing**

Policy-based routing is configured using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the policy-based routing for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

### **Option 1: Use the IBM Configuration Assistant for z/OS Communications Server**

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface to simplify configuration of TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create policy-based routing configuration files for any number of z/OS images with any number of TCP/IP stacks per image.

With the IBM Configuration Assistant for z/OS Communications Server you use traffic descriptors, reusable objects that define traffic by its ports, protocol, security zone, security label, or sending application job name. The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects. For each TCP/IP stack, you then create a set of policy-based route tables and routing rules, which map traffic descriptors and IP addresses to the policy-based route tables to be used when making routing decisions for that traffic.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create policy-based routing files, contributing to ease of configuration and

maintenance. Using the GUI ensures that you have a consistent and easily manageable interface for implementing policy-based routing.

This information primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand policy-based routing concepts and the relationship between Policy Agent and policy-based routing.

## Option 2: Manual configuration

You can manually create the policy-based routing configuration files by coding all the required statements in a z/OS UNIX file or MVS data set. This information describes the procedure for creating a routing policy by manually creating and editing the configuration files. For details about the [Policy-based routing policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

### Specifying the routing configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information about these different roles, see “Policy types and infrastructure overview” on page 813. Regardless of which option you use to configure Routing policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves Routing policies from the policy server, specify the configuration files using the `DynamicConfigPolicyLoad` statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve Routing policies from the policy server, specify the configuration files using the `RoutingConfig` statement on the policy client.
- If you are not using a policy client and policy server environment, specify the configuration files using the `RoutingConfig` statement on the single Policy Agent.

When specifying configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

## Routing policy configuration

Routing policy is provided to the stack by the Policy Agent. The Policy Agent main configuration file contains a `TcpImage` statement for each stack that is to receive policy, and can optionally contain a `CommonRoutingConfig` statement that identifies a local shared routing policy file. The `TcpImage` statement identifies the z/OS UNIX file or MVS data set that contains policy for that stack. This policy file can contain a `RoutingConfig` statement to identify the z/OS UNIX file or MVS data set that contains the local routing policy. The `RoutingConfig` statement is required for each stack that is to receive routing policy. If both a `RoutingConfig` statement and a `CommonRoutingConfig` statement are defined, the specified `CommonRoutingConfig` file is processed before the `RoutingConfig` policy file specified for that stack.

On the policy server, use the `DynamicConfigPolicyLoad` statement to specify the remote routing policies. On the policy client, use the `PolicyServer` statement to retrieve the remote routing policies from the policy server.

In the routing policy file, routing rules define sets of conditions that are compared when a route is being selected to send TCP or UDP traffic that originates in the TCP/IP stack. If a rule match is found, an appropriate route for the traffic is selected based on the route tables that are specified in the action that is associated with the rule.

### Routing rules

A `RoutingRule` statement consists of a set of conditions that are compared against the traffic that is being sent. When a match is found, policy lookup stops and the traffic is assigned the actions that are associated with the rule. The rule conditions are as follows:

**IPSourceAddr**

Source IP address or addresses. The source IP address for a TCP outbound connection, or for a UDP outbound packet, can be influenced by a number of configuration and application options. For the hierarchy of ways that the source IP address of an outbound packet is determined, see [“Source IP address selection”](#) on page 272. For the following source IP address selection methods, a route lookup is needed to determine the source IP address.

- SOURCEVIPA: Static VIPA address from the HOME list (IPv4 interface defined with the LINK statement) or from the SOURCEVIPAINTERFACE parameter (IPv4 or IPv6 interface defined with the INTERFACE statement)
- HOME IP address of the interface over which the packet is sent

Do not use the IpSourceAddr condition as a selector for traffic that relies on these methods to select its source IP address. At the time that the route lookup is performed, the source IP address is not yet selected.

**IPDestAddr**

Destination IP address or addresses.

**SourcePortRange**

Source port or ports.

**DestinationPortRange**

Destination port or ports.

**Protocol**

TCP or UDP.

**Jobname**

Job name of the sending application or wildcard job name.

**SecurityZone**

NetAccess security zone that outbound traffic must match. The outbound traffic destination IP address is used to determine the NetAccess security zone in the NetAccess table that is defined in the TCP/IP profile. For more information about network access control and the [NETACCESS statement](#) TCP/IP profile statement, see [z/OS Communications Server: IP Configuration Reference](#).

**SecurityLabel**

Multilevel secure networking security label of the NetAccess security zone that outbound traffic must match. The outbound traffic destination IP address is used to determine the NetAccess security zone of the packet in the NetAccess table that is defined in the TCP/IP profile. The security label is the label that is associated with the NetAccess zone. For more information, see [Chapter 4, “Preparing for IP networking in a multilevel secure environment,”](#) on page 213.

If a condition is not specified, that condition is not considered when the rule and the traffic are compared for a match. You can specify multiple values for the conditions, either directly in the condition or as a referenced group.

Each RoutingRule statement can also have a priority. Priority values can be integers in the range 1 – 2000000000; 2000000000 is the highest priority. When assigning priorities, skip some values to accommodate future rule insertion between existing rules.

If traffic does not map to any of the active routing rules, the IP layer routes traffic by searching the main route table.

**Tip:** If traffic can map to more than one rule, always use priority and leave priority space between rules.

A RoutingRule statement must reference an action by using the RoutingActionRef parameter. The RoutingActionRef parameter includes the name of a globally defined RoutingAction statement.

**Routing actions**

The RoutingAction statement must specify a minimum of one policy-based route table using the RouteTableRef parameter, or it must specify UseMainRouteTable YES. Specify UseMainRouteTable YES and no RouteTableRef parameters if you want traffic that matches the corresponding RoutingRule statement to be routed using only the main route table.

A maximum of eight RouteTableRef parameters can be specified on a RoutingAction statement. Each RouteTableRef parameter includes the name of a globally defined RouteTable statement. The order in which the RouteTableRef parameters are specified on the RoutingAction statement determines the order in which the TCP/IP stack uses the route tables when making routing decisions. The stack searches the first table for a route that can be used to reach the destination of the traffic. If no usable route (host, subnet, network, or default) exists in that route table, the next table is searched. This continues until a usable route to the destination is found, or all specified tables are exhausted. Specify the UseMainRouteTable parameter to indicate whether the main route table should also be searched when no usable route is located in any of the specified policy-based route tables. For a description of the algorithm used by the IP layer to search a route table for a usable route to a destination, see [“Route selection algorithm”](#) on page 309.

**Performance guideline:** There is a performance cost for each policy-based route table that is searched on a route lookup. Minimize the number of RouteTableRef parameters that you specify on a RoutingAction statement.

## Routing tables

The RouteTable statement can include the following items:

- A set of static routes (both replaceable and non-replaceable static routes are supported)
- A set of dynamic routing parameters that are used for the following purposes:
  - To control the scope of dynamic routes that OMPROUTE computes
  - For IPv6 only, to control the scope of router advertisement routes added to the table
- A dynamic XCF routes indicator

A static route is included by using the Route parameter of the RouteTable statement. A dynamic routing parameter is included by using the DynamicRoutingParms parameter of the RouteTable statement. A dynamic routing parameter consists of an interface, and optionally a next-hop router.

OMPROUTE adds dynamic routes to a policy-based route table only if the interfaces that the routes use are included in the dynamic routing parameters for that table. If a next-hop router is specified with an interface, dynamic indirect routes that use the specified interface are added only if they also use the specified next-hop router.

For IPv6, router advertisement routes are added to a policy-based route table only if the interface that received the router advertisement is included in the dynamic routing parameters for that table. If a next-hop router is specified with an interface, indirect router advertisement routes that use the specified interface are added only if the router advertisement was sent by the specified next-hop router.

Including only static routes, only dynamic routing parameters, or both in a RouteTable statement produces the following results:

- If only static routes are included, the static routes are added to the policy-based route table, but no dynamic routes are added to the table by OMPROUTE and no IPv6 router advertisement routes are added to the table.
- If only dynamic routing parameters are included, dynamic routes are added to the policy-based route table by OMPROUTE and IPv6 router advertisement routes are added to the table based on received router advertisements, but no static routes are added to the table.
- If both static routes and dynamic routing parameters are included, the static routes are added to the policy-based route table. OMPROUTE updates the table with the appropriate dynamic routes, and IPv6 router advertisement routes are added to the table based on received router advertisements.

A dynamic route that is added to a policy-based route table by OMPROUTE is the best route that is known by OMPROUTE to that destination. The calculation of the best route is based on the current network topology. The best route might be a route that is learned from the OSPF protocol or from the RIP protocol, depending on the OMPROUTE configuration. For a description of these protocols, see [“IPv4 dynamic routing using OMPROUTE”](#) on page 316 and [“IPv6 dynamic routing using OMPROUTE”](#) on page 319. When OMPROUTE is computing the best routes for a policy-based route table, it considers only routes that adhere to the dynamic routing parameters configured on the RouteTable statement as described.

**Performance guideline:** Each policy-based route table that is configured for dynamic routing adds more processing cost to OMPROUTE. Do not configure duplicate route tables, and limit the use of policy-based route tables that use dynamic routing.

If `DynamicXCFRoutes Yes` is specified on the `RouteTable` statement and `IPCONFIG DYNAMICXCF` is specified in the TCP/IP profile, direct host routes to IPv4 dynamic XCF addresses on other TCP/IP stacks are added to the route table when the IPv4 dynamic XCF links to those stacks are active. If `DynamicXCFRoutes6 Yes` is specified on the `RouteTable` statement and `IPCONFIG6 DYNAMICXCF` is specified in the TCP/IP profile, direct host routes to IPv6 dynamic XCF addresses on other TCP/IP stacks are added to the route table when the IPv6 dynamic XCF links to those stacks are active. These same routes are automatically generated in the main route table when dynamic XCF links are active. For information about the dynamic XCF function and the definitions that are automatically generated when `IPCONFIG DYNAMICXCF` or `IPCONFIG6 DYNAMICXCF` is specified in the TCP/IP profile, see [“Dynamic XCF” on page 468](#).

After a new routing policy is installed in the TCP/IP stack, traffic is mapped by using the new policy, even for existing connections.

## Getting started with policy-based routing

Assume you have a TCP application that has the name `SECBATCH` running on a z/OS TCP/IP stack. Because this application handles sensitive data sent as batch traffic, you want the traffic to be sent only over secure networks and you want to prefer high bandwidth links over lower bandwidth links. The application creates a TCP socket bound to IP address `INADDR_ANY` and port 7000.

For the tasks that must be completed to configure the local routing policy to control routing decisions made for traffic sent by the application, see [“Configuring policy-based routing” on page 382](#). Assuming that the link names specified on the routing policy statements are already defined to TCP/IP and OMPROUTE, you do not need to perform additional configuration in the TCP/IP profile or in the OMPROUTE configuration file to enable policy-based routing.

## Configuring policy-based routing

### Before you begin

This topic describes the tasks that must be completed to configure the local routing policy to control routing decisions made for traffic sent by an application. Assuming that the link names specified on the routing policy statements are already defined to TCP/IP and OMPROUTE, you do not need to perform additional configuration in the TCP/IP profile or in the OMPROUTE configuration file to enable policy-based routing.

### Procedure

1. Determine your requirements for the TCP/IP stack to make routing decisions based on more than just destination IP address.  
The additional criteria can include job name, source port, destination port, protocol type (TCP or UDP), source IP address, NetAccess security zone, and security label.
2. Create Policy Agent files
  - a) Create a Policy Agent main configuration file containing a `TcpImage` statement for the stack.
  - b) Create a Policy Agent image configuration file for the stack.
  - c) If routing policies are to be retrieved from the policy server, create image-specific routing configuration files, and optionally, common routing configuration files, on the policy server.
3. Add routing configuration
  - a) For local Routing policies, add a `RoutingConfig` statement to the Policy Agent image configuration file, identifying the `RoutingConfig` policy file location:

```
RoutingConfig configFilepath
```

- b) For remote Routing policies, add a PolicyServer statement to the policy client image configuration file:

```
PolicyServer
{
 ClientName name
 PolicyType Routing
 {
 ...
 }
 ...
}
```

Add a DynamicConfigPolicyLoad statement to the policy server main configuration file:

```
DynamicConfigPolicyLoad clientname
{
 PolicyType Routing
 {
 PolicyLoad configFilepath
 }
 ...
}
```

4. Add statements to the Routing policy file to configure the policy-based route tables to be used by the TCP/IP stack for routing the application traffic.

Add the following Routing policy statements to the *configFilepath* file:

```
RouteTable SecFast # Secure link, high bandwidth
{
 # Static Routes:
 # Destination Subnet Mask First Hop Link Name Packet Size Options
 Route DEFAULT 9.67.101.3 SECHIGH1 MTU 2000 Replaceable
 #
 # Dynamic Routing Parameters:
 # Link Name First Hop
 DynamicRoutingParms SECHIGH2 9.67.101.3
 DynamicRoutingParms SECHIGH1
}

RouteTable SecSlow # Secure link, low bandwidth
{
 # Static Routes:
 # Destination Subnet Mask First Hop Link Name Packet Size Options
 Route DEFAULT 9.67.106.7 SECLW1 MTU 2000 Replaceable
 #
 # Dynamic Routing Parameters:
 # Link Name First Hop
 DynamicRoutingParms SECLW2 9.67.104.3
 DynamicRoutingParms SECLW1 9.67.106.7
 DynamicRoutingParms SECLW1 9.67.106.15
}
```

Table SecFast contains a replaceable static default route. The dynamic routing parameters for SecFast direct OMPROUTE to compute routes that use only link SECHIGH2, with any first hop, and link SECHIGH1, with a first hop of 9.67.101.3.

Table SecSlow contains a replaceable static default route. The dynamic routing parameters for SecSlow direct OMPROUTE to compute only routes that use link SECLW2, with a first hop of 9.67.104.3, and link SECLW1, with a first hop of either 9.67.106.7 or 9.67.106.15.

5. Add statements to the Routing policy file to ensure that the application traffic is sent over only secure links, favoring high bandwidth links over lower bandwidth links.

Add the following Routing policy statements to the *configFilepath* file:

```
RoutingRule SecBatchRule
{
 TrafficDescriptor
 {
 Protocol TCP
 }
}
```

```

SourcePortRange 7000
Jobname SECBATCH
}
RoutingActionRef SecBatchAction
}
RoutingAction SecBatchAction
}
UseMainRouteTable No
RouteTableRef SecFast
RouteTableRef SecSlow
}

```

## 6. Start Policy Agent

### Results

You know you are done when the Routing policies are installed to the TCP/IP stack and the following console message is displayed:

```
EZZ8771I PAGENT CONFIG POLICY PROCESSING COMPLETE FOR image : ROUTING
```

## Considerations for using policy-based routing with IP security

Policy-based routing allows traffic that is described in a routing rule to be routed by using one or more route tables. When IP security is active on a TCP/IP stack that is using policy-based routing, it is important to understand how the two functions interact. On a stack with IP security active, traffic can be encapsulated in an AH, ESP, or UDP-encapsulated ESP header. An additional IP header can be added if the encapsulated traffic is being sent to a security gateway (that is, the remote tunnel endpoint is not the same as the remote data endpoint). A matching routing rule is selected based on the characteristics of the original non-encapsulated traffic. The route tables that are associated with the matching routing rule and action are used to route the encapsulated traffic.

For example, assume the following configuration:

- An IPSec filter rule, FilterRule1, is configured for traffic with source address 9.1.1.1 and destination address 167.0.0.0/8 to have IPSec protection. Traffic is encapsulated and sent to router 9.2.2.2, the security gateway.
- A routing rule, FTPRULE, is configured for FTP traffic with source address 9.1.1.1. The associated action specifies that route table FTPRTES is to be used to route traffic and that the main route table is not to be searched.

Given this configuration, the following processing is performed for FTP traffic sent from IP address 9.1.1.1 to IP address 167.1.1.1:

1. The FTP traffic matches routing rule FTPRULE, and a route is found in route table FTPRTES that is used to route to destination 167.1.1.1.
2. The FTP traffic matches IPSec filter rule FilterRule1.
3. The FTP traffic is encapsulated and a new IP header is added with destination address 9.2.2.2.
4. The encapsulated packet is routed based on the routes that are defined in route table FTPRTES. To successfully send the traffic, route table FTPRTES must also contain a route that is used to route to destination 9.2.2.2. Otherwise, the traffic would be sent by using the route that is found to destination 167.1.1.1. The success of the traffic depends on network connectivity.

**Requirement:** When a routing rule applies to traffic that is to be IPSec encapsulated and sent to a security gateway, the route tables that are associated with the routing rule and action must contain a route that can be used to reach the security gateway, as well as a route that can be used to reach the original destination.

For more information about IP security, see [Chapter 17, “IP security,” on page 911](#).

## Considerations for mixed routing environments

---

Read this topic if you will be using any combination of static, dynamic, and policy-based routing on a single TCP/IP stack. These considerations will help you understand how these different types of routing interact, and how to configure them to get the results that you want.

### Use of static routing with OMPROUTE

Do not use non-replaceable static routes with OMPROUTE because those routes cannot be dynamically updated in response to network topology changes. An exception is when routes must be defined to destinations that, for some reason, cannot be learned dynamically through the routing protocol. Use the `BEGINROUTES` statement in `PROFILE.TCPIP` to define IPv4 or IPv6 static routes if they are required.

TCP/IP treats static routes that are defined as replaceable on the `BEGINROUTES` statement as last-resort routes. If a dynamic route is learned for the destination that was specified in a replaceable static route, the dynamic route replaces the static route in the route table. Additionally, if a replaceable static route is replaced with a dynamic route, TCP/IP always retains knowledge of the replaceable static route and reinstalls it if the destination becomes unreachable using dynamic routes. TCP/IP does not relearn replaceable static routes that were replaced. For this reason, replaceable static routes can be used with OMPROUTE as backup routes to use if nothing is found dynamically.

Another situation in which static routes might be required is when multiple, equal-cost routes to a destination are needed and the RIP or IPv6 RIP routing protocol is used. Static routes might be required in this case because, except for directly attached resources, the RIP and IPv6 RIP protocols do not create multiple, equal-cost routes to a destination. In other words, if multiple adjacent routers are advertising through RIP or IPv6 RIP that they can reach the same destination, OMPROUTE adds a route to the TCP/IP route table through only one of those adjacent routers. If more than one of these routes must exist, they must be statically configured in `PROFILE.TCPIP` by using the `BEGINROUTES` statement. For example, in Figure 51 on page 310, this configuration would be necessary if you wanted host TCP4S4 to have two routes to the IPv6 prefix `2001:DB8:0:A10::/60` (one through router A and one through router B).

If a TCP/IP stack has multiple interfaces to a directly attached network and you want to use one interface for input packets and one for output packets (traffic splitting), you can use static routes. To use traffic splitting, you can define a static route for only one interface, forcing all output packets to use that interface. The other routers on the directly attached network must be defined with a similar static route, but for the other interface. Although this method is the easiest way to implement traffic splitting, if one of the interfaces fails, a host might become unreachable even though the other interface remains active.

**Tip:** A more robust way of accomplishing traffic splitting is to use dynamic routes and make one route preferred over the other through the configured interface costs. For more information, see step “7” on page 347.

The `BSDROUTINGPARMS` statement in `PROFILE.TCPIP` is not used when the OMPROUTE routing daemon is used. Instead, the IPv4 interface characteristics, including subnet mask, are defined in the OMPROUTE configuration file.

### Use of IPv6 static routing with router advertisements

Do not use non-replaceable static routes with IPv6 router discovery, when those routes are to destinations that are to be learned through received router advertisements. If these non-replaceable static routes are defined, they cannot be dynamically updated in response to network topology changes.

TCP/IP treats replaceable static routes as last-resort routes. These routes can be replaced by dynamic (router discovery) routes. In addition, if a replaceable static route is replaced with a dynamic route, TCP/IP always retains knowledge of the replaceable static route and can reinstall it if the destination becomes unreachable using dynamic routes. TCP/IP does not need to relearn replaceable static routes that are replaced. For this reason, replaceable static routes can be used with IPv6 router discovery as backup routes, to be used if nothing is learned dynamically.

## Use of policy-based routing with static or dynamic routing

If a policy-based route table is configured with both static routes and dynamic routing parameters, review the considerations in [“Use of static routing with OMPROUTE” on page 385](#) and in [“Use of IPv6 static routing with router advertisements” on page 385](#). The same considerations apply with one exception; references that are made to static routes in those topics refer to static routes that are configured by using the Route parameter on the RouteTable policy statement.

When policy-based routing is used, policies are defined that instruct the TCP/IP stack to use specific policy-based route tables when it is making routing decisions, which are based on the traffic that is being routed. The main route table is used only when one of the following conditions are true:

- The traffic for which a route is being selected does not match any active policy-based routing rule.
- The traffic for which a route is being selected matches an active policy-based routing rule. However, no usable route exists in the policy-based route tables that are specified by policy to be used for the traffic, and the policy indicates that the main route table is to be used when this situation occurs.

## Verifying static, dynamic, and policy-based routing

- If OMPROUTE is used for the OSPF protocol only and AUTOLOG is not configured correctly (see step [“2” on page 325](#)), OMPROUTE is periodically restarted and the following messages are displayed:

```
$HASP100 OMPROUTE ON STCINRDR
$HASP373 OMPROUTE STARTED
IEF403I OMPROUT1 - STARTED
 OMPROUT1 OMPROUTE BPXBATCH 0000
EZZ7800I OMPROUTE STARTING
EZZ7872I OMPROUTE FOUND ANOTHER ROUTING APPLICATION ALREADY
ACTIVE
EZZ8074I OMPROUTE PROCESSING ERROR
EZZ7805I OMPROUTE EXITING ABNORMALLY - RC(11)
OMPROUT1 *OMVSEX BPXPRECP 0011
IEF404I OMPROUT1 - ENDED
$HASP395 OMPROUT1 ENDED
```

- If a configuration statement in the OMPROUTE configuration file has a missing semicolon, the syntax checker might issue the following message:

```
EZZ7830I SYNTAX ERROR AT LINE 22 OF OMPROUTE CONFIGURATION FILE
PROCESSING END OF FILE
```

- If policy-based routing is in use, see the Netstat ALL/-A command report to determine the policy-based routing information in use by a TCP connection or UDP socket. If the value Yes is displayed for RoutingPolicy, then the RoutingTableName and RoutingRuleName values reflect the last traffic attempted to be sent by the displayed TCP connection or UDP socket. RoutingRuleName displays the name of the routing policy rule that was last mapped to the traffic sent by the displayed TCP connection or UDP socket. RoutingTableName displays the name of the route table that was used to select the route for the last traffic that was sent by the displayed TCP connection or UDP socket. This value can be the name of a policy-based route table that is associated with the displayed RoutingPolicyRule, EZBMAIN if the main route table was used, or \*NONE\* if a route was not found.

If no traffic was sent or the last traffic sent did not map to a configured routing rule, the value No is displayed for RoutingPolicy. RoutingTableName and RoutingRuleName are not included in the display when RoutingPolicy has the value No.

## Verifying connections with Netstat, Ping, and Traceroute

The interfaces were verified with the instructions in Chapter 2, [“IP configuration overview,” on page 11](#). The first thing to verify is that the devices and interfaces are started. In the case of point-to-point links like the CTCs in TCPCS4, the following message is written to the z/OS console when the device starts:

```
EZZ4313I INITIALIZATION COMPLETE FOR DEVICE CTCE02
```

In the case of IPv6 interfaces like OSAQDIO46 in TCPCS4, the following message is written to the z/OS console when the interface starts:

```
EZZ4340I INITIALIZATION COMPLETE FOR INTERFACE OSAQDIO46
```

The same information can be determined by using the Netstat DEvlinks/-d command. The following example is a portion of the output of the Netstat DEvlinks/-d command with the CTCE02 device shown as ready. The Netstat DEvlinks/-d command can be issued on TCPCS4 and TCPCS7 to verify that the devices on both systems are ready.

```
DevName: CTCE02 DevType: CTC DevNum: 0E00
DevStatus: Ready
LnkName: CTC4T07 LnkType: CTC LnkStatus: Ready
NetNum: 0 QueSize: n/a
ActMtu: 32760
Routing Parameters:
MTU Size: 01500 Metric: 01
DestAddr: 0.0.0.0 SubnetMask: 255.255.255.0
Multicast Specific:
Multicast Capability: Yes
GROUP REFCNT

224.0.0.5 0000000001
224.0.0.1 0000000001
Link Statistics:
BytesIn = 488
Inbound Packets = 0
Inbound Packets In Error = 0
Inbound Packets Discarded = 0
Inbound Packets With No Protocol = 0
BytesOut = 1092
Outbound Packets = 0
Outbound Packets In Error = 0
Outbound Packets Discarded = 0
```

The following example is a portion of the output of the Netstat DEvlinks/-d command with an IPv6 interface (OSAQDIO46) shown as ready.

```
IntfName: OSAQDIO46 IntfType: IPAQENET6 IntfStatus: Ready
NetNum: n/a QueSize: 0 Speed: 0000001000
MacAddress: 0002559A3F65
DupAddrDet: 1
CfgRouter: Non ActRouter: Non
CfgMtu: None ActMtu: 8992
Multicast Specific:
Multicast Capability: Yes
RefCnt Group

0000000001 ff02::1:ff03:1
0000000002 ff02::1
Interface Statistics:
BytesIn = 592
Inbound Packets = 0
Inbound Packets In Error = 0
Inbound Packets Discarded = 0
Inbound Packets With No Protocol = 0
BytesOut = 1008
Outbound Packets = 0
Outbound Packets In Error = 0
Outbound Packets Discarded = 0
```

If the devices do not have a LnkStatus or IntfStatus of Ready, this must be resolved before continuing. There are several things that might cause the LnkStatus or IntfStatus to not be ready. For example, the device might not be defined to z/OS correctly, the device might not be defined in PROFILE.TCPIP correctly, and so on.

You can use the PING command to verify indirect routes exist to others hosts within the network .

```
ping 9.67.107.7
CS V2R5: Pinging host 9.67.107.7
Ping #1 response took 0.048 seconds.(48.012 milliseconds)
READY
ping 2001:0db8:0:a1b:2:559a:3f65:3
CS V2R5: Pinging host 2001:0db8:0:a1b:2:559a:3f65:3
```

```
Ping #1 response took 0.051 seconds.(51.012 milliseconds)
READY
```

Use the Traceroute command to verify that the correct route is being taken for each indirectly attached host:

```
tracerte 9.67.107.5
CS V1R6: Traceroute to 9.67.107.5 (9.67.107.5)
 1 9.67.106.7 (9.67.106.7) 40 ms 7 ms 6 ms
 2 9.67.107.5 (9.67.107.5) 9 ms 8 ms 9 ms
READY
```

The following example shows IPv6 for indirectly attached hosts:

```
tracerte 2001:0db8:0:a1c:2:36a4:b39a:7
CS V1R6: Traceroute to 2001:0db8:0:a1c:2:36a4:b39a:7
at IPv6 address: 2001:0db8:0:a1c:2:36a4:b39a:7
 1 fe80::1:2:3:4
 (fe80::1:2:3:4) 13 ms 25 ms 40 ms
 2 2001:0db8:0:a1c:2:36a4:b39a:7
 (2001:0db8:0:a1c:2:36a4:b39a:7) 29 ms 263 ms 196 ms
```

---

## Chapter 7. Virtual IP Addressing

This topic contains information about the following subtopics:

- Terminology
- Introduction to VIPA
- Moving VIPA (Upon outage of TCP/IP)
- Static VIPAs, dynamic VIPAs (DVIPAs), and distributed dynamic VIPAs
- Using static VIPAs
- Using dynamic VIPAs (DVIPAs)
- Choosing which form of dynamic VIPA to use
- Configuring distributed DVIPAs — sysplex distributor
- Resolution of DVIPA conflicts
- IPv6 considerations
- Other considerations
- Example of configuring dynamic and distributed VIPAs
- Verifying the DVIPAs in a sysplex
- Verifying sysplex distributor workload
- DVIPAs and routing protocols

**Note:** This information applies to both IPv4 and IPv6, unless otherwise noted.

---

### Terminology

#### Virtual IP Address (VIPA)

A VIPA is a generic term that refers to an internet address on a z/OS host that is not associated with a physical adapter. There are two types of VIPAs:

- A *Static VIPA* cannot be changed except through a VARY TCPIP,,OBEYFILE operator command.
- A *dynamic VIPA (DVIPA)* can move to other TCP/IP stack members in a sysplex or it can be activated by an application program, an instance of z/OS Container Extensions, or by a supplied utility. Dynamic VIPAs are used to implement sysplex distributor as described in [“Considerations for VIPA” on page 56](#).

A unique type of application instance dynamic VIPA, referred to as the IBM z/OS Container Extensions (zCX) DVIPA is created for each IBM z/OS Container Extensions address space. For more information about z/OS Container Extensions, see [“IBM z/OS Container Extensions network overview” on page 132](#).

#### Distributed DVIPA

A distributed DVIPA, which is a special type of DVIPA, can distribute connections within a sysplex.

#### Dynamic routing

VIPAs are designed to interoperate with a dynamic routing daemon. Therefore, it is highly recommended that a routing daemon be used on a z/OS host that uses VIPAs.

---

### Introduction to VIPA

Traditionally, an IP address is associated with each end of a physical link (or each point of access to a shared-medium LAN), and the IP addresses are unique across the entire visible network, which can be the Internet or a closed intranet. The majority of IP hosts have a single point of attachment to the network, but some hosts (particularly large server hosts) have more than one link into the network. A TCP/IP host with multiple points of attachment also has multiple IP addresses, one for each link.

Within the IP routing network, failure of any intermediate link or adapter disrupts user service only if there is not an alternate path through the routing network. Routers can route IP traffic around failures of intermediate links in such a way that the failures are not visible to the end applications or IP hosts. However, because an IP packet is routed based on ultimate destination IP address, if the adapter or link associated with the destination IP address fails, there is no way for the IP routing network to provide an alternate path to the stack and application. Endpoint (source or destination) IP adapters and links thus constitute single points of failure. While this might be acceptable for a client host, where only a single user will be cut off from service, a server IP link might serve hundreds or thousands of clients, all of whose services would be disrupted by a failure of the server link.

The virtual IP address (VIPA) removes the adapter as a single point of failure by providing an IP address that is associated with a stack without associating it with a specific physical network attachment. Because the virtual device exists only in software, it is always active and never experiences a physical failure. A VIPA has no single physical network attachment associated with it. Also, with the exception of a zCX DVIPA, the TCP/IP stack does not maintain interface counters for VIPA interfaces (VIRTUAL links).

To the routing network, a VIPA appears to be a host address indirectly attached to the z/OS. When a packet with a VIPA destination reaches the stack, the IP layer recognizes the address and passes it to the protocol layer in the stack.

The failure of the physical interface can be extended to the failure of the TCP/IP address space, the entire z/OS, or for planned outages. A VIPA just needs to move to a backup stack, and the routes to the VIPA need to be updated. Then clients can transparently connect to the backup stack. This process is known as VIPA takeover.

VIPA takeover improved with the introduction of dynamic virtual IP address (DVIPA) and distributed dynamic virtual IP address (distributed DVIPA). The DVIPA function improves VIPA takeover by allowing a system programmer to plan for system outages and provide for backup systems to take over without operator intervention or external automation. The distributed DVIPA function allows the connections for a single DVIPA to be serviced by applications on several stacks listed in the configuration statement (the distribution list). This adds the benefit of limiting the scope of an application or stack failure, while also providing enhanced work load balancing.

In general, z/OS configured with VIPA provides the following advantages:

- Automatic and transparent recovery from device and adapter failure.

When a device (for example, a channel-attached router) or adapter (for example, an OSA adapter) fails, if there is another device or link that provides the alternate paths to the destination:

- IP will detect the failure, find an alternate path for each network, and route outbound traffic to hosts and routers on those networks via alternate paths.
- Inbound and outbound traffic will not need to reestablish the active TCP connections that were using the failed device.
- For connection requests originating at a z/OS TCP/IP stack, tolerance of device and adapter failures can be achieved by using source VIPA addressing.

- Recovery from z/OS TCP/IP stack failure (where an alternate z/OS TCP/IP stack has the necessary redundancy).

Assuming that an alternate stack is installed to serve as a backup, the use of VIPAs enables the backup stack to activate the VIPA address of the failed stack.

Connections on the failed primary stack will be disrupted but they can be reestablished on the backup using the same IP address as the destination. In addition, the temporarily reassigned VIPA address can be restored to the primary stack after the cause of failure has been removed.

- Limited scope of a stack or application failure.

If a DVIPA is distributed among several stacks, the failure of only one stack affects only the subset of clients connected to that stack. If the distributing stack experiences the failure, a backup assumes control of the distribution and maintains all existing connections.

- Enhanced workload management through distribution of connection requests.

With a single DVIPA being serviced by multiple stacks, connection requests and associated workloads can be distributed across multiple z/OS images, according to Workload Manager (WLM) and Service Level Agreement policies (for example, QOS) or according to configured active connection distribution goals.

- Allows the non-disruptive movement of an application server to another stack so that workload can be drained from a system in preparation for a planned outage.

## Moving a VIPA (for TCP/IP outage)

---

While a VIPA provides non-disruptive rerouting of IP data during failure of a physical interface, termination of the stack or the associated z/OS (including planned outages) will disrupt connections or UDP sessions to applications on the terminated stack. While failure of the TCP connection or UDP session will be visible to the clients, the duration of the outage is determined by how long the client application is unable to reconnect to an appropriate server application. Because it is common in large enterprises to have multiple instances of an application on different z/OS images, if the VIPA address can be moved to another stack that supports the application, the clients can reconnect and the perceived outage will be over.

An IP address associated with a particular physical device is unavailable until the owning stack is restarted; however, a VIPA is not associated with any particular physical interface. If termination of a stack is detected and a suitable application already is active on another stack, the VIPA can be moved. Connections on the terminated stack will be disrupted, but they can be reestablished on the backup stack using the original VIPA.

Movement of a static VIPA to a backup stack can be accomplished by using VARY TCPIP,,OBEYFILE commands on the backup. The data set specified on the command must contain an appropriate set of DEVICE, LINK, HOME, and optionally, BSDROUTINGPARMS statements for IPv4 static VIPAs or INTERFACE statements for IPv6 static VIPAs. If OMROUTE is used as the routing daemon, an appropriate interface statement is needed in the OMROUTE configuration file. If the TCP/IP configuration file with the statements defining the VIPA is created in advance, the transfer can be accomplished via automation. This procedure is documented in [z/OS Communications Server: IP Configuration Reference](#). Movement of a DVIPA, on the other hand, can be accomplished by configuring a stack to back up a specific DVIPA that is defined on another stack. In this case, failure of the defining stack causes the DVIPA to move without operator intervention or extra automation. See [“Planning for dynamic VIPA takeover” on page 397](#) for more information. Regardless of the type of VIPA to be moved, it is up to the system programmer or operator to ensure that the VIPA is moved to a backup stack that has the appropriate server applications.

In the absence of a failure, a VIPA is just like any other IP address, and routing for a VIPA is the same as for an IP address associated with a physical link.

## Static VIPAs, dynamic VIPAs, distributed DVIPAs

---

z/OS TCP/IP stack supports two types of VIPAs: static and dynamic. Dynamic VIPAs (DVIPAs) can be used to distribute connections in a sysplex. This is referred to as a distributed DVIPA.

All three VIPAs can coexist on a given stack, but there are differences in how these VIPAs are configured and used.

Static VIPAs have the following characteristics:

- They can be activated during TCP/IP initialization or VARY TCPIP,,OBEYFILE command processing, and are configured using an appropriate set of DEVICE, LINK, HOME, and optionally, OMROUTE configuration statements or BSDROUTINGPARMS statements for IPv4 Static VIPAs or INTERFACE statements for IPv6 Static VIPAs.
- Using the SOURCEVIP configuration option, static VIPAs can be used as the source IP address for outbound datagrams for TCP, RAW, UDP (except routing protocols), and ICMP requests. For IPv6 static VIPAs to be used as source addresses, the SOURCEVIP configuration option must be enabled and the VIPA interface must appear on the SOURCEVIP keyword on some other INTERFACE statement.

This provides tolerance of device and adapter failures for connection requests originating at a z/OS TCP/IP stack.

- They can be specified as the source IP address for outbound TCP connection requests for all applications using this stack with TCPSTACKSOURCEVIPA.
- They can be specified as the source IP address for outbound TCP connection requests for specific jobs or specific destinations through the use of the SRCIP profile statement block.
- The number of static VIPAs on a stack is limited only by the range of host IP addresses that are available for that host.
- They can be moved to a backup stack after the original owning stack has failed, by using VARY TCPIP,,OBEYFILE command processing to configure the VIPA on the backup stack and updating the routers.

Dynamic VIPAs have the following characteristics:

- They can be configured to be moved dynamically from a failing stack to a backup stack within the same sysplex without operator intervention or external automation.
- They can be moved manually by deactivating or reactivating them with the VARY TCPIP,,SYSPLEX operator command.
- They can be dynamically activated by an application program.
- They can distribute connections within a sysplex.
- They can be specified on a TCPSTACKSOURCEVIPA statement. This allows a user to specify one VIPA to be used as the source IP address for outbound datagrams for TCP-only requests.
- They can be specified as the source IP address for outbound TCP connection requests for specific jobs or specific destinations by using the SRCIP profile statement block.
- Unlike static VIPAs, dynamic VIPAs:
  - Are limited to 1024 per stack.
  - Cannot be specified as the VIPA used by Enterprise Extender for connectivity purposes. (See [“Configuring static VIPAs for Enterprise Extender”](#) on page 396 for details.)

Distributed DVIPAs have the following characteristics:

- They have all the characteristics of DVIPAs, except that they cannot be dynamically activated by an application program.
- One stack defines a DVIPA and advertises its existence to the network. Stacks in the target distribution list activate the DVIPA and accept connection requests.
- Connection workload can be distributed across several stacks.

See [“Configuring distributed DVIPAs - sysplex distributor”](#) on page 410 for more detailed descriptions.

**Guideline:** OSA devices have a limit on the number of IP addresses (both IPv4 and IPv6 addresses) that can be registered to the device. The limit is dependent on the microcode level of the OSA device. This limit applies across all TCP/IP stacks that share the OSA device. When defining a large number of VIPAs, take care not to exceed this limit. If the limit is exceeded, IP addresses beyond the limit will not be registered with the OSA devices, and incoming packets with those IP addresses will not be routed to the correct stack unless that stack is designated as the primary router.

## Using static VIPAs

---

The following topics describe how to configure static VIPAs, the special case of static VIPAs and Enterprise Extender, and how to implement static VIPA takeover.

Because a VIPA is associated with a z/OS TCP/IP stack and it is not associated with a specific physical network attachment, it can be moved to a stack on any image in the sysplex or even to any z/OS TCP/IP stack if the address fits into the network configuration.

## Steps for configuring static VIPAs for a z/OS TCP/IP stack

A virtual IP address (VIPA) is an internet address on a z/OS host that is not associated with a physical adapter. A VIPA removes the adapter as a single point of failure by providing an IP address that is associated with a stack without associating it with a specific physical network attachment.

### Procedure

Perform the following steps to configure a static VIPA address in one stack:

1. When configuring static VIPAs for the IPv4 network, add an INTERFACE statement of type VIRTUAL for each static VIPA to be defined. Alternatively, add DEVICE, LINK, HOME, and optionally BSDROUTINGPARMS statements for each static VIPA to be defined. When configuring static VIPAs for the IPv6 network, add INTERFACE statements of type VIRTUAL6 for each static VIPA to be defined.

#### Notes:

- a. A VIPA link or VIPA interface cannot be coded on a static route in the BEGINROUTES statement.
  - b. If you want to add a static VIPA in an IPv4 network with an address that already exists in the HOME list, you must first delete the existing address using the VARY TCPIP,,OBEYFILE command with the existing address omitted from the HOME list. Then use the VARY TCPIP,,OBEYFILE command with a new and complete HOME list.
2. For IPv4 networks, if tolerance of device and adapter failures is wanted for connection requests that originate at a z/OS TCP/IP stack, specify the SOURCEVIPAs option on the IPCONFIG statement.

#### Tips:

- For the SOURCEVIPAs option to work properly, the receiving nodes in the network must be configured to recognize the SOURCEVIPAs addresses using the static or dynamic routing protocols. Otherwise, timeouts for the connection or request responses will occur as a result of the VIPA addresses being network unreachable.
- If TCPSTACKSOURCEVIPAs is specified on the IPCONFIG statement, it overrides SOURCEVIPAs for outbound IPv4 TCP connections. If the SRCIP profile statement block is defined to establish one or more job-specific or destination-specific source IPv4 addresses, these IP addresses override TCPSTACKSOURCEVIPAs or the VIPAs in the HOME list for IPCONFIG SOURCEVIPAs, or both, for the specified job names and destinations. For information about the hierarchy of various ways that the source IP address of an outbound connection is determined, see [“Source IP address selection” on page 272](#).

For more information on configuring IPv4 SOURCEVIPAs or TCPSTACKSOURCEVIPAs addresses on the [IPCONFIG statement](#) statement, or SRCIP addresses in the [SRCIP statement](#) statement block, see [z/OS Communications Server: IP Configuration Reference](#).

3. For IPv6 networks, if tolerance of device and adapter failures is wanted for connection requests that originate at a z/OS TCP/IP stack, specify the following option or keyword:
  - The SOURCEVIPAs option on the IPCONFIG6 statement.
  - The SOURCEVIPAsINT keyword with a VIPA interface name on the INTERFACE statements of the real (physical) interfaces, or on the DYNAMICXCF specification on the IPCONFIG6 statement.

#### Tips:

- For the SOURCEVIPAs option to work properly, the receiving nodes in the network must be configured to recognize the SOURCEVIPAsINT addresses using the static or dynamic routing protocols. Otherwise, timeouts for the connection or request responses will occur as a result of the VIPA addresses being network unreachable.
- If the TCPSTACKSOURCEVIPAs parameter is specified on the IPCONFIG6 statement, it overrides the SOURCEVIPAs value for outbound IPv6 TCP connections. If the SRCIP profile statement block is defined to establish one or more job-specific or destination-specific source IPv6 addresses, these IP addresses override the TCPSTACKSOURCEVIPAs value, the SOURCEVIPAsINT value, or both, for the specified job names and destinations. For information about the hierarchy of various ways that the

source IP address of an outbound connection is determined, see [“Source IP address selection”](#) on page 272.

For more information on configuring IPv6 SOURCEVIPA or TCPSTACKSOURCEVIPA addresses on the IPCONFIG6 statement, or SRCIP addresses in the [SRCIP statement](#) statement block, see [z/OS Communications Server: IP Configuration Reference](#).

4. For host name resolution of a VIPA address, configure the domain name servers to associate the host name with the VIPA.
5. Configure the routing daemon to advertise the presence of the VIPA.

As described in prior steps, remember that the VIPA to be advertised can be determined by the SOURCEVIPA or TCPSTACKSOURCEVIPA parameters on the IPCONFIG statement and IPCONFIG6 statements, or by the SRCIP statement statement. For more information, see [z/OS Communications Server: IP Configuration Reference](#).

## Results

Figure 53 on page 394 illustrates a simple configuration showing multiple network attachments using a single static VIPA address. Because any other network interface can be used with static VIPA's, see [“Setting up physical characteristics in PROFILE.TCPIP”](#) on page 278 for descriptions of other network interfaces. The simple configuration will be used as the TCPCS6 system throughout this information.

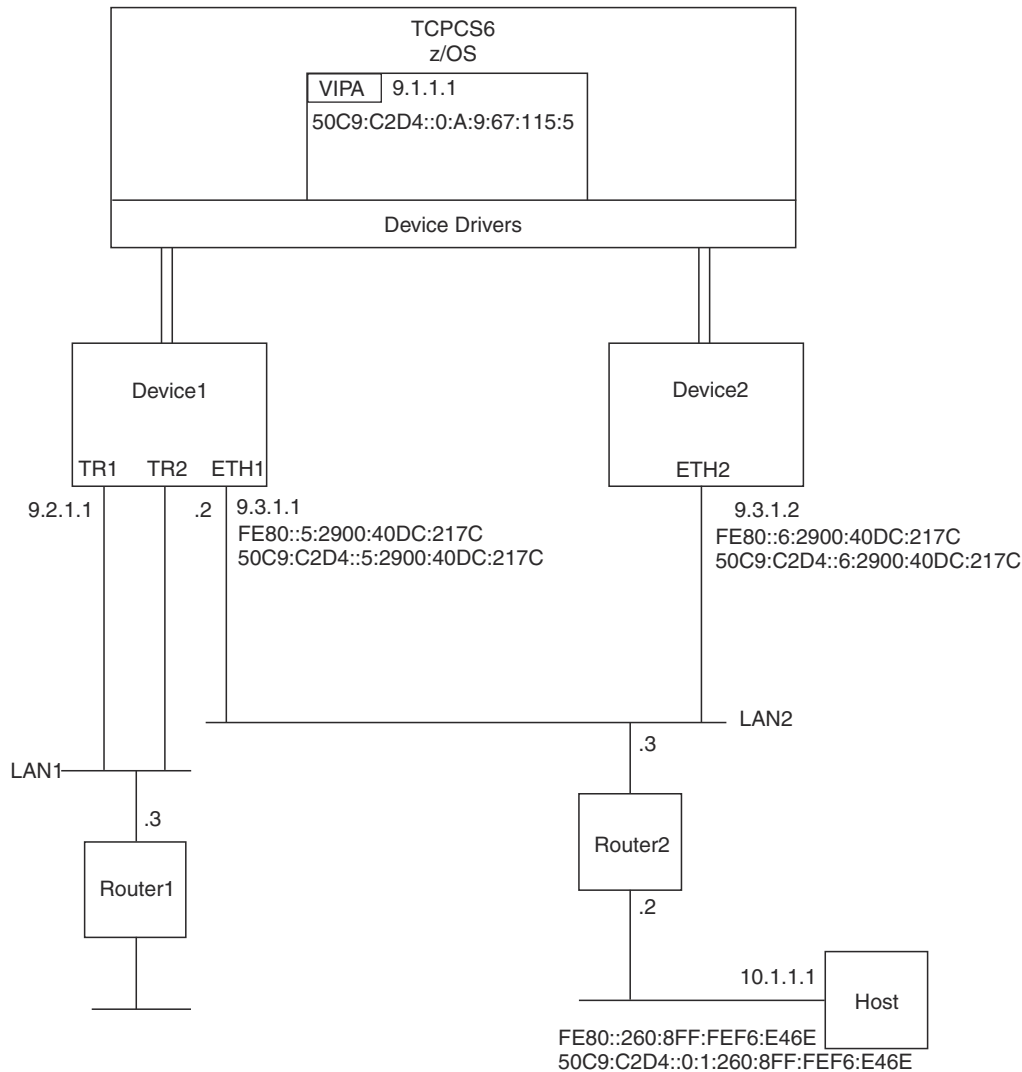

Figure 53. Static VIPA configuration

## Steps for converting from IPv4 VIRTUAL DEVICE, LINK, and HOME definitions to the IPv4 VIRTUAL INTERFACE statement

You can use the INTERFACE statement in the TCP/IP profile to configure IPv4 definitions for static VIPAs rather than using the DEVICE, LINK, and HOME statements. Using the INTERFACE statement simplifies stack configuration for VIRTUAL interfaces.

### Before you begin

If a static VIPA is being used as a source VIPA for any IPv4 interfaces that are configured using DEVICE and LINK statements, then you cannot convert that static VIPA to an IPv4 INTERFACE statement.

### Procedure

Perform the following steps to convert your TCP/IP profile so that it uses the INTERFACE statement to configure IPv4 definitions for static VIPAs.

1. Convert the IPv4 VIRTUAL DEVICE, LINK, and HOME statements to an IPv4 VIRTUAL INTERFACE statement.

The values used in the following substeps are based on the sample profile shown in [Figure 54 on page 395](#).

- a. Copy the LINK name (VIPA1 in the example) and specify this name as the interface name on the INTERFACE statement.

**Tip:** When you use the original LINK name as the new INTERFACE name, you do not have to change OMROUTE definitions or the PRIMARYINTERFACE statement.

- b. Copy the VIRTUAL parameter from the LINK statement and specify this parameter after the DEFINE parameter of the INTERFACE statement.
- c. Copy the HOME list entry IP address (201.16.1.1 in the example) and specify this address on the IPADDR parameter of the INTERFACE statement.
- d. Remove the HOME list entry.

Example of the profile before conversion:

```
DEVICE VIPA VIRTUAL 0
LINK VIPA1 VIRTUAL 0 VIPA
;
HOME
 201.16.1.1 VIPA1
```

Example of the profile after conversion:

```
INTERFACE VIPA1
 DEFINE VIRTUAL
 IPADDR 201.16.1.1
```

*Figure 54. Examples of the profile before and after conversion*

**Tip:** Optionally, you can dump the TCP/IP address space and use the CONVERT parameter on the TCPIP CS PROFILE subcommand to display the configuration information at the time of the dump. The resulting output reflects your IPAQENET, IPAQIDIO, and VIRTUAL DEVICE, LINK, and HOME definitions in INTERFACE statement format, which might be helpful in converting your profile to use INTERFACE statements. Review the output before you implement any changes. For more information about using the CONVERT parameter on the TCPIP CS PROFILE, see [z/OS Communications Server: IP Diagnosis Guide](#).

For more information about the IPv4 VIRTUAL INTERFACE statement, see [z/OS Communications Server: IP Configuration Reference](#).

2. Remove any BSDROUTINGPARMS entries for the interface.

## Results

For information about the [TCP/IP profile](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Configuring static VIPAs for Enterprise Extender

Defining at least one static VIPA is required by VTAM to access the IP network. Because VTAM does not move within a sysplex, a dynamic VIPA cannot be used. Enterprise Extender supports the use of multiple static VIPA addresses, and a VIPA address is chosen as follows:

1. VTAM uses the IPADDR value specified on the Enterprise Extender XCA major node GROUP definition statement, or the VIPA address obtained when name-to-address resolution is performed on the HOSTNAME value specified on the Enterprise Extender XCA major node GROUP definition statement.
2. If the GROUP definition statement specifies neither IPADDR nor HOSTNAME, VTAM uses the static VIPA address specified on the VTAM IPADDR start option, or the static VIPA address returned by the resolver when name-to-address resolution is performed on the value of the VTAM HOSTNAME start option.
3. If neither the IPADDR nor the HOSTNAME start option is specified, VTAM uses the first IPv4 static VIPA in the HOME list.

If remote APPN nodes use a host name and not a host address to define the destination of an Enterprise Extender connection, the domain name server must return the VIPA address used by VTAM for the host name. Alternatively, if the Enterprise Extender endpoints are behind a firewall or for another reason require network address translation, the domain name server should return a network address translation (NAT) address. This NAT address should in turn map, on the destination side, to the static VIPA address of the intended target VTAM host.

**Rule:** If you plan on using IPv4 protocols for your Enterprise Extender communication, you must define DEVICE, LINK, and optionally HOME statements for IUTSAMEH, or specify IPCONFIG DYNAMICXCF in the appropriate TCP/IP profile data set. If you plan on using IPv6 protocols for your Enterprise Extender communication, you must define an INTERFACE statement for IUTSAMEH or specify IPCONFIG6 DYNAMICXCF in the appropriate TCP/IP profile data set.

For more information about [using Enterprise Extender](#), see [z/OS Communications Server: SNA Network Implementation Guide](#).

## Considerations when using static VIPAs with IPv6

When static VIPAs are configured for use with IPv6, it is recommended that the prefixes of the IPv6 VIPA addresses be different than the prefixes used for addresses assigned to real interfaces. This reduces the likelihood of address collisions between the manually configured VIPA addresses and the autoconfigured addresses of the real interfaces.

To allow other hosts that share links with the z/OS TCP/IP stack to access the IPv6 VIPA addresses, without the need for manual route configuration, a router on each of the links should include the VIPA prefix in its router advertisements. The router advertisements should define the prefix as being on-link and should indicate that the prefix should not be used for autoconfiguration.

## Planning for static VIPA takeover and takeback

Because a VIPA is associated with a z/OS TCP/IP stack and is not associated with a specific physical network attachment, it can be moved to a stack on any image in the sysplex or even to any z/OS TCP/IP stack as long as the address fits into the network configuration. Moving a static VIPA can be done manually by an operator or by customer-programmed automation. Movement of the static VIPA allows other hosts that were connected to the primary stack to reestablish connections with a backup TCP/IP stack using the same VIPA. After the primary TCP/IP stack has been restored, the reassigned VIPA address can be moved back.

Consider the following items when backing up and restoring a z/OS TCP/IP stack:

- All connections on the failing host will be disrupted.

- The client can use any ephemeral port number when reestablishing the connection to the backup server.
- Having a different port number for the backup and primary server is not recommended. For example, if the primary FTP used port 21 and the backup FTP used port 1021, when backing up and restoring a z/OS TCP/IP stack, the client would have to know whether to use port 21 or 1021.

If you are deploying both static VIPA and OSA, see [“VIPAs, OSA, and Spanning Tree Protocol” on page 444](#) to determine whether or not network bridge or switch configuration settings might potentially impact the environment for VIPA takeover and takeback.

## Using dynamic VIPAs

---

Dynamic VIPA (DVIPA) support allows:

- Dynamic movement of a VIPA from a failing TCP/IP stack to a backup stack
- Dynamic allocation of a VIPA by an application program
- Manual movement of a VIPA by deactivating or reactivating it with the VARY TCPIP,,SYSPLEX command

Dynamic VIPAs (DVIPAs) are IP addresses like all other IP addresses associated with a TCP/IP, and they appear as though they had been defined at the end of the HOME list.

Dynamic VIPAs can be either IPv4 or IPv6, and both can be configured within the same VIPADYNAMIC block. A single statement (for example, VIPADEFINE or VIPABACKUP) must contain either IPv4 addresses or IPv6 addresses, but not both. However, statements that contain IPv4 addresses can be intermixed with statements that contain IPv6 addresses within the same VIPADYNAMIC block in any manner wanted.

## Configuring DVIPA support

Unlike static VIPAs, DVIPAs are not configured by using DEVICE, LINK, and HOME statements (for IPv4) or by using INTERFACE statements (for IPv6). The configuration statements for the DVIPA support are contained within the VIPADYNAMIC block and consist of the following statements:

- VIPADEFINE and VIPABACKUP statements that are used to configure DVIPAs to be dynamically moved from a failing TCP/IP to a backup TCP/IP
- VIPARANGE used to specify a range of IP addresses which can be dynamically activated as a VIPA by:
  - an application program
  - a z/OS Container Extensions address space (using the VIPARANGE ZCX keyword)
- VIPADELETE used to delete existing DVIPAs
- VIPADISTRIBUTE used to configure a DVIPA as a distributed DVIPA and designate the target stacks

The following topics discuss how these statements are used to provide the DVIPA support. For syntax details, see [z/OS Communications Server: IP Configuration Reference](#). For more information, see *IBM z/OS V1R13 Communications Server TCP/IP Implementation, Volume 3: High Availability, Scalability, and Performance*, SG24–7998.

When dynamically created DVIPAs are deleted, any applications that are bound to those DVIPAs (VIPARANGE or MODDVIPA) receive an asynchronous error, EUNATCH (3448) - the protocol required to support the address family is unavailable.

## Planning for dynamic VIPA takeover

Movement by network management automation or operator intervention is not always desirable. Operator intervention takes time and is subject to errors. Automation requires correct detection of the failure and is also prone to error if the failure does not produce the exact console messages anticipated.

The dynamic VIPA takeover function addresses this problem. It is important to understand that dynamic VIPA takeover does not introduce functions that could not be accomplished by operator action or automation. It just removes the dependency on human detection of the error or customer programming for automation. Dynamic VIPA takeover is completely accomplished by the TCP/IP stacks.

DVIPA takeover is possible when a DVIPA is configured as active (using VIPADefine) on one stack and as backup (using VIPABackup) on another stack within the sysplex. When the stack on which the DVIPA is active terminates or leaves the sysplex group, the backup stack automatically activates the DVIPA and notifies the routing daemon. For information on what causes a stack to leave the sysplex group, see [“Sysplex problem detection and recovery”](#) on page 480.

For DVIPA takeover to be useful, the applications that service the DVIPA addresses must be available on the backup stacks. In the absence of the application, the DVIPA will be active, but client connections to the application will still fail. If OMROUTE is used, it is recommended that GLOBALCONFIG SYSPLEXMONITOR DELAYJOIN be configured. This causes DVIPA takeover to be delayed until OMROUTE is active and able to advertise DVIPAs on the takeover stack. For more information on how DELAYJOIN works, see [“Sysplex problem detection and recovery”](#) on page 480.

To preserve connections during DVIPA takeover, the TCP/IP stacks require XCF links. The DYNAMICXCF option must be coded in the TCP/IP profile of both stacks.

A determination of how the workload will be distributed among the backup stacks when the primary stack fails should be made. It is possible to designate a single stack as a backup and move all the workload to it, or the workload can be distributed among several stacks. In the first case, you need to configure only one DVIPA with a VIPADefine statement on the primary stack, and only one VIPABackup statement is required on the backup stack. For the second option, you must configure multiple DVIPAs with a VIPADefine statement on the primary stack.

After determining the workload distribution, each of the secondary stacks will require a VIPABackup statement for the DVIPA it will be supporting.

The following example shows how to implement a single stack backup for multiple applications.

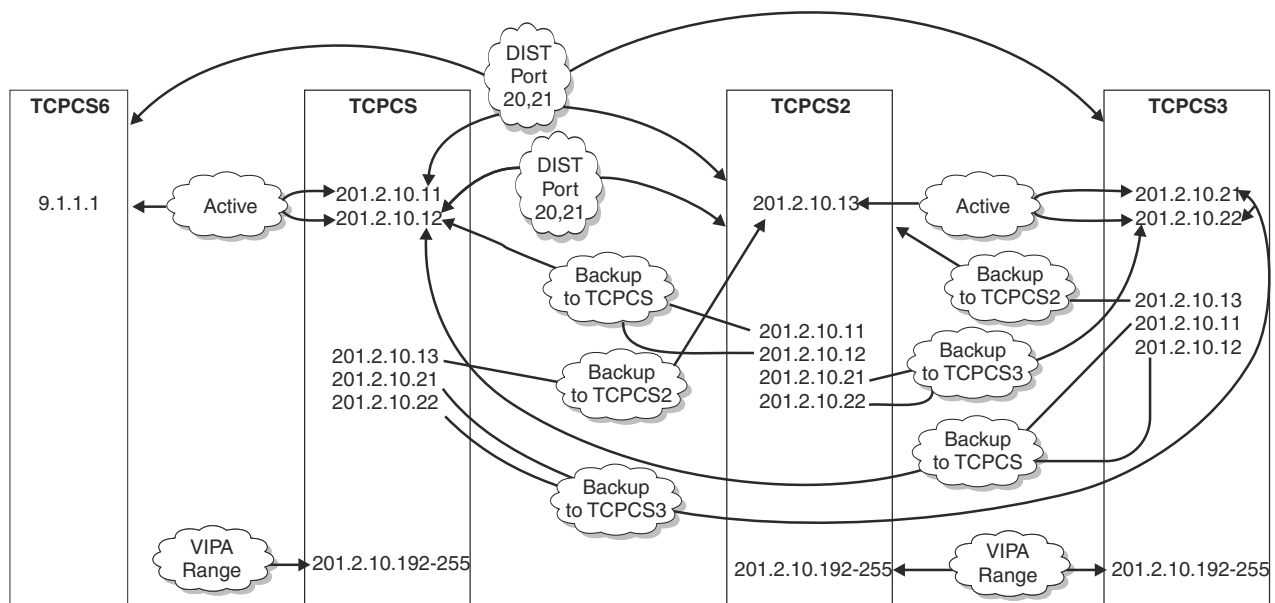

Figure 55. Sample DVIPA addressing in a sysplex environment

#### Stack TCPCS:

```
Uses VIPADefine to define 201.2.10.11
Has a Web server running that binds to INADDR_ANY.
 Web client programs use 201.2.10.11 as their destination address.
Has an FTP server running that binds to INADDR_ANY.
 FTP client programs use 201.2.10.11 as their destination address.
```

#### Stack TCPCS3:

```
Uses VIPABackup to define 201.2.10.11 as backup for stack TCPCS.
Has a Web server running that binds to INADDR_ANY.
Has an FTP server running that binds to INADDR_ANY.
```

In the preceding scenario, when stack TCPCS goes down, stack TCPCS3 receives all new connection requests for both the web and FTP servers. FTP and web client programs continue to use 201.2.10.11 as their destination address, but they now connect to stack TCPCS3.

The following example shows how to implement a multiple stack backup for multiple applications.

Stack TCPCS:

```
Uses VIPADEFINE to define 201.2.10.11 and 201.2.10.12
Has a Web server running that binds to INADDR_ANY.
 Web client programs use 201.2.10.11 as their destination address.
Has an FTP server running that binds to INADDR_ANY.
 FTP client programs use 201.2.10.12 as their destination address.
```

Stack TCPCS2:

```
Uses VIPABACKUP to define 201.2.10.11 as backup for stack TCPCS.
Has a Web server running that binds to INADDR_ANY.
```

Stack TCPCS3:

```
Uses VIPABACKUP to define 201.2.10.12 as backup for stack TCPCS.
Has an FTP server running that binds to INADDR_ANY.
```

In the preceding scenario, when stack TCPCS goes down, new connections for the web server at 201.2.10.11 will connect with stack TCPCS2, and new connections for the FTP server at 201.2.10.12 will connect with stack TCPCS3.

## Manually initiating takeover for an individual dynamic VIPA

There might be times when you want a takeover to occur for an individual DVIPA for temporary, operational purposes, such as dealing with temporary shifts in available capacity. An operator command, `VARY TCPIP,,SYSPLEX,DEACTIVATE`, is provided to deactivate an active `VIPADEFINE` DVIPA so that it appears to have been deleted from the stack. This enables an already-configured backup stack to takeover the DVIPA. This command also saves the original configuration definition.

When you want to move the DVIPA back to the original stack, you can issue another operator command, `VARY TCPIP,,SYSPLEX,REACTIVATE`, on the original stack to cause the DVIPA to be redefined with its saved configuration. This causes a `VIPADEFINE` DVIPA to be activated again on the original stack, and causes the backup stack to relinquish ownership of the DVIPA and return to being a backup stack.

The following example shows how to deactivate a DVIPA:

```
VARY TCPIP,,SYSPLEX,DEACTIVATE,DVIPA=203.1.1.99
```

The following example shows how to reactivate a DVIPA that has been deactivated:

```
VARY TCPIP,,SYSPLEX,REACTIVATE,DVIPA=203.1.1.99
```

Deactivating a DVIPA can be done only for DVIPAs that have been configured on the stack with `VIPADEFINE` or `VIPABACKUP`. You cannot deactivate a `VIPARANGE` DVIPA created by `BIND`, the `SIOCSVIP` or `SIOCSVIP6` `ioctl` command, or the `MODDVIPA` utility. When you deactivate a DVIPA, if there are any existing connections to the DVIPA on this stack and there is another stack able to maintain the connections, the DVIPA is kept in `QUIESCING` status until the last connection terminates, and then the DVIPA is deactivated.

You can also use these operator commands to deactivate and reactivate a backup DVIPA. If you deactivate a DVIPA that is in backup status, it makes that stack ineligible to takeover the DVIPA. Reactivating a `VIPABACKUP` DVIPA makes the stack eligible again to takeover the DVIPA.

While a DVIPA is deactivated it still appears in the Netstat VIPADCFG/-F report, where it is identified as deactivated, but it does not appear in any other Netstat reports unless the DVIPA is in QUIESCING status or this stack is a target for that DVIPA from some other distributing stack.

## Different application uses of IP addresses and DVIPAs

Not all IP-based server applications relate to IP addresses in the same way. Automated movement of DVIPAs, and the planning for dynamic VIPA takeover, must take this difference into account.

Some IPv4 or IPv6 applications, such as FTP or the TN3270E Telnet server (Telnet) will accept client requests on any IP address by binding to INADDR\_ANY or the IPv6 unspecified address (in6addr\_any). The distinguishing feature of such an application is the function it provides, such as the particular set of SNA applications for Telnet. If the function is replicated across multiple z/OS images in the sysplex, as is often the case for distributed workload, the DVIPA must merely be moved to a stack supporting the application. This scenario is called the multiple application-instance scenario. For the multiple application-instance scenario, the stacks in the sysplex do all the work of activating a DVIPA in the event of a failure.

For other types of applications, each application instance must have a unique IP address. This scenario is called the unique application-instance scenario and uses DVIPAs that are activated with an `ioctl` or a `bind()`.

To maintain the relationship between an application instance and its DVIPA, the application must indicate to the stack that the DVIPA needs to be activated. This occurs in the following cases:

- When the application instance issues a `bind()` function call and specifies an IP address that is not active on the stack. The stack will activate the address as a DVIPA, provided it meets certain criteria. When the application instance closes the socket, the DVIPA is deleted.
- Some applications cannot be configured to issue `bind()` for a specific IP address, but are unique application-instance scenario applications. For such applications, a utility is provided (MODDVIPA), which issues `SIOCSVIPA` or `SIOCSVIPA6 ioctl()` to activate or deactivate the DVIPA. This utility can be included in a JCL procedure or OMVS script to activate the DVIPA before initiating the application. As long as the same JCL package or script is used to restart the application instance on another node in the event of a failure, the same DVIPA will be activated on the new stack. For information about the authorization required to execute the MODDVIPA utility, see [“Using the MODDVIPA utility” on page 404](#).
- An alternative for unique application-instance scenario server applications that cannot themselves bind to a unique IP address is to use the `BIND` parameter on the `PORT` reservation statement. It is always a good practice to reserve a port for the listening socket of a server application. If the `BIND` parameter and an IP address are specified on the `PORT` reservation statement for a server application, and the application binds a socket to that port and either the IPv4 `INADDR_ANY` address or the IPv6 unspecified address (`in6addr_any`), z/OS TCP/IP will convert the bind to be specific to the IP address specified on the `PORT` reservation statement. From that point on, it will appear as though the application itself had issued the `bind()` specifying the designated IP address, including having the IP address deleted when the server application closes the socket.

## Configuring dynamic VIPAs

To allow continued and unchanged operation of static VIPAs in z/OS TCP/IP, DVIPAs are defined with configuration statements in the `PROFILE.TCPIP` data set. An overview of the relevant configuration statements is provided in the following topics, and also see [“Verifying the DVIPAs in a sysplex” on page 449](#) for a description of the configuration statements. For an example of the `VIPADYNAMIC` configuration statement and display commands for dynamic VIPAs, see [z/OS Communications Server: IP Configuration Reference](#).

## Configuring the multiple application-instance scenario

For the multiple application-instance scenario, each instance is assigned a unique DVIPA. The `VIPADYNAMIC` keyword of the `VIPADYNAMIC` configuration statement is used to create the DVIPA on the stack where the DVIPA is normally expected to be active. When the `VIPADYNAMIC` statement is

processed in a TCP/IP profile, corresponding DEVICE, LINK, HOME, and BSDROUTINGPARMS statements are generated automatically for IPv4 addresses. For IPv6 addresses, an INTERFACE statement is automatically generated. Routing daemons are automatically informed.

Additional configuration is required on other stacks in the sysplex to indicate which stack should take over the DVIPA in the event of a failure. The VIPADYNAMIC statement has a VIPABACKUP keyword for this purpose. A VIPABACKUP configures the DVIPA but does not activate it until it is necessary. Because more than one TCP/IP can back up a single DVIPA, a rank parameter on the VIPABACKUP statement determines the order in which several stacks will assume responsibility for a DVIPA.

The stacks in the sysplex exchange information on all VIPADYNAMICs and VIPABACKUPs defined in the sysplex, so that all are aware of which stack should take over a particular DVIPA. The list of backup stacks for a specific DVIPA can be different from the list of backup stacks for all other DVIPAs.

In the multiple application-instance scenario, instances of the application in question are activated among sysplex nodes according to some plan, presumably related to balancing workload across available capacity. This activation is done independently of VIPA takeover. Configure the associated DVIPAs as follows:

1. For each instance of a particular application to be supported via DVIPA, add a VIPADYNAMIC statement to the TCP/IP profile for the TCP/IP associated with the application instance.
2. For each of the dynamic VIPAs in step 1, determine which application instance or instances should take over the workload (considering probable capacity and any other application-related considerations). If more than one TCP/IP is to provide backup for a DVIPA, determine the order in which the selected TCP/IPs should be designated as backup. Add a VIPABACKUP statement to each TCP/IP that is to provide backup for the DVIPA, with appropriate rank values to determine the order. Do this for each of the DVIPAs in step 1.
3. Perform steps 1 and 2 for each other application to be supported by DVIPAs.

**Note:** It is possible to share a dynamic VIPA among several different applications, but in doing so, ensure that instances of all such applications will exist together on any TCP/IP to which the DVIPA may be moved in case of a failure.

After these steps are complete, start the affected TCP/IPs (or modify their configuration using the VARY TCPIP,,OBEYFILE command), if applicable, configure DNS for the application names, and start the application instances. From that point on, the TCP/IPs in the sysplex will collaborate to ensure that each dynamic VIPA is kept active somewhere within the sysplex as long as there is at least one functioning TCP/IP which has been designated as backup for the dynamic VIPA.

**Note:** The limit of 1024 DVIPAs on a single TCPIP applies to the DVIPAs that are defined by the VIPADYNAMIC or VIPABACKUP configuration statements or by a VIPADISTRIBUTE statement on another stack.

## Configuring the unique application-instance scenario

The unique application-instance scenario ties a DVIPA to a specific instance of an application. To isolate errors in configuring applications, TCP/IP needs a mechanism to identify permissible DVIPAs. This is provided with one or more VIPARANGE statements. The VIPARANGE statement identifies a range of IP addresses which can be activated as DVIPAs by an application instance. Each TCP/IP stack can have up to 4096 VIPARANGE definition statements for both IPv4 and IPv6. The VIPARANGE statement consists of an IPv4 address and subnet mask, or an interface name and an IPv6 address and prefix length, and defines a subnet for DVIPAs. More than one VIPARANGE statement with different ranges can be defined on a TCP/IP. VIPARANGE does not itself cause any DVIPAs to be activated. Rather, DVIPAs are activated either by an application issuing a bind() for a specific IP address, by use of the SIOCSVIPA or SIOCSVIPA6 ioctl() command issued by an authorized application, or by the MODDVIPA utility.

When an application issues bind() for a specific IP address or an address was selected using the BIND keyword on the PORT statement, the receiving stack checks it against addresses in the HOME list. If the IP address has already been activated on this stack (whether for a physical device, a static VIPA, or a dynamic VIPA), the bind() execution is successful. If the IP address is not active on this TCP/IP, the current VIPARANGE statements are checked to see if the IP address falls within one of them. If an

appropriate VIPARANGE is found, the IP address is activated as a DVIPA and the operation succeeds. If no appropriate VIPARANGE is found, or if the IP address is active elsewhere in the sysplex other than by a NONDISRUPTIVE bind(), the request fails and bind() returns EADDRNOTAVAIL.

When an authorized application issues the SIOCSVIPA or SIOCSVIPA6 ioctl() command to create a DVIPA, or when the MODDVIPA utility is executed in JCL or an OMVS script to activate a DVIPA on behalf of an application instance, the current VIPARANGE statements are checked to see whether the IP address falls within one of them. If an appropriate VIPARANGE is found, and the IP address is not currently active on this TCP/IP as a VIPADEFINE/VIPABACKUP dynamic VIPA, then the IP address is activated as a DVIPA. However if no appropriate VIPARANGE is found on this TCP/IP, or if the IP address is currently defined on this TCP/IP or configured elsewhere in the sysplex as a VIPADEFINE/VIPABACKUP dynamic VIPA, then the request fails with errno and errnojr set to indicate the reason for the failure and the utility ends with a nonzero condition code. See [“Dynamic VIPA creation results”](#) on page 434 for more information.

**Tip:** If the requested IP address has been activated as a dynamic VIPA by a bind(), SIOCSVIPA ioctl, or SIOCSVIPA6 ioctl elsewhere in the sysplex, the result depends on how the stacks were configured. See [“Dynamic VIPA creation results”](#) on page 434 for more information.

Application-instance DVIPAs provide high availability features for applications and workloads that exploit them. The creation and movement of these DVIPAs is quite flexible, as it can be triggered without modification to the TCP/IP profile and without issuing TCP/IP operator commands. While this flexibility is useful, it can also present problems for the network administrator in determining when and how a DVIPA is activated on a TCP/IP stack.

To help alleviate these problems, TCP/IP provides auditing facilities to track the state changes of application-instance DVIPAs. When an application-instance DVIPA is created or deleted dynamically through an explicit bind, by executing the MODDVIPA utility or by invoking the SIOCSVIPA or SIOCSVIPA6 ioctl command, messages are issued (EZD1204I, EZD1205I, EZD1206I, or EZD1207I) to the job log of the TCP/IP started procedure and to the system log. These messages include the method (bind, ioctl, or MODDVIPA utility) used to create or delete the DVIPAs, and the job name at the time the bind, ioctl, or MODDVIPA utility was invoked. For more information about EZD1204I, EZD1205I, EZD1206I, and EZD1207I, see [z/OS Communications Server: IP Messages Volume 2 \(EZB, EZD\)](#).

The Netstat VIPADyn/-v report is enhanced for application-instance DVIPAs to include the job name and the time stamp that this DVIPA was activated on the local TCP/IP stack (either because it is the owner of the DVIPA or is a target for this DVIPA). For more details about Netstat VIPADyn/-v, see [z/OS Communications Server: IP System Administrator's Commands](#).

In the unique application-instance scenario, each application instance is assigned a unique IP address as its DVIPA. Before defining individual DVIPAs, one or more blocks of IP addresses must be defined for these DVIPAs, and the individual DVIPAs must be defined from within the blocks. Each block should be represented as a subnet, so that a VIPARANGE statement can be defined for it.

Follow these steps when setting up any unique application instances:

1. For each application instance, assign a DVIPA from one of the blocks of IP addresses for this purpose. Do not assign an IP address which is also assigned to another application instance, or which is defined by VIPADEFINE for the multiple application-instance scenario. Configure the application to use this DVIPA [if it issues bind() for a particular IP address], or add a BIND parameter to the PORT reservation statement for the port of the application's listening socket to cause the listening socket to be bound to this DVIPA. Alternatively, add the MODDVIPA utility to the JCL or OMVS script and configure the MODDVIPA utility to activate the DVIPA before starting the application. When the application ends, use the MODDVIPA utility to delete the DVIPA.
2. For each application instance, determine on which stack the application instance will normally be executed and to which stacks the application instance could be moved in case of failure of the normal stack or the application itself. For each such stack, add a valid VIPARANGE statement to the profile.

**Note:** The dynamic VIPA must be within the VIPARANGE subnet. The broadcast address and the net prefix cannot be used.

3. Perform steps 1 and 2 until all application instances have been allocated a unique DVIPA.

The application restart strategy should ensure that the worst-case failure scenario does not attempt to activate more than 4096 DVIPAs on a single stack. If such an attempt is made, activation of the 4097th DVIPA fails, with possible resulting loss of connectivity from clients to the server application.

**Note:** The limit of 4096 DVIPAs on a single TCP/IP applies to all DVIPAs, whether the DVIPAs are defined by the VIPADefine or VIPABackup configuration statements, by a VIPADISTRIBUTE statement on another stack, by a bind() call, or by executing the MODDVIPA utility.

Defining a single block makes the definition process easier, but also provides less individual control. Alternatively, because the smallest subnet consists of four IP addresses, defining a unique subnet for each DVIPA in this scenario wastes three other IP addresses that could have been used for DVIPAs.

## Use of the SIOCSVIPA or SIOCSVIPA6 ioctl command

An ioctl command, SIOCSVIPA or SIOCSVIPA6, allows an application to create or delete a dynamic VIPA on the stack where the application is running. The application can issue the IOCTL call by using the run time XL C/C++ or by using the UNIX System Services Callable Services BPX1IOC API. The application that is issuing the SIOCSVIPA or SIOCSVIPA6 ioctl command must be APF-authorized. If there is no security product, or if the security product indicates that no profile for MODDVIPA is defined, the application must be running under a user ID with superuser authority. If the profile for the MODDVIPA program is defined, the user ID must be permitted READ access to the profile even if the ID has superuser authority. Some security products indicate that there is no access available when no profile is defined. If you are not using RACF, you might need to define the profile to use these ioctl commands. For more information, see [“Defining a security profile for SIOCSVIPA, SIOCSVIPA6, and MODDVIPA”](#) on page 405.

To create a new dynamic VIPA, the requested IP address must be within a subnet that is previously specified by a VIPARANGE configuration statement in the PROFILE.TCPIP data set for this stack. The SIOCSVIPA or SIOCSVIPA6 ioctl command can be used to delete any existing dynamic VIPA on the stack, except for distributed DVIPAs. A dynamic VIPA can be created by using the DVR\_DEFINE option or the DVR\_DEFINE\_AFFINITY option. The DVR\_DEFINE\_AFFINITY option creates the DVIPA with affinity to the address space that created it. A connection request for a DVIPA that is created with affinity is sent to a TCP listener if the application instance that created the DVIPA issues the bind() call. If no matching listener is found, a TCP listener is selected by using the normal shareport load balancing.

The following example shows how to set up the SIOCSVIPA ioctl command for applications that are to use IPv4 addresses.

```
#include "ezbzdvp.c" /* header that contains
 the structure for
 SIOCSVIPA ioctl
 and needed constants*/
struct dvreq dv; /* the structure passed
 on the ioctl command*/
dv.dvr_version = DVR_VER1; /*version */
dv.dvr_length = sizeof(struct dvreq); /* structure length */
dv.dvr_option = DVR_DEFINE; /* to define a new
 dynamic VIPA. Use
 DVR_DELETE to delete
 a dynamic VIPA */
dv.dvr_addr.s_addr = inet_addr(my_ipaddr); /* where my_ipaddr is
 a character string
 in standard
 dotted-decimal
 notation */
```

The ioctl command is then invoked as follows:

```
rc = ioctl(s, SIOCSVIPA, &dv);
```

The following example shows how to set up the SIOCSVIPA6 ioctl command with the input parameter list that supports IPv6 addresses.

```
#include "ezbzdvp.c" /* header that contains
 the structure for
 SIOCSVIPA6 ioctl
 and needed constants */
```

```

struct dvreq6 dv6; /* the structure passed on
 the ioctl command */
dv6.dvr6_version = DVR_VER2; /* version */
dv6.dvr6_length = sizeof(struct dvreq6); /* structure length */
dv6.dvr6_option = DVR_DEFINE; /* to define a new dynamic
 VIPA. Use DVR_DELETE to
 delete a dynamic VIPA. */
inet_pton(AF_INET6, my_ipv6addr, dv6.dvr6_addr6.s6_addr);
/* where my_ipv6addr
 is a character string in
 standard IPv6 address
 notation, representing a
 fully qualified IPv6
 address */

```

The ioctl command is then invoked as follows:

```
rc = ioctl(s, SIOCSVIP6, &dv6);
```

The SIOCSVIP6 or SIOCSVIP6 ioctl command sets nonzero errno and errnojr values to indicate error conditions. See [z/OS Communications Server: IP and SNA Codes](#) for a description of the errnojr values returned.

## Using the MODDVIPA utility

You can use the MODDVIPA utility to activate or delete a dynamic VIPA. The utility can be initiated from JCL or an OMVS script. MODDVIPA must be loaded from an APF-authorized library and be run under a user ID that has an OMVS segment. If there is no security product, or if the profile for MODDVIPA has not been defined, the application must be running under a user ID with superuser authority. If the profile for the MODDVIPA program has been defined, the user ID must be permitted READ access to the profile even if the ID has superuser authority. For more information, see [“Defining a security profile for SIOCSVIP6, SIOCSVIP6, and MODDVIPA”](#) on page 405.

**Restriction:** The MODDVIPA utility cannot be used to create or delete a dynamic VIPA from a VIPARANGE statement for zCX.

### Input parameters

The input parameters for the utility are:

**-p <tcpipname>**

Specifies the TCP/IP which is to create or delete a DVIPA.

**-c <IPaddress>**

Specifies that the IP address is to be created.

**-a <IPaddress>**

Specifies that the IP address is to be created with affinity. A connection request for a DVIPA that is created with affinity is sent to a TCP Listener if the application instance that created the DVIPA issues the bind() call. If no matching listener is found, a TCP Listener is selected by using normal shareport load balancing.

**-d <IPaddress>**

Specifies that the IP address is to be deleted.

### Notes:

1. The input parameters -p, -c, -a, and -d must be entered in lowercase.
2. <tcpipname> must be entered in uppercase.
3. For IPv4 addresses, <IPaddress> is dotted decimal notation. For IPv6 addresses, <IPaddress> is standard colon-hexadecimal notation for specifying IPv6 addresses.
4. To create a DVIPA, the specified IP address must be within a subnet that is previously specified by a VIPARANGE configuration statement in the PROFILE.TCPIP data set for the specified TCP/IP.

## Output

The MODDVIPA utility sets the following exit (completion) codes for create (-c):

**0**

Success: The DVIPA was activated.

**4**

Warning: The requested DVIPA is within the VIPARANGE subnet but it is already active on this stack; another application created this DVIPA. Your application can use the DVIPA, but the application that created the DVIPA can delete it at any time.

**8**

Error: The IP address was not defined as a DVIPA on this TCP/IP.

**12**

An error was found in the input parameters

The MODDVIPA utility sets the following exit (completion) codes for delete (-d):

**0**

Success: The dynamic VIPA was deleted.

**8**

Error: The requested DVIPA was not deleted.

**12**

An error was found in the input parameters

### Notes:

1. When an error is detected, the errno text and errnojr value are printed to stderr.
2. If the IP address requested for the DVIPA is not within a VIPARANGE configured on this stack, completion code 8 is returned even if the IP address is currently active on this stack

## Examples

Within JCL:

```
//TCPDVP EXEC PGM=MODDVIPA,REGION=0K,TIME=1440, X
// PARM='POSIX(ON) ALL31(ON)/-p TCPCS3 -c 1.2.3.4'
```

From OMVS shell:

```
moddvipa -p TCPCS3 -c 1.2.3.4
```

From the TSO command prompt:

```
moddvipa -p TCPCS3 -c 1.2.3.4
```

**Restriction:** MODDVIPA must be listed in the AUTHCMD NAMES section of the IKJTSOxx member of SYS1.PARMLIB.

## Defining a security profile for SIOCSVIPA, SIOCSVIPA6, and MODDVIPA

You can define a System Authorization Facility (SAF) resource profile in the SERVAUTH class to control access to dynamic VIPAs (DVIPAs) in a VIPARANGE statement in the following ways:

- Control which applications can issue a SIOCSVIPA or SIOCSVIPA6 ioctl call, or call the MODDVIPA utility (which issues the SIOCSVIPA or SIOCSVIPA6 ioctl call on behalf of the application), to create a DVIPA

**Guideline:** Wherever SIOCSVIPA is used in this information, the information also applies to SIOCSVIPA6.

- Control whether an application can issue a SIOCSVIPA ioctl call or call the MODDVIPA utility to create a DVIPA within a specific VIPARANGE subnet

For information about controlling which applications can bind to create a DVIPA, see [“Defining a security profile for binding to DVIPAs in the VIPARANGE statement”](#) on page 430.

This information includes examples that use RACF. If you are using another security product, see the documentation for that product for the equivalent commands. For more information about RACF, see [z/OS Security Server RACF Security Administrator's Guide](#).

### ***Steps for controlling which applications can issue a SIOCSVIPA ioctl call or call the MODDVIPA utility to create a DVIPA***

You can define a System Authorization Facility (SAF) resource profile in the SERVAUTH class to control access to dynamic VIPAs (DVIPAs) in a VIPARANGE statement.

## **Procedure**

Perform the following steps to control whether an application can issue a SIOCSVIPA ioctl call or call the MODDVIPA utility to create a DVIPA:

1. Define the EZB.MODDVIPA.*sysname.tcpname* resource profile in the SERVAUTH class by issuing the following RACF command:

```
RDEFINE SERVAUTH (EZB.MODDVIPA.sysname.tcpname) UACC(NONE)
```

2. Give the user ID that is associated with the application READ access to the resource by issuing the following RACF command:

```
PERMIT EZB.MODDVIPA.sysname.tcpname ACCESS(READ) CLASS(SERVAUTH) ID(userid)
```

3. Refresh the profile by issuing the following RACF command:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

## **Results**

In this example, *sysname* is the name of the MVS system, *tcpname* is the job name of the TCP/IP started task, and *userid* is the user ID that is associated with the application. The job name for started tasks, such as TCP/IP, is derived depending on how it is started:

- If the START command is issued with the name of a member in a cataloged procedure library (for example, S TCPIPX), the job name will be the member name (for example, TCPIPX).
- If the member name on the START command is qualified by a started task identifier (for example, S TCPIPX.ABC), the job name will be the started task identifier (for example, ABC). The started task identifier is not visible to all MVS components, but TCP/IP uses it to build the RACF resource name.
- The JOBNAME parameter can also be used on the START command to identify the job name (for example, S TCPIPX, JOBNAME=XYZ).
- The JOBNAME can also be included on the JOB card.

### **Results:**

- If this resource profile is defined and the user ID has READ access to the resource, then the call is processed.
- If this resource profile is not defined and the user ID is not APF authorized and is not a UNIX System Services superuser, the call fails.
- If this resource profile is defined and the user ID does not have READ access to the resource, then the call fails with a permission denied error, regardless of whether the user is a superuser.

### **Rules:**

- If specific and wildcard resource profile names are defined, the user ID must have READ access to the resource that has the most specific match. For example, defining EZB.MODDVIPA.MVS1.TCPCS1 and EZB.MODDVIPA.MVS1.\* has the following results:

- To create a DVIPA on system MVS1, TCP/IP stack TCPCS1, the user ID must have READ access to EZB.MODDVIPA.MVS1.TCPCS1.
- To create a DVIPA on system MVS1, TCP/IP stack TCPCS2, the user ID must have READ access to EZB.MODDVIPA.MVS1.\*.
- If a user ID tries to create a DVIPA on a TCP/IP stack on system MVS2, there is no matching resource profile.
- If this resource profile is defined, the user ID must also have READ access to the resource to delete a DVIPA that was created using the SIOCSVIPA ioctl call, the SIOCSVIPA6 ioctl call, or the MODDVIPA utility.

### ***Steps for controlling whether an application can issue a SIOCSVIPA ioctl call or call the MODDVIPA utility to create a DVIPA within a specific VIPARANGE subnet***

You can define a System Authorization Facility (SAF) resource profile in the SERVAUTH class to control access to dynamic VIPAs (DVIPAs) within a specific VIPARANGE subnet.

## **Procedure**

Perform the following steps to protect a specific VIPARANGE subnet so that only a particular application can issue a SIOCSVIPA ioctl call or call the MODDVIPA utility to create a DVIPA in the protected range.

1. Define the EZB.MODDVIPA.*sysname.tcpname.resname* resource profile in the SERVAUTH class.

For example, to protect a VIPARANGE subnet for application APPL1, you can define the EZB.MODDVIPA.*sysname.tcpname*.APPL1 resource profile using the following command:

```
RDEFINE SERVAUTH (EVB.MODDVIPA.sysname.tcpname.APPL1) UACC(NONE)
```

2. On the VIPARANGE statement, include the SAF parameter with a *resname* value that matches the *resname* value on the EZB.MODDVIPA.*sysname.tcpname.resname* resource profile.

For example:

```
VIPARANGE DEFINE 255.255.255.255 10.10.10.1 SAF APPL1
```

For more information about the SAF parameter on the [VIPARANGE statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

3. Give the user ID that is associated with the application READ access to the EZB.MODDVIPA.*sysname.tcpname.resname* resource.

For example:

```
PERMIT EVB.MODDVIPA.sysname.tcpname.APPL1 ACCESS(READ) CLASS(SERVAUTH) ID(userid)
```

4. Refresh the resource profile by issuing the following RACF command:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

## **Results**

In this example, *sysname* is the name of the MVS system, *tcpname* is the job name of the TCP/IP started task, and *userid* is the user ID that is associated with the application. For information about how the job name for a started task, such as TCP/IP, is determined, see [“Steps for controlling which applications can issue a SIOCSVIPA ioctl call or call the MODDVIPA utility to create a DVIPA” on page 406](#).

### **Results:**

- If the SAF parameter is specified and the user ID has READ access to the resource, then the call is processed.
- If the SAF parameter is specified and the user ID does not have READ access to the resource, then the call fails.
- If the SAF parameter is specified but the resource profile is not defined, then the call fails.

- All of the following profile specifications that include wildcard values match the EZB.MODDVIPA.sysname.tcpname.resname resource profile name:
  - EZB.MODDVIPA.\*\*
  - EZB.MODDVIPA.\*\*
  - EZB.MODDVIPA.\*\*.

The most specific match to a resource profile name is always used. For example, consider the following VIPARANGE definitions:

```
VIPARANGE DEFINE 255.255.255.0 10.10.10.1
VIPARANGE DEFINE 255.255.255.255 10.10.10.210 SAF APPL1
VIPARANGE DEFINE 255.255.255.255 10.10.10.211 SAF APPL2
```

If `moddvipa -p TCP -c 10.10.10.20` is issued, then the first VIPARANGE statement matches and EZB.MODDVIPA.sysname.tcpname is used.

If `moddvipa -p TCP -c 10.10.10.210` is issued, although the first VIPARANGE statement matches, the most specific VIPARANGE statement match from these sample statements is the second statement, so the EZB.MODDVIPA.sysname.tcpname.APPL1 resource is used.

**Rule:** If this resource profile is defined and you want to delete a DVIPA that was created using the SIOCSVIPA ioctl call, the SIOCSVIPA6 ioctl call, or the MODDVIPA utility, the user ID must have READ access to the resource that was used to create the DVIPA.

## Configuring application-instance DVIPAs for IBM z/OS Container Extensions (zCX)

IBM z/OS Container Extensions (zCX) provides an execution environment allowing z/OS to host applications based on Linux docker containers. Each instance of zCX (unique zCX job) is provisioned within a unique z/OS address space. The zCX address space represents a virtual server. The virtual server does not require operational tasks from the z/OS administrator. From an operational perspective, the virtual server is transparent to the z/OS environment. z/OS Communications Server TCP/IP provides network communications for the zCX workloads.

The zCX server (address space) is represented by a unique z/OS application instance Dynamic VIPA. Both IPv4 and IPv6 zCX DVIPAs are defined using VIPARANGE with the ZCX keyword. Each zCX address space can connect to the network using a single IPv4 DVIPA or both a single IPv4 and a single IPv6 DVIPA.

For an overview of the z/OS Communications Server networking support provided for the zCX docker environment, see [“IBM z/OS Container Extensions network overview” on page 132](#).

### Configuring the zCX server IP address

The zCX job for the docker environment must be configured using z/OSMF workflows. The zCX configuration requires defining various job related parameters, including some network related parameters which includes the virtual server's IP address. The IP address specified in the zCX configuration (workflows) must match (be coordinated with) your z/OS TCP/IP configuration for VIPARANGE ZCX. For more information about using z/OSMF workflows for zCX, see [z/OS Container Extensions](#) and [IBM z/OS Management Facility Online Help for Configuration Workflow](#).

### zCX DVIPA operational characteristics and considerations

- Dynamic VIPAs created from the VIPARANGE subnet with ZCX will not move from one stack to another stack. The MOVEable parameter is ignored.
- The value of ZCX for a VIPARANGE statement cannot be changed without first removing the existing VIPARANGE statement and then redefining it.
- The SAF parameter can be dynamically changed.
- The creation of zCX DVIPAs is protected by the same authorization functions provided for all VIPARANGE DVIPAs. The zCX instance and the associated user ID of the zCX started task must

adhere the VIPARANGE authorization requirements. See [“Use of the SIOCSVIP or SIOCSVIP6 ioctl command”](#) on page 403 for more information. Refer to the z/OSMF workflows for configuring your zCX job.

- zCX DVIPAs are controlled by internal processing related to the zCX workload. When the zCX server is started, the DVIPA will automatically be activated and added to the home list. TCP/IP creates a static route to the zCX DVIPAs for its own internal use. This static route is local to and controlled by the stack that owns the zCX instance and it is not advertised using dynamic routing. Native z/OS applications cannot bind to a zCX DVIPA and IOCTls cannot change the state of a zCX DVIPA.
- If IP filters are defined, updates to the IP filter rules are required for all zCX DVIPAs. Two IPsec rules are required for all of the zCX DVIPAs, one rule defining the zCX DVIPAs as the source and another rule for the zCX DVIPAs as the destination. Both rules must be defined with ROUTING EITHER, permitting both ROUTED and LOCAL traffic for all of the zCX DVIPAs. When configuring the IPsec rules through the z/OSMF Network Configuration Assistant, the topology should indicate **Filtering only**. Be sure to check both **For local traffic - Host** and **For routed traffic - Gateway** under the **Filtering only** option.

### zCX DVIPA resiliency

There are usage scenarios where the zCX job (workload) will need to be relocated to another instance of z/OS. For this reason, the zCX DVIPA should be defined in all z/OS systems that could become eligible to host this zCX workload. The zCX DVIPA can only be active (used) within a single instance of z/OS at one time. However, using the z/OS Dynamic VIPA support, the zCX job could terminate (planned or unplanned) and then be restarted in another z/OS instance without reconfiguring the zCX job or z/OS TCP/IP.

When using dynamic routing, the zCX DVIPAs must be added to the OMPROUTE configuration. The DVIPAs are treated by OMPROUTE as normal application-instance DVIPAs where the DVIPAs are advertised accordingly.

When using static routes you must ensure the zCX DVIPAs can be reached by other hosts by defining static routes on other hosts that need to reach the zCX instance. If a zCX DVIPA is moved to another z/OS, updates to the static route definitions will be required.

## Choosing which form of dynamic VIPA support to use

---

The following list explains which of the features to use for the type of application that is being used.

- When to use VIPADEFINE and VIPABACKUP to define a dynamic VIPA:
  - One or more applications bind to the IPv4 INADDR\_ANY address or to the IPv6 unspecified address (in6addr\_any), and the applications exist on multiple TCP/IP stacks.
  - Dynamic VIPA takeover is wanted.
  - The DVIPA does not need to be deleted when the application is stopped.
- When to use VIPARANGE and bind() to define a dynamic VIPA:
  - The application cannot bind to INADDR\_ANY or in6addr\_any, or dynamic VIPA takeover is not wanted.
  - The IP address to which the application binds can be controlled by the user. The first explicit bind (the listening socket) of the application remains for the life of the application. Otherwise, the DVIPA is removed every time the DVIPA owning socket of the application is closed, and readded every time there is a new DVIPA owning socket (another explicit bind is done and the DVIPA does not exist).
  - Automatic deletion of the dynamic VIPA when the application is stopped is acceptable.
  - A specific dynamic VIPA address must be associated with a specific application.
  - The application is not APF-authorized, or not run under a user ID with superuser authority.
- When to use the VIPARANGE and the MODDVIPA utilities, or the SIOCSVIP or SIOCSVIP6 ioctl command to define a dynamic VIPA:

- The application cannot bind to INADDR\_ANY or in6addr\_any, or dynamic VIPA takeover is not wanted. The IP address to which the application binds is known but cannot be controlled by the user. Automatic deletion of the dynamic VIPA when the application is stopped is not acceptable.
- The application opens an AF\_INET6 listener and binds to in6addr\_any. The application needs to receive connections for multiple application-specific IPv4 and IPv6 destinations that are targeted for the port of this socket. The application can use MODDVIPA or the SIOCSVIPA and SIOCSVIPA6 ioctl command to create the IP address targets.

The MODDVIPA utility or application that is issuing the ioctl command is to be run from an APF-authorized library and under a user ID with appropriate authority. See [“Use of the SIOCSVIPA or SIOCSVIPA6 ioctl command” on page 403](#) or [“Using the MODDVIPA utility” on page 404](#).

## Configuring distributed DVIPAs - sysplex distributor

A distributed DVIPA exists on several stacks, but is advertised outside the sysplex by only one stack. This stack receives all incoming connection requests and routes them to all the stacks in the distribution list for processing. This provides the benefit of distributing the workload of incoming requests and providing additional fail-safe precautions in the event of a server failure.

You can distribute connections destined for a dynamic VIPA (DVIPA) by adding a VIPADISTRIBUTE configuration statement for a previously defined dynamic VIPA. The order of the statements is important. The VIPA is first defined with the VIPADEFINE statement and then included on a VIPADISTRIBUTE statement. Another TCP/IP can act as a backup for the distributed DVIPA by properly coding a VIPABACKUP statement; the backup will perform the routing function in the event of a failure. The options specified on a VIPADISTRIBUTE statement are inherited by a backup stack unless the second stack has its own VIPADISTRIBUTE statement for that DVIPA, in which case it will use its own VIPADISTRIBUTE statement for distributing. You can also code a VIPADISTRIBUTE statement with just the VIPABACKUP statement and not for the VIPADEFINE statement. This would allow workload distribution only during a primary outage.

You can change the distribution of a DVIPA after a backup stack has activated it. However, if the backup stack did not have its own distribution defined by a VIPADISTRIBUTE statement before it activated the DVIPA, any distribution changes made while the DVIPA is active on the backup stack are temporary. Those changes will be in effect while the DVIPA remains active on the backup stack, but will not be remembered if this stack takes over the DVIPA again in the future.

The following example is a properly coded distributed DVIPA:

```
IPCONFIG SYSPLEXROUTING DYNAMICXCF 193.9.200.4 255.255.255.240 1
IPCONFIG6 DYNAMICXCF 2000::93:9:200:4
VIPADYNAMIC
 VIPADEFINE 255.255.255.192 9.67.240.02
 VIPADISTRIBUTE DEFINE 9.67.240.02 PORT 20 21 8000 9000 DESTIP
 193.9.200.2
 193.9.200.4
 193.9.200.6
 VIPADEFINE V6DVIPA1 2000::9:67:240:2
 VIPADISTRIBUTE DEFINE V6DVIPA1 PORT 20 21 8000 9000 DESTIP
 2000::93:9:200:2
 2000::93:9:200:4
 2000::93:9:200:6
ENDVIPADYNAMIC
```

Prior to z/OS V1R6 Communications Server, the TCP/IP stack that was configured as a distributor of dynamic VIPAs was required to enable IP forwarding using the IPCONFIG (or IPCONFIG6) DATAGRAMFWD TCP/IP profile statement. For installations that do not want to configure their TCP/IP stack as a forwarding node, it is no longer a requirement for distributing dynamic VIPAs. However, if your installation is configured such that target TCP/IP stacks have only XCF connectivity, datagram forwarding still needs to be configured on the distributor, as all packets originating from the target will be forwarded by the distributor.

There are several configuration changes that can be made to affect the method the distributing stack will use to forward connections to the target stacks. In each of the following items, *all participating stacks* is used to refer to the distributing stack and all target stacks.

### **WLM-based forwarding based on target system workload**

If the DISTMethod BASEWLM parameter is specified on the respective VIPADISTRIBUTE statement, or if the DISTMethod parameter is not specified, this distribution method is enabled. This is the default distribution method. To enable the distributing stack to forward connections based upon the workload of each of the target stacks, specify SYSPLEXROUTING on the IPCONFIG statement in all participating stacks. This registers all participating stacks with WLM and enables the distributing stack to request workload information from WLM.

The WLM workload information is based on a comparison of available general CPU capacity for each target system. If the application uses System z Application Assist Processor (zAAP) capacity or System z Integrated Information Processor (zIIP) capacity, you can configure the VIPADISTRIBUTE statement so that available zAAP CPU capacity and zIIP CPU capacity are also considered. For these additional processor types to be considered, no distributor and target systems used by this application can be earlier than z/OS V1R9 Communications Server. If you need to consider zAAP and zIIP CPU capacity, evaluate whether you can use SERVERWLM distribution as an alternative to BASEWLM distribution for this application. SERVERWLM distribution has the advantage that processor proportions are automatically determined and dynamically updated by WLM based on the actual CPU usage of the application. If you need BASEWLM distribution, to determine the processor proportions to configure, study the workload usage of assist processors by analyzing SMF records, using performance monitors reports such as RMF, and so on.

### **WLM-based forwarding based on server-specific workload**

If the DISTMethod SERVERWLM parameter is specified on the respective VIPADISTRIBUTE statement, the distributing stack selects from the available servers for a DVIPA/port and forwards connections based on a WLM recommendation indicating how well each server is executing on its system. To enable the distributing stack to forward connections based on server-specific workload, specify SYSPLEXROUTING on the IPCONFIG statement in all participating stacks.

If the server uses System z Application Assist Processor (zAAP) capacity or System z Integrated Information Processor (zIIP) capacity, processor proportions are automatically determined and dynamically updated by WLM, based on the actual CPU usage of the application; however, you can influence the WLM server-specific recommendation with configuration options on the VIPADISTRIBUTE statement. You can use the PROCXCOST parameter on the VIPADISTRIBUTE statement so that the WLM recommendation favors servers with available zAAP or zIIP capacity over servers on which work targeted for the specialty processors might instead run on the conventional processor. You can also use the ILWEIGHTING parameter on the VIPADISTRIBUTE statement to influence how aggressively the WLM recommendation favors servers on systems with displaceable capacity at lower importance levels over servers on systems with displaceable capacity at higher importance levels. For these additional factors to be considered by WLM, no systems can run a release prior to z/OS V1R11 Communications Server.

### **WLM/QoS-based forwarding**

Regardless of whether BASEWLM or SERVERWLM weights are being used, to enable the distributing stack to forward connections based upon a combination of workload information and network performance information (TCP retransmissions and time-outs), specify SYSPLEXROUTING on the IPCONFIG statement in all participating stacks, and also define a sysplex distributor performance policy on the target stacks. For information on configuring these policies, see [“Sysplex distributor policy example” on page 866](#).

### **Round-robin forwarding**

If the DISTMethod ROUNDROBIN parameter is specified on the respective VIPADISTRIBUTE statement, the distributing stack uses a round-robin mechanism to select one of the DVIPA/port targets for each connection.

### **Weighted active forwarding**

If the DISTMethod WEIGHTEDActive parameter is specified on the respective VIPADISTRIBUTE statement, the distribution of incoming TCP connection requests is balanced across the targets, such that the number of active connections on each target is proportionally equivalent to a configured active connection weight for each target. However, server-specific abnormal completion information, server-specific health information, and the TSR value are used to reduce the active connection weight when these indicators are not optimal. To enable the distributing stack to use

server-specific abnormal completion and health information to affect the active connection weight, specify `SYSPLEXROUTING` on the `IPCONFIG` statement for all participating stacks.

### Hot-standby forwarding

If the `DISTMethod HOTSTANDBY` parameter is specified on the respective `VIPADISTRIBUTE` statement, one preferred target server and one or more backup (hot-standby) target servers are configured. The distributing stack does not perform load balancing of new connection requests across multiple targets; instead, the preferred target server with an active listener receives all new incoming connection requests, and the hot-standby target servers, which typically also have a ready listener application, do not receive any new connection requests. If the preferred target server becomes unavailable, then the highest ranked backup server becomes the active target server and receives all new connection requests. To enable the distributing stack to use server-specific abnormal completion and health information to affect the availability of the preferred target, specify `SYSPLEXROUTING` on the `IPCONFIG` statement for all participating stacks.

**Result:** If you have not made the changes needed to enable WLM-based forwarding (`SYSPLEXROUTING` has not been specified for all participating stacks), and `BASEWLM` or `SERVERWLM` is specified, the distributing stack will use round-robin forwarding to distribute connections.

**Tip:** The weights received from WLM are returned based on the first 24 characters of the `HOSTNAME` value. The `HOSTNAME` value is determined by the search path at initialization time. To ensure correct distribution, verify that the first 24 characters of each `HOSTNAME` value are unique for every system.

Regardless of the distribution method used, sysplex distributor routing policies can further affect the distribution of connections. Sysplex distributor routing policies, configured on the distributing stack, are used to specify a set of target stacks for a given set of traffic. For example, all traffic destined to a given port/DVIPA from a specified subnet can be assigned one group of target stacks, while traffic for the same port/DVIPA from another subnet can be assigned to a different group of target stacks. For more information on configuring these types of policies, see [“Sysplex distributor policy example” on page 866](#).

Distribution of connections to target servers can also be affected by the responsiveness of the target stacks or target servers. The sysplex distributor stack monitors how well target servers respond to connection setup requests, calculating a target server responsiveness (TSR) value for each server.

For WLM-based forwarding based on target system workload, WLM/QoS-based forwarding, WLM-based forwarding based on server-specific workload, or weighted active forwarding, new connection setup requests are diverted away from target servers that are handling connection setup requests relatively poorly. For round-robin forwarding, if the sysplex distributor determines that a target server is not successfully accepting connection setup requests at all, that target server is bypassed. Periodically, the distributor sends a new connection request to a target with a TSR of 0, to check whether the responsiveness of that target has improved.

By default, the sysplex distributor updates the status of each target server at 1-minute intervals as follows:

- When `BASEWLM` distribution is being used, the distributor polls WLM for new system weights.
- When `SERVERWLM` distribution is being used, each target stack polls WLM for server-specific weights and sends these weights to the distributor.
- The TSR value for each server is updated.

The default 1-minute interval is sufficient for most workloads. However, in some environments, particularly when the load on each target system will be close to 100% capacity and when the workload consists of a high volume of short-lived connections, you might want to use a shorter interval so that the distributor reacts faster to changes in a target server's status. You can change the interval by using the `SYSPLEXWLM POLL` parameter on the `GLOBALCONFIG` statement.

Each distributing stack and each target stack must have an IPv4 or IPv6 `DYNAMICXCF` address, or both. This address is used by other distributing stacks as a destination point. When using sysplex distributor, do not define an `IUTSAMEH` link. These links will be created automatically from the `DYNAMICXCF` statement. See [z/OS Communications Server: IP Configuration Reference](#) for directions for coding `DYNAMICXCF` on the `IPCONFIG` or `IPCONFIG6` statements. For more information on additional configuration parameters

required, also see the usage notes related to the DYNAMICXCF parameter under the IPCONFIG or IPCONFIG6 statements in [z/OS Communications Server: IP Configuration Reference](#).

The VIPADISTRIBUTE statement specifies how new connection requests are routed to a set of candidate target stacks. The VIPADISTRIBUTE DVIPA can be followed by up to 256 ports. The preceding example shows the well-known ports for FTP and the ports for a custom application.

Up to 32 target TCP/IPs follow the DESTIP keyword and are identified by their respective dynamic XCF IP addresses. Alternatively, the VIPADISTRIBUTE statement can specify DESTIP ALL, in which case all current and future stacks with activated dynamic XCF can participate in the distribution as candidate target stacks. As an application listens to one of the specified ports on each listed TCP/IP, the routing TCP/IP begins to forward connections to that stack.

**Guideline:** If you are using OMPROUTE for connectivity to a dynamic VIPA, the LPAR with the distributing stack that owns that dynamic VIPA is the only target stack (no remote target stacks are available), and a HiperSockets (iQDIO) interface is not configured, code a static route that represents the shared IP address in the attached network router to maintain connectivity; otherwise, because a HiperSockets interface is not configured, OMPROUTE does not advertise the routing information representing the shared IP address for the dynamic XCF interfaces in that LPAR, and the address might become unreachable because the interfaces to the remote target stacks are deleted or marked inactive. Unlike IUTSAMEH and DXCF interfaces, a HiperSockets interface that shares an IP address can remain active when there are no more remote target stacks available, and OMPROUTE advertises the routing information to the neighboring network routers (for example, Cisco) for connectivity to the shared IP address.

For more information about sysplex distributor, see *IBM z/OS V1R13 Communications Server TCP/IP Implementation, Volume 3: High Availability, Scalability, and Performance*, SG24-7998.

## Manually quiescing DVIPA sysplex distributor server applications

### Quiescing distribution to a target stack

You can stop a particular server application, or all server applications, on a target stack from receiving new DVIPA sysplex distributor workload using the VARY TCPIP,,SYSPLEX command with the QUIESCE parameter and either the PORT=*portnum*, JOBNAME=*jobname*, or TARGET parameter.

This command, entered on the target stack where the application exists, prevents the application from receiving any new DVIPA sysplex distributor connections but does not affect existing connections. This command can be issued to gracefully quiesce a target application or target system, before the application or system is brought down for planned maintenance. It can also be used to temporarily divert new workload requests from a particular application or a target stack.

The VARY TCPIP,,SYSPLEX command with the RESUME parameter and either the PORT=*portnum*, JOBNAME=*jobname*, or TARGET parameter can then be used to resume using the application as a target for new DVIPA sysplex distributor connections.

### Quiescing distribution to all target stacks

You can stop all target stacks from receiving new sysplex distributor connections for a specific DVIPA by using the VARY TCPIP,,SYSPLEX command with the DISTPAUSE parameter, the DVIPA parameter, and optional PORT=*portnum* parameter.

This command, entered on the distributing stack, prevents all target stacks from receiving any new DVIPA sysplex distributor connections but does not affect existing connections. If the PORT=*portnum* parameter is specified, only those applications on all target stacks will be prevented from receiving new connections.

Target stacks can be prevented from receiving DVIPA sysplex distributor connections at TCP/IP stack startup by configuring the PAUSE keyword on the VIPADISTRIBUTE statement for a specific DVIPA and optional port(s). For more details about the PAUSE keyword on the VIPADISTRIBUTE statement, see [z/OS Communications Server: IP Configuration Reference](#).

To resume sysplex distribution to all target stacks, use the VARY TCPIP,,SYSPLEX command with the DISTRESUME parameter, the DVIPA parameter, and optional PORT=*portnum* parameter.

**Tips:**

- To stop distribution for a specific target, use the VARY TCPIP,,SYSPLEX,QUIESCE command.
- To stop distribution across all target stacks, use the PAUSE keyword on the VIPADISTRIBUTE statement or by using the VARY TCPIP,,SYSPLEX,DISTPAUSE command on the distributing stack. This will permanently pause distribution until the VARY TCPIP,,SYSPLEX,DISTRESUME command is issued on the distributing stack.

For more details about the [VARY TCPIP,,SYSPLEX](#) command and its parameters, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Route selection for distributing packets

Sysplex distributor uses the dynamic XCF interfaces (DYNAMICXCF parameter on the IPCONFIG or IPCONFIG6 statements) to distribute all incoming packets to target stacks.

Using dynamic XCF interfaces has several advantages, such as simplified configuration, because you can leverage the existing XCF communication links in your sysplex environment and do not have to define separate communication paths to all target systems. This is especially useful in scenarios where target systems do not have direct network connectivity, but rather rely on the network connectivity of the routing stacks.

Sysplex distributor also includes some optimization logic that enables it to select alternative network paths for forwarding DVIPA packets. This optimization logic is automatically performed by the sysplex distributor in the following configurations:

- When the routing stack and the target stacks are in the same MVS image, the routing stack uses internal communication links (IUTSAMEH) to forward DVIPA packets to the target, avoiding an external network altogether.
- When the routing stack and a target stack are running in different LPARs but on the same System z central processor complex (CPC), and HiperSockets connectivity is available, the HiperSockets connectivity is automatically used for forwarding DVIPA packets instead of the dynamic XCF interfaces.

These optimizations provide the best performance characteristics for forwarding DVIPA packets within the same CPC.

For configurations where the routing and target stacks are in different CPCs, there are some scenarios where it might be desirable to use interfaces other than the dynamic XCF interfaces for forwarding distributed DVIPA packets:

- When sysplex XCF communication interface links, whether configured through CTCs or through the coupling facility, are constrained or are heavily used by other, non-DVIPA communications.
- When the routing and target stacks have direct network connectivity over high speed, low latency, and wide bandwidth networks, such as access to the same Gigabit Ethernet segments using the OSA-Express feature.

In these configurations, forwarding DVIPA packets over these alternative network connections can actually improve performance (that is, reduce latency and CPU cost) while reducing the usage of sysplex XCF interfaces.

You can use the VIPAROUTE statement in the VIPADYNAMIC block in the TCP/IP profile to influence the sysplex distributor's logic in selecting a route and interface to forward DVIPA packets to a target stack. Using the VIPAROUTE statement, you can indicate which IP address on the target stack is to be used as the destination or target IP address during the route lookup selection. When sysplex distributor processes the incoming packet, it determines whether a matching VIPAROUTE statement has been defined, and if it has, the TCP/IP stack returns the best available route to reach the target IP address. The incoming packet is then encapsulated using a destination of the VIPAROUTE target IP address in the outer header, and forwarded to the target stack. Generic routing encapsulation (GRE) is used to encapsulate IPv4 packets, while an outer IPv6 header is used to encapsulate IPv6 packets. This enables you to select

the optimal interface for forwarding DVIPA packets across different CPCs, while retaining the optimized communication paths when the routing and target stacks are on the same MVS image, the same CPC, or both.

If you do not want to use the dynamic XCF interfaces at all, you must define the dynamic routes so that the cost to reach the IP address on the target stack using the dynamic XCF interfaces is higher than the cost to reach that IP address using other interfaces. For more information, see [“Steps for configuring OSPF and RIP \(IPv4 and IPv6\)”](#) on page 333. If this is not done, it is possible that dynamic XCF interfaces will be used if the normal routing tables select those interfaces. By ensuring that the route using the dynamic XCF interfaces has a higher cost, you can exploit the other interfaces for forwarding most DVIPA traffic, yet maintain the dynamic XCF interface as a backup should the preferred network interfaces fail.

In the following cases, even though VIPAROUTE was specified, the dynamic XCF interface is used for distribution:

- A target IP address is specified that is not owned by the target stack.
- The defined dynamic XCF address is for a pre-V1R7 target stack.

When these conditions are detected, messages are issued at the distributing stack, as well as when the distributing stack first attempts to route a connection request to the target stack.

The dynamic XCF address must still be configured even if VIPAROUTE definitions are used, as sysplex distributor continues to use a dynamic XCF address to identify every target TCP/IP stack in the sysplex. In addition, there are several functions that continue to depend on dynamic XCF connectivity for intra-sysplex communications:

- Sysplex-Wide Security Associations (SWSA)
- Multilevel security packets
- QoS performance data collection of Policy Agent

## Generic routing encapsulation

Generic routing encapsulation (GRE) is a standard protocol described by RFC 1701, and is used for several TCP/IP functions. GRE is implemented for only IPv4 packets. GRE enables a wrapper to be placed around a packet during transmission of the data. A receiving stack that supports GRE removes the GRE wrapper, enabling the original packet to be processed by the receiving stack. GRE is often used to deliver a packet to a stack using an alternate destination IP address.

## Fragmentation considerations

For IPv4, when incoming packets destined for a DVIPA address need to be forwarded to a target TCP/IP stack using a route that was determined by a VIPAROUTE statement, the packet is encapsulated using Generic routing encapsulation (GRE) prior to being forwarded. This enables the packet to be forwarded through the network to the target stack while preserving the original packet's destination IP address (that is, the DVIPA address). The GRE encapsulation process increases the size of the forwarded packet by 28 bytes. As a result, if the size of the encapsulated GRE packets are larger than the maximum transmission unit (MTU) of the network interface that will be used for forwarding the packet, the TCP/IP stack might need to perform fragmentation, creating two or more packets that are forwarded to the target stack. The target stack then reassembles the fragmented packets.

While fragmentation and reassembly processing is not unusual in an IP network, it is desirable to eliminate the need for this processing, optimizing performance. For fragmentation as a result of GRE encapsulation, the cost of the fragmentation and reassembly processing might become a concern if a large percentage of the incoming DVIPA packets to be forwarded require fragmentation. Fortunately, configuration options do exist that can help eliminate the need for this fragmentation and reassembly processing, including the following options:

- The AdjustDVIPAMSS parameter on the GlobalConfig statement defaults to **AUTO**. The value of **AUTO** indicates that TCP/IP automatically adjusts the Maximum Segment Size (MSS) on the TCP connections to compensate for the extra length of the GRE header if the connections meet the following criteria:

- For inbound connections, if the SYN packet was forwarded by a sysplex distributor using VIPAROUTE or the local stack is also a sysplex distributor and VIPAROUTE is coded.
- For outbound connections, if the source IP address is a distributed DVIPA.

If the **ALL** subparameter on the AdjustDVIPAMSS is specified, TCP/IP adjusts the MSS if the source IP address is a DVIPA, whether the DVIPA is distributed or not.

**Note:** Both sides of the TCP connection must support the TCP MSS option. z/OS Communication Server supports this option.

- Enable path MTU discovery on the client IP hosts (that is, client hosts sending packets to the DVIPA). This enables the client hosts to dynamically discover the smallest MTU along the path from the client to the server. In the case of forwarded DVIPA traffic, the path MTU is adjusted (reduced) by the length of the GRE header, if the addition of this header would have resulted in fragmentation being required. For IPv6, path MTU discovery is automatically enabled for all hosts, and no explicit configuration should be required.
- Ensure that the MTU size of the routes over the network interfaces that are used to forward the DVIPA packets is large enough to account for the largest client packet plus the length of the GRE header. This might be an option if the clients are connected to networks with a smaller MTU size than what is available in the network paths between the z/OS hosts (that is, the TCP/IP stack forwarding the DVIPA packets and the target TCP/IP stack). Consider the following example:
  - The majority of the client hosts are connected to the network using Fast Ethernet, and as result use an MTU of 1492.
  - The route selected using the VIPAROUTE statement specifies a network path over OSA Gigabit Ethernet between the two z/OS hosts. Gigabit Ethernet accommodates a much larger MTU size than Fast Ethernet (8992 versus 1492). This larger MTU size with Gigabit Ethernet is often referred to as jumbo frames.

In this configuration, the z/OS hosts can be configured to take advantage of the larger MTU size when communicating with each other over the Gigabit Ethernet network. As a result, fragmentation is avoided for these forwarded DVIPA packets, as the larger MTU easily accommodates the increased packet size resulting from the GRE encapsulation. However, it is important to ensure that this larger MTU size is used only for communications among hosts where the entire network path supports the larger MTU size. Otherwise, packets sent from the z/OS hosts using the larger MTU size might need to be fragmented as they cross network boundaries that support only lower MTU sizes. As a result, when configuring larger MTU sizes, such as jumbo frames for Gigabit Ethernet, it is also important to consider enabling path MTU discovery on the hosts using the larger MTU size. This enables these hosts (in this example, the z/OS hosts) to use the larger MTU size only where appropriate, without introducing fragmentation. For more information on specifying MTU sizes on z/OS, see [“Determining the maximum transmission unit” on page 130](#).

## Dynamic port assignment

Sysplex distributor can also react dynamically to servers binding to the distributed DVIPA and creating a listening socket, adding a port to the list of ports for which connection workload balancing will occur. If the PORT parameter is omitted from the VIPADISTRIBUTE statement for the distributed DVIPA, any server that binds to the distributed DVIPA and a nonzero port will be eligible for workload distribution. If only one server binds to the distributed DVIPA and port and establishes a listening socket, that server will get all of the work. When the second server binds to the distributed DVIPA and the same port and establishes a listening socket, it will immediately become eligible to participate in connection workload balancing. TCP/IP will not enforce a limit on the number of ports that can participate in connection workload balancing per distributed DVIPA, other than the total number of allowable ports.

## Sysplex-wide source VIPA

Sysplex distributor addresses the requirement of providing to clients outside a parallel sysplex a single-IP-address appearance to application instances throughout the sysplex, and also the distribution of the incoming work among the various instances. Many applications are part of a cooperative network

of applications, and the sysplex applications that serve as clients to users might also have to initiate (client-like) outbound connection requests to cooperating applications. The SOURCEVIPA feature allows applications to attain independence of any physical adapter, but SOURCEVIPA is limited to statically defined VIPAs within a stack. Different instances of the same application using sysplex distributor, and thus having a single IP address for inbound connection requests, will use different IP addresses for their outbound connection requests.

These problems are resolved by allowing a single sysplex-wide VIPA to be used as the source IP address for TCP applications and to have the sysplex stacks collaborate on assigning ephemeral ports to prevent duplicate connection 4-tuples (combination of source and destination IP addresses and ports). These solutions are provided by SYSPLXEXPORTS, in conjunction with either job-specific source IP addressing or sysplex-wide source VIPAs for TCP connections.

For information on job-specific or destination-specific source IP addressing using the [SRCIP statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Sysplex-wide source VIPAs for TCP connections

The TCPSTACKSOURCEVIPA keyword on the IPCONFIG or IPCONFIG6 statements allows users to specify a single VIPA, static or dynamic, to be used as a source IP address for TCP applications that initiate outbound connections on that stack. TCPSTACKSOURCEVIPA is in effect only when SOURCEVIPA is enabled and an application issues a connect() without a bind(). Applications that perform an explicit bind() do not use the TCPSTACKSOURCEVIPA address, such as the following applications:

- LPQ
- LPR
- REXEC as a TSO command
- RSH
- TELNET client

In addition, applications that use the Pascal API TcpOpen() call have an explicit bind() performed for them.

**Guideline:** Because the SRCIP profile statement provides all of the functionality of the TCPSTACKSOURCEVIPA parameter and more granularity, consider use of the SRCIP statement instead of specifying the TCPSTACKSOURCEVIPA parameter. Specifying JOBNAME \* in an SRCIP profile statement provides the same result as specifying the TCPSTACKSOURCEVIPA parameter for implicit bind scenarios, and also applies to applications that issue a bind to the IPv4 INADDR\_ANY address or to the IPv6 unspecified address (in6addr\_any).

**Tip:** The TCPSTACKSOURCEVIPA parameter overrides the VIPA IP addresses in the HOME list or the SOURCEVIPAINTERFACE specification, but the TCPSTACKSOURCEVIPA parameter can be overridden. For information about the hierarchy of various ways that the source IP address of an outbound connection is determined, see [“Source IP address selection”](#) on page 272.

If you specify TCPSTACKSOURCEVIPA and do not specify SOURCEVIPA in a profile, a warning message is issued and TCPSTACKSOURCEVIPA is not enabled. The address that is specified does not need to be active on the stack at profile processing time. For example, a valid TCPSTACKSOURCEVIPA address can be an address that is to be a target address on this stack for sysplex distribution.

If the TCPSTACKSOURCEVIPA address is not an active VIPA on the stack at the time a connect() is issued, the connect() call goes through normal source IP address selection. A warning message is issued no more than once every 5 minutes (to avoid flooding the system console), indicating an attempt to use the address that is specified in TCPSTACKSOURCEVIPA failed.

TCPSTACKSOURCEVIPA can be coded on all target stacks. The target TCPSTACKSOURCEVIPA statements can specify individual unique addresses, or can be duplicates of the addresses that are specified on the distributing stack (a target DVIPA). Specifying the same DVIPA address for TCPSTACKSOURCEVIPA on the distributor and all target stacks creates a sysplex-wide source VIPA and raises the concern for coordination of ephemeral ports across the sysplex.

For information about diagnosing sysplex-wide source VIPAs for TCP connections problems, see [z/OS Communications Server: IP Diagnosis Guide](#).

## SYSPLEXPORTS

Whenever two or more application instances use the same source IP address and initiate connections to the same destination IP address and port, sysplex-wide coordination of assignment of ephemeral ports is required so that the 4-tuple for each connection remains unique. As long as the source IP address is on a single stack, this coordination is not a problem because the stack manages assignment of ephemeral ports. However, with sysplex distributor applications, multiple application instances might need to initiate connections using the same distributed DVIPA, potentially to the same destination IP address and port, so uniqueness of the connection 4-tuples cannot be guaranteed unless the stacks collaborate across the sysplex for ephemeral port assignment for distributed DVIPAs. This can be done by adding the optional SYSPLEXPORTS parameter to the VIPADISTRIBUTE statement.

You must specify the SYSPLEXPORTS parameter on the first VIPADISTRIBUTE statement processed for a particular DVIPA. SYSPLEXPORTS cannot be enabled after a DVIPA has been configured for distribution. After you have enabled SYSPLEXPORTS, you cannot disable it until you have deleted all distribution for the DVIPA. If you want to specify the SYSPLEXPORTS parameter on a VIPADISTRIBUTE statement in the data set referenced by a VARY TCPIP,,OBEYFILE command, you must delete the existing VIPADISTRIBUTE statement in one data set, and then add the statement back in a second data set. An example of the contents of a data set that deletes an existing distributed DVIPA is as follows:

```
VIPADYNAMIC
VIPADISTRIBUTE DELETE
10.1.1.1 PORT 20 21
DESTIP ALL
ENDVIPADYNAMIC
;
```

An example of the contents of a data set that adds SYSPLEXPORTS to this DVIPA is as follows:

```
VIPADYNAMIC
VIPADISTRIBUTE DEFINE SYSPLEXPORTS
10.1.1.1 PORT 20 21
DESTIP ALL
;
ENDVIPADYNAMIC
```

When a distributed DVIPA can be active on more than one target stack, SYSPLEXPORTS can be specified to cause the stacks to collaborate in the assignment of ephemeral ports for outbound initiated TCP connections. This ensures that two different connections do not end up with the same connection 4-tuple.

At profile processing time, a stack with a profile that contains a SYSPLEXPORTS parameter on a VIPADISTRIBUTE statement connects to the coupling facility SYSPLEXPORTS structure containing sysplex port assignment information. The name of this structure is in the format EZBEPOR $vv$  $tt$ , where  $vv$  is the 2-character VTAM group ID suffix specified on the XCFGRPID start option, and  $tt$  is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM group ID suffix is specified, but a TCP/IP group ID suffix is specified,  $vv$  is 01. If no TCP/IP group ID suffix is specified, but a VTAM group ID suffix is specified,  $tt$  is not present. If neither group ID suffix is specified, both  $vv$  and  $tt$  are not present. The structure will be a list structure with an entry for each DVIPA address that has a VIPADISTRIBUTE statement with SYSPLEXPORTS specified anywhere in the sysplex (or within the subplex, if subplexing is being used). The first stack to connect to the EZBEPOR $vv$  $tt$  structure for a particular DVIPA creates an entry for that DVIPA in the coupling facility. The stack creates and initializes, in the EZBEPOR $vv$  $tt$  structure, a sublist for this DVIPA of assigned ports for this stack. For more information about setting up EZBEPOR $vv$  $tt$ , see [Setting up the sysplex environment for VTAM and TCP/IP functions in z/OS Communications Server: SNA Network Implementation Guide](#).

The stack also maintains a list of allowable ephemeral ports on this stack. These ports are not reserved for TCP by a PORT or PORTRANGE statement, are not reserved in a GLOBALCONFIG EXPLICITBINDPORTRANGE statement, and are in the range provided on the EPHEMERALPORTS parameter of the TCPCONFIG statement. The default ephemeral port range is 1024 – 65535. Only port number values in the list maintained by the stack are allocated for use by the SYSPLEXPORTS DVIPAs of

the stack. Because this list is unique to a particular stack and determined by stack configuration, a port number that is not permissible for one stack because it is reserved might be allowable for another stack, and could actually be allocated for use by that stack for a SYSPLEXPORTS DVIPA.

Under the following conditions, the first time that an application issues a TCP bind() with port 0 or a connect() request, TCP/IP receives an unassigned group of ports from the coupling facility structure that are allowable as ephemeral ports on the stack (not otherwise reserved by PORT or PORTRANGE or limited by the EPHEMERALPORTS parameter):

- The bind() or connect() request uses a distributed DVIPA as the source address (whether by the application explicitly binding the socket to the designated DVIPA or by the stack assigning the TCPSTACKSOURCEVIPA address).
- The distributed DVIPA is designated as SYSPLEXPORTS.

The stack will assign an ephemeral port from the obtained group as the source port for the TCP connection request, and the coupling facility structure will be updated to show the group of ports as assigned. The stack will assign ports from within this group for each subsequent equivalent bind() request. If all the ports within the group are used, the stack will obtain another group of ports from the coupling facility.

**Guideline:** The maximum number of simultaneously active outbound connections that use sysplex-wide ephemeral port assignment is affected by the following parameters just like ephemeral port assignment within a single stack:

- The EPHEMERALPORTS parameter on the TCPCONFIG statement
- The EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG statement
- The PORT and PORTRANGE statements

That is, a single z/OS TCP stack supports no more than about 63000 simultaneously active, locally initiated TCP connections whose source ports are ephemeral ports assigned by the stack. If a stack is unable to successfully obtain an ephemeral port from the coupling facility for a SYSPLEXPORTS DVIPA, the connection request is terminated with an error indication.

If you send a connection request to a distributed DVIPA that is enabled for SYSPLEXPORTS and a random ephemeral port with no associated listener, then this connection will time out.

For information on diagnosing SYSPLEXPORTS problems, see [z/OS Communications Server: IP Diagnosis Guide](#).

## GLOBALCONFIG EXPLICITBINDPORTRANGE

You must specify the EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG profile statement if you are using or intend to use either of the following configurations:

- A distributed DVIPA as a source IP address in a DESTINATION rule in a SRCIP block
- A distributed DVIPA as a source IP address in a JOBNAME rule in a SRCIP block for an application that might use an IPv6 socket to connect to a mapped IPv4 destination address (this applies only if the stack is IPv6 enabled)

The EXPLICITBINDPORTRANGE parameter on the GLOBALCONFIG statement establishes a pool of ephemeral ports that is managed to guarantee the uniqueness of an assigned port across the sysplex (or subplex). This pool of ports is used to provide a sysplex-wide unique ephemeral port for any application that issues an explicit bind() to INADDR\_ANY or the IPv6 unspecified address (in6addr\_any) and port 0 before issuing a connect() request.

If an application uses an explicit bind() to INADDR\_ANY or in6addr\_any and port 0 before connecting, TCP assigns an ephemeral port from this pool to assure uniqueness across the sysplex, because it cannot be determined at the time of the explicit bind() whether the source IP address determined at connect() time might be a distributed DVIPA derived from a match on a JOBNAME or DESTINATION rule in the SRCIP block. Sysplex-wide coordination of the assigned ephemeral port value is required when the source IP address is a distributed DVIPA, so that each connection 4-tuple remains unique across the sysplex.

**Restriction:** The use of the EXPLICITBINDPORTRANGE pool of sysplex-wide unique ports is not supported in some common INET (CINET) configurations. It is supported if stack affinity is established, or if there is only one active TCP/IP stack for CINET to manage. In other cases, the parameter is accepted, but the results are unpredictable.

When EXPLICITBINDPORTRANGE is configured, selecting a distributed DVIPA during connect processing from a matching SRCIP JOBNAME or DESTINATION rule is also permitted when the application has explicitly bound the source port to either a port number less than 1024 or to an ephemeral port that is reserved for the job by a PORT or PORTRANGE profile statement. However, if the source port is bound to an ephemeral port that is not reserved for the job and the source address selected from a SRCIP rule during connect processing is a distributed DVIPA, the connect request will fail.

**Rule:** If the source port is either less than 1024 or a port that is reserved for this job and the specified source is a distributed DVIPA, ensure that multiple outbound connections to the same destination IP address and port cannot occur concurrently with the same source IP address and port.

When a profile is processed, a stack with a profile that contains a GLOBALCONFIG statement with an EXPLICITBINDPORTRANGE parameter takes the following actions:

- Connects to the coupling facility SYSPLXEXPORTS structure that contains sysplex port assignment information
- Associates the stack with the pool established by the EXPLICITBINDPORTRANGE parameter

The structure is a list structure with an entry for each DVIPA address that has a VIPADISTRIBUTE statement with the SYSPLXEXPORTS parameter anywhere in the sysplex (or within the subplex, if subplexing is being used). List 0 contains entries to maintain the explicit bind port range pool. Each stack that associates itself with the pool sets the port range for that pool. The stack creates and initializes, in the structure, a sublist in list 0 of assigned ports for that stack.

**Note:** The name of this structure is in the format EZBEPOR $vv$  $tt$ , where the  $vv$  value is the 2-character VTAM group ID suffix specified on the XCFGRPID start option, and the  $tt$  value is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM group ID suffix is specified, but a TCP/IP group ID suffix is specified,  $vv$  is 01. If no TCP/IP group ID suffix is specified, but a VTAM group ID suffix is specified,  $tt$  is not present. If neither group ID suffix is specified, both  $vv$  and  $tt$  are not present. For more information about setting up EZBEPOR $vv$  $tt$ , see [Setting up the sysplex environment for VTAM and TCP/IP functions in z/OS Communications Server: SNA Network Implementation Guide](#).

#### Guidelines:

- When the GLOBALCONFIG EXPLICITBINDPORTRANGE statement in the TCP/IP profile is processed, each stack sets the range for the pool established by the EXPLICITBINDPORTRANGE parameter for all the participating stacks in the sysplex. If each stack defines a different range, the last EXPLICITBINDPORTRANGE parameter processed supercedes any previously specified port ranges. To prevent the range from varying based on the order in which stacks complete their profile processing, specify the same port range for each stack that configures GLOBALCONFIG EXPLICITBINDPORTRANGE. You can do this by specifying the GLOBALCONFIG EXPLICITBINDPORTRANGE statement in a file that is included in each stack's TCP/IP profile using an INCLUDE statement.
- Avoid overlap of the explicit bind port range with other ports or port ranges reserved through either the PORT or PORTRANGE profile statements. If you are using the EPHEMERALPORTS parameter of the TCPCONFIG profile statement, ensure that the explicit bind port range does not consume too many of the ephemeral ports that the stack might need for general use. If a port in the pool established by the EXPLICITBINDPORTRANGE parameter is reserved on a TCP/IP stack through the PORT or PORTRANGE statements, the port cannot be allocated to that stack for EXPLICITBINDPORTRANGE processing, which might restrict the number of ports in the explicit bind port range that are available for EXPLICITBINDPORTRANGE processing. For example, if you defined an explicit bind port range 40000 – 41000, and you have a PORTRANGE statement on that stack that reserves ports 40500 – 41000, only ports 40000 – 40499 are available to that stack for EXPLICITBINDPORTRANGE processing.

If an application binds to a port in the explicit bind port range that is reserved using a PORT or PORTRANGE statement, the bind is allowed, but the port is not treated as an EXPLICITBINDPORTRANGE port. It is not marked in the SYSPLXEXPORTS coupling facility structure for

coordination across the sysplex. This situation might cause connections to fail as a result of duplicate connection 4-tuples.

If an application binds to a port in the explicit bind port range that is not reserved using a PORT or PORTRANGE statement, the bind fails with errno `JrExpBndPortRangeConflict (x734C)`.

Ports that are specified by the EXPLICITBINDPORTRANGE parameter cannot be used for normal ephemeral port allocation. Therefore, if the range of ports specified by the EXPLICITBINDPORTRANGE parameter overlaps the range of ports specified in the EPHEMERALPORTS parameter, this overlap might restrict the number of ports in the ephemeral port range. For example, if you defined an explicit bind port range 40000 – 41000, and you have an EPHEMERALPORTS parameter on the TCPCONFIG statement on that stack that limits ephemeral ports to 40000 – 41500, only ports 41001 – 41500 are available to that stack for general ephemeral port processing.

**Result:** EXPLICITBINDPORTRANGE takes precedence over TCPCONFIG EPHEMERALPORTS, which means that if TCPCONFIG EPHEMERALPORTS is in use, EXPLICITBINDPORTRANGE might specify ports outside the EPHEMERALPORTS range.

To remove a stack's participation in the EXPLICITBINDPORTRANGE pool, specify the GLOBALCONFIG statement with the NOEXPLICITBINDPORTRANGE parameter using a VARY TCPIP,,OBEYFILE command. This causes that stack to disassociate itself from the EXPLICITBINDPORTRANGE pool. If you do this and you have applications that issue an explicit bind() to INADDR\_ANY or in6addr\_any and port 0 on this stack that might match the following rules, you must ensure that no distributed DVIPAs are used as the source IP address on the matching rule.

- The DESTINATION rule of the SRCIP block on this stack
- A JOBNAME rule of the SRCIP block on this stack, where the application associated with the job name might use an IPv6 socket to connect to an IPv4 mapped destination address (this applies only to stacks that are IPv6 enabled)

## Timed affinities

Sysplex distributor normally distributes each connection request, as it arrives to one of the candidate server instances, based on available capacity and policies in effect when the connection request arrives. In particular, each connection is assumed to be independent of all other existing and future connections, with respect to the server instance that will receive the incoming connection request.

Some applications, however, establish an affinity between a client and a particular server instance that needs to span multiple connections. TN3270E Telnet server printer sessions, for example, are based on a connection request from a Telnet client, and that printer session connection request needs to be routed to the same TN3270E Telnet server that is serving the LU2 session. Similarly, web-based applications, such as shopping carts, might need to have all connections from a particular client come to the server instance that has the contents of the shopping cart stored as session state.

The TIMEDAFFINITY parameter on the VIPADISTRIBUTE statement indicates to sysplex distributor that connections to a particular distributed DVIPA need to take into account the client origin. Connections from the same client, as identified by IP address, need to be routed to the same server instance, even when multiple server instances are hosted by a single target stack.

If a nonzero value for the TIMEDAFFINITY parameter is specified on a VIPADISTRIBUTE statement, the first connection from a particular client is routed as normal to a target stack and listening application. At that time, both the sysplex distributor routing stack and the target stack establish an affinity to govern subsequent connection requests from the same client. This affinity maintains a connection count, initially one. As subsequent connection requests for the same distributed DVIPA and port come in from the same client IP address, they are routed to the same server instance and the affinity connection count is incremented. As affinity-based connections, including the first one, are closed, the connection count is decremented.

When the last existing connection is closed and the count gets to zero, a timer of the duration (in seconds) specified by the TIMEDAFFINITY parameter is started. If another connection request is received from the same client to the same distributed DVIPA and port, the timer is stopped and the connection request is routed to the designated server instance. If no connection request is received from that client for the

designated distributed DVIPA and port before the timer expires, the affinity is removed from the sysplex distributor routing and target stacks. The next connection request from that client for the distributed DVIPA and port will be routed according to normal sysplex distributor considerations of relative capacity and policies.

Connection requests that map to an existing affinity are always routed to that target regardless of the distribution method being used. This also applies to weighted active connection distribution. Although the established affinities are honored, distribution decisions for connection requests that have no affinity will include the active connections that were established as a result of an affinity relationship.

Using the VARY TCPIP,,OBEYFILE command with a profile containing a VIPADISTRIBUTE statement that specifies the TIMEDAFFINITY value as 0 prevents new affinities from being established. However, an existing affinity remains until all connections using the affinity end and the timer for the affinity expires. The timer value is not changed for an existing affinity by the new statement; instead, it continues to use the configured TIMEDAFFINITY value that was active when the affinity was established. To remove existing affinities, issue the VARY TCPIP,,OBEYFILE command with a profile containing a VIPADISTRIBUTE DELETE statement, followed by a VIPADISTRIBUTE DEFINE statement with a TIMEDAFFINITY value of 0.

Note that under some circumstances, a client's affinity with a specific target application server instance might be terminated prior to the specified time interval if key resources needed to satisfy new client TCP connection requests are not available. This includes the following scenarios:

- A target application server instance terminates, is quiesced for DVIPA sysplex distributor workload balancing, or is no longer listening on its specified port. Any affinities to the target application instance are terminated and new connections for that port are no longer routed to this server.

One exception to this scenario occurs for configurations where multiple applications are on the same system and TCP/IP stack, and also listen on the same port (that is, the set of applications comprises a shareport group). In this case, when one of the application instances in the shareport group terminates, is quiesced for DVIPA sysplex distributor workload balancing, or is no longer listening on the specified port, the routing stack continues to maintain any existing affinities, but only to this target system and TCP/IP stack, as long as at least one application instance in the shareport group is active, is not quiesced, and is listening to the specified port. When a new TCP connection is received from a client that previously had an affinity to the server that is no longer active, the request is routed to the same target system and TCP/IP stack. One of the other available servers in the shareport group is selected to process the request and a new affinity is established.

- A target system or TCP/IP stack is no longer available. All affinities associated with applications running on that system and TCP/IP stack are terminated.
- A target TCP/IP stack is no longer reachable across dynamic XCF links (that is, the dynamic XCF link to the target stack is no longer active). Any existing client affinities to applications on that target stack are terminated if new connection requests from these clients are received while the dynamic XCF link is not active. Note that this scenario occurs only if a dynamic XCF link becomes inactive and all attempts to automatically restart the link are unsuccessful.
- A target server is found to be unresponsive to accepting new connection requests. All affinities to the target server are terminated and new connections for that port are no longer routed to that server.
- A target server is unable to support new connections requests. Connections that are protected by IPsec UDP-encapsulated security associations that are negotiated with a peer behind a NAPT must be distributed to a V1R8 or later target. It is not always possible for the distributing stack to detect that a security association is being negotiated with a peer behind a NAPT. If an initial connection is distributed to a V1R7 target and an affinity to that target is established, and during negotiation of a subsequent security association it is determined that the peer is behind a NAPT, the affinity to the target is terminated.

The sysplex distributors notion of *client* is tied exclusively to source IP address on the connection request. This notion is not new, and is also true of other functions such as Policy Agent and IPsec. However, it can present problems in situations where many different connections from truly different client instances all appear with the same source IP address. Examples include the following situations:

- Proxy applications, such as a web HTTP server proxy, that initiate secondary connections on behalf of a large number of different clients. The secondary connections into sysplex distributor all look as though they come from the same client, and any affinity for those connections directs all connection requests to the same server.
- Network address translation (NAT), which keeps connection tables so that it can map multiple client-side addresses into a single server-side source IP address.
- Clients on z/OS configured for SOURCEVIPA, or in general, many instances of a client on the same network node with one or very few IP addresses (as far as outbound connection requests are concerned).
- Clients running on the sysplex distributor routing stack, which is a special instance of the previous scenario. The source IP address for a client running on the sysplex distributor routing node is the distributed DVIPA, the same as the destination IP address. This is not new, and is true for any connection request issued for a server on the same stack, if the connection request socket was not bound to a particular IP address before issuing the connect() call.

In cases like this, distribution might be significantly less than optimal, because sysplex distributor has no way to distinguish among connection requests from different real clients all using the same source IP address. In the worst case, where all source IP addresses are the same (for example, where there is a single proxy instance in a firewall), there will be no load balancing at all as long as an affinity exists.

Essentially, timed affinity was created to allow connection workload distribution where it was not possible before, due to the client/server application model requiring a particular client to go to a particular server instance for some period of time. Such applications are not, at present, workload balanced. If a network configuration is such that a reasonable number of source IP addresses do not allow workload balancing, techniques to partition the work at the source must be implemented (configuring the clients to go to unique server addresses, or configuring the proxy to distribute the workload among multiple servers, as the WebSphere HTTP server plug-in does). Where the anticipated number of different source IP addresses, and the connection request arrival rate, is large enough to provide reasonable balancing and reaction to changing sysplex workloads, this provides a reasonable solution while respecting affinities between clients and servers as required for the application. The main reason for configuring the affinity on the basis of each distributed DVIPA and port pair is that affinity requirements differ from application (port number) to application, and some applications do not need affinity at all. You must take into account your specific network configuration, and specifically the arrival rate of connections from different IP addresses, in determining whether timed affinity with sysplex distributor is appropriate for a particular application in your network.

Affinity information needs to be handled on the sysplex distributor routing stack, backup stacks, and target stacks. If a target stack is not z/OS V1R5 or later, server application instances that are part of a shareport group on that stack will not work properly, and affinities for that target stack will not be communicated to the backup routing stack on failure of a primary routing stack. If a backup routing stack is not z/OS V1R5 or later, affinity information will not be sent to it from surviving target stacks if it takes over from a failed routing stack. Therefore, it is strongly recommended that all TCP/IP stacks participating in distribution for a distributed DVIPA with affinities be at least z/OS V1R5.

You can use the Netstat VCRT/-V report option with the DETAIL modifier to display the affinity related information for each connection, as follows:

```

The following notes apply to the preceding example.

**Notes:**

1. Affinity CRT entry for the three regular CRT entries that follow. If there is an affinity entry, it is shown before the regular CRT entries.
2. Three regular CRT entries, associated with the single preceding affinity entry.
3. Affinity CRT entry for the regular CRT entry that follows.
4. Regular CRT entry associated with the previous affinity entry.
5. An affinity CRT entry that has no connection associated with it. The use count is zero. There are 99 seconds affinity time left before this affinity entry is removed.
6. Regular CRT entry. There is no affinity associated with it.

## Sysplex-Wide Security Associations

To enable Sysplex-Wide Security Associations (SWSA) on a stack that has IP security enabled, add the DVIPSEC parameter in the IPSEC statement block of the TCP/IP profile.

To take advantage of the functions described here, you must add the DVIPSEC parameter to the primary stack that owns a DVIPA and to all backup TCP/IP stacks. It is not necessary to add the DVIPSEC parameter to hosts that serve only as targets for sysplex distributor.

You should add DVLOCALFLTR, a DVIPSEC subparameter, to the IPSEC statement block of the TCP/IP profile when intra-sysplex traffic should be protected by security associations. The DVLOCALFLTR parameter enables IP filtering and IPsec protection of TCP traffic between a client and an IPv4 dynamic VIPA that are defined on the same TCP/IP stack, when the traffic is forwarded to another TCP/IP stack.

**Restriction:** A security association cannot be negotiated if the source and destination IP addresses for client connections are the same dynamic VIPA. To help avoid this scenario, do not code a dynamic VIPA that can be used as a destination IP address on the TCPCONFIG TCPSTACKSOURCEVIPA or SRCIP statement in the TCP/IP profile.

For more information about configuring SWSA, see [“Sysplex-Wide Security Associations and IP security” on page 1107](#) in this document, and [IPSEC statement](#) in [z/OS Communications Server: IP Configuration Reference](#).

SWSA also requires the use of a coupling facility structure with a name in the form EZBDVIPAvvtt, where vv is the 2-digit VTAM group ID suffix specified on the XCFCRPID start option, and tt is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM group ID suffix is

specified, but a TCP/IP group ID suffix is specified, *vv* is 01. If no TCP/IP group ID suffix is specified, but a VTAM group ID suffix is specified, *tt* is not present. If neither group ID suffix is specified, both *vv* and *tt* are not present. For information about [Setting up the sysplex environment for VTAM and TCP/IP functions](#) and the use of the EZBDVIPAvvtt coupling facility structure, see [z/OS Communications Server: SNA Network Implementation Guide](#).

Dynamic IPsec security associations (SA), negotiated by IKE, can use a DVIPA address as the SA endpoint. Manually configured SAs are not supported by SWSA. For more information on IPsec, see Chapter 17, “IP security,” on page 911.

When using SWSA, there are two possible configurations to consider:

- DVIPA takeover
- Sysplex distributor

To support IPsec in conjunction with DVIPA takeover and sysplex distributor, some IKE and IPsec configuration is required. Loss of access to the coupling facility is also discussed in the following subtopics.

For information on diagnosing SWSA problems, see [z/OS Communications Server: IP Diagnosis Guide](#).

## **DVIPA takeover**

When a DVIPA is moved during a DVIPA takeover (planned or unplanned), new Sysplex-Wide Security Associations (SWSAs) are automatically reestablished with the same security service characteristics as the Security Associations (SAs) that existed on the host that previously owned the DVIPA. When you are using IKEv1 and the SA is reestablished, the process is transparent to the client that owns the other end of the SA. The process appears to be a normal SA refresh when IKEv1 is used to negotiate the SA. When IKEv2 is used, the SA reestablishment appears as a new SA. Figure 56 on page 426 shows DVIPA 192.168.253.4 being taken over by the backup host; SAs are transparently reestablished between the client and the backup host.

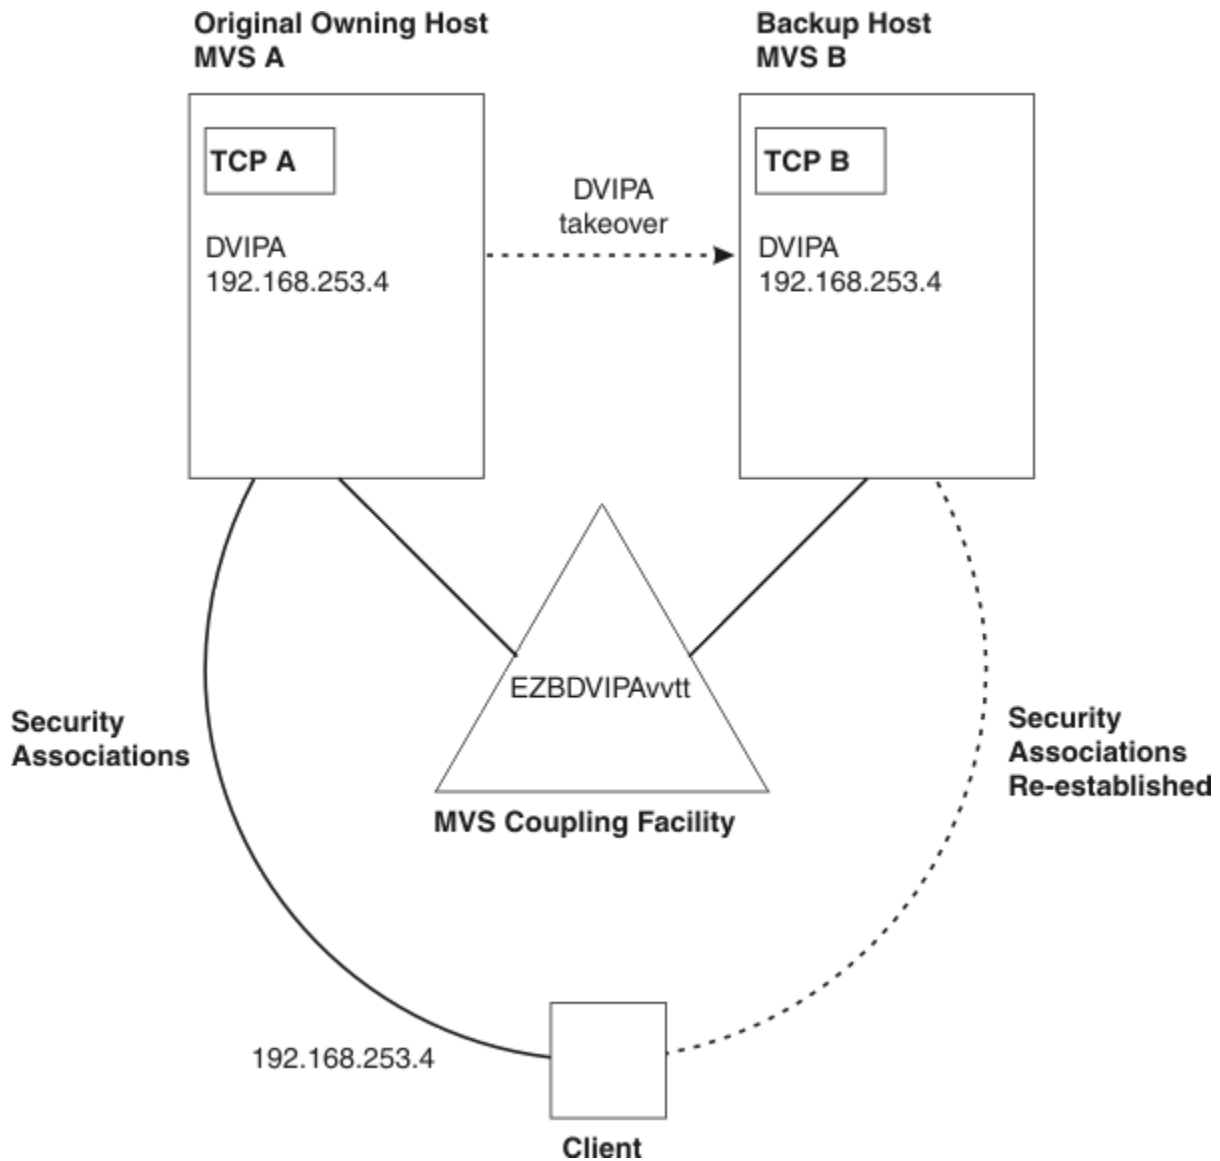

Figure 56. DVIPA takeover with SWSA

The IKE running on behalf of the TCP stack of the DVIPA owner is responsible for all IKE SA negotiations. The TCP stack owning the DVIPA is responsible for keeping the coupling facility updated with information needed to reestablish the SAs in the event of a DVIPA takeover. When a takeover occurs, the IKE on the backup host assumes responsibility for renegotiating new SAs based on information read from the coupling facility by the TCP stack of the new DVIPA owner.

When the SA is reestablished using the IKEv2 protocol, it appears as a new SA. The old SA on the client system might not be deleted immediately. This typically happens when a phase 1 SA exists on the backup system that has the same local and remote identities as the phase 1 SA protecting the SA that is being reestablished. When this scenario occurs, the old SA on the client remains active until it is deleted by liveness checking, which is described in RFC 5996. For more information about liveness checking as implemented on the z/OS platform, see the [LivenessInterval](#) parameter on the [KeyExchangePolicy](#) statement in [z/OS Communications Server: IP Configuration Reference](#). For more information about the IKEv1 and IKEv2 protocols, see the [IKE protocol details](#) appendix in [z/OS Communications Server: IP Diagnosis Guide](#).

## Sysplex distributor

TCP traffic protected by an IPSec SA with a sysplex-distributed DVIPA endpoint can be distributed to target hosts. IPSec cryptography for inbound traffic is performed on the target host whenever possible. If

not possible, the distributor performs the cryptography before forwarding the packet to the target stack. IPSec cryptography for outbound traffic is performed on the target host, and then sent directly into the network without being routed through the distributor. Figure 57 on page 427 shows the target stack performing the cryptography for the inbound and outbound traffic.

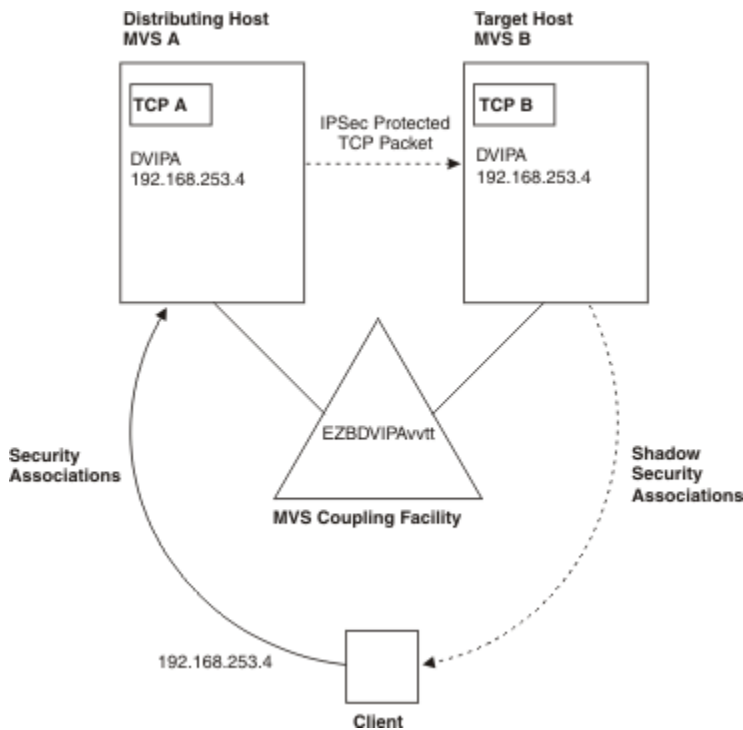

Figure 57. Sysplex distributor with SWSA

The IKE running on behalf of the distributor TCP stack (the DVIPA owner) is responsible for all IKE SA negotiations. The distributor stack keeps the master copy of the SA associated with the DVIPA. Whenever a new SA is negotiated or refreshed and the SA is installed in the distributor stack, a copy (shadow) of the SA, which contains information necessary to perform IPSec cryptography, is sent within the sysplex to the target hosts. The shadow SAs enable the distribution of cryptography to the target stacks. The coupling facility is used as a central repository for SA replay protection sequence numbers used for outbound operations. The SA lifetimes (bytes sent and received over an SA) are maintained in the master SA.

## Using IPSec with DVIPAs and sysplex distributor

To support IPSec with DVIPA takeover and sysplex distributor, some IKE and IPSec configuration on the primary or distributing host must be replicated onto all systems that can either serve as a backup host for a VIPA takeover or a target host for sysplex distributor. This configuration includes IP Security policy that affects traffic using distributed DVIPA (from an IKE definition perspective).

- From a stack perspective, all anchor rules that are applicable to distributed DVIPA traffic must be identical on all systems. In addition, the ordering of the rules must allow for consistent application of security policy on all systems.
- To be considered a sysplex-wide SA, the SA negotiated that applies to DVIPAs must be at a granularity no coarser than host for the local address. That is, a dynamic SA cannot use a subnet or range that encompasses a DVIPA address. This rule ensures that on a DVIPA Giveback the SA can be moved from host to host without concerns about an SA being applicable to both the backup and primary host simultaneously. If such a dynamic SA is negotiated, the IPSec traffic using it cannot be distributed or recovered through the DVIPA takeover support.
- The configured IKE identity for a sysplex-wide SA must be identical on the primary and backup hosts. This configuration allows the backup host for a VIPA takeover to retrieve data from the coupling facility and renegotiate the SA.

## Loss of access to coupling facility

If access is lost to the coupling facility that contains the DVIPA structure EZBDVIPAvvtt, it is possible the TCP connections that are using this DVIPA might stop and new connections that need IPsec fail to establish. Loss of access can be caused by any of the following events:

- A disconnect from the coupling facility structure.
- The structure is rebuilt.
- The structure encounters a critical storage shortage.

Loss of coupling facility access should affect only sysplex distributor connections that are being encrypted or authenticated. When access to EZBDVIPAvvtt is restored, the sessions can be reestablished.

If a list is not available in the EZBDVIPAvvtt structure for a DVIPA or a security association sequence number, it is possible new connections that need IPsec fail to establish. See [Sysplex-wide security associations in z/OS Communications Server: SNA Network Implementation Guide](#) for more information about increasing the number of lists for the EZBDVIPAvvtt structure.

## Resolution of dynamic VIPA conflicts

---

The same dynamic VIPA can exist on more than one stack in the sysplex, playing different roles on the different stacks. The TCP/IP stacks collaborate to prevent conflicting definitions. For example, at any given time only one stack will advertise a given dynamic VIPA to the routers.

Potentially conflicting dynamic VIPA definitions can arise during profile processing or as the result of changes within the sysplex due to a stack or application failure or as the result of movement of workload to a different stack. The following scenarios are examples of dynamic VIPA conflict resolution handled automatically by the TCP/IP stacks. For a summary of dynamic VIPA conflict identification and resolution, see [“Dynamic VIPA creation results” on page 434](#).

## Restart of the original VIPADEFINE TCP/IP after an outage

When a dynamic VIPA is defined using VIPADEFINE on one TCP/IP, and other stacks are designated as backup using VIPABACKUP statements for the same dynamic VIPA, the stack with the highest backup rank for that DVIPA will activate it if or when the VIPADEFINE stack fails.

If the failed stack is later restarted with the same VIPADEFINE profile statement, it is likely that connections to that DVIPA will exist on the backup stack that now has the DVIPA activated and advertised to the routers. How and when ownership of the DVIPA is returned to the restarted stack is determined by how the DVIPA was originally configured.

### VIPADEFINE MOVEABLE IMMEDIATE

If the DVIPA is an IPv6 DVIPA, or is an IPv4 DVIPA that was originally configured with MOVEABLE IMMEDIATE, the following events occur:

- The DVIPA ownership is immediately transferred to the restarting stack which adds the DVIPA to its HOME list and the routers are dynamically notified. The restarted stack receives all new connections for that DVIPA. The stack also can receive packets for existing connections, and it routes these to the backup stack to preserve those connections.
- At the same time, the backup stack notifies the routers that it no longer is the owner of the DVIPA.
  - If there are no current connections to the DVIPA, it is removed from the HOME list on the backup stack and it reverts to backup status.
  - If there are any existing connections, the DVIPA remains in the HOME list of the backup stack and the DVIPA is put into Moving status until the last existing connection is terminated. At that time, the DVIPA is removed from the HOME list and reverts to backup status.

IBM recommends this form of a planned DVIPA takeback occur only during low periods of connection activity. This gives the attached routers time to update their routing tables and avoid connections being reset due to receiving an ICMP\_HOST\_UNREACH or ICMP6\_DST\_UNREACH from the router.

**Tip:** If OMPROUTE is used, it is recommended that GLOBALCONFIG SYSPLEXMONITOR DELAYJOIN be configured. This causes DVIPA takeback to be delayed until OMPROUTE is active and able to advertise DVIPAs on the takeback stack. For more information on using DELAYJOIN, see [“Sysplex problem detection and recovery” on page 480](#).

**Notes:**

1. To ensure preservation of existing connections on the prior owning stack, you must define DYNAMICXCF on both stacks, on the IPCONFIG statement for IPv4 dynamic VIPAs or on the IPCONFIG6 statement for IPv6 dynamic VIPAs.
2. MOVEABLE IMMEDIATE is the default for IPv4 DVIPAs, and the only behavior for IPv6 DVIPAs.

## VIPADefine MOVEABLE WHENIDLE

If an IPv4 DVIPA was originally configured with MOVEABLE WHENIDLE, the following events occur:

- If it appears that there are no active connections to the DVIPA on the backup stack:
  - The DVIPA is removed from the HOME list on the backup stack and reverts to backup status.
  - The restarted stack assumes ownership of the DVIPA by adding it to its HOME list and notifying the routers.
- If there are existing connections to the DVIPA on the backup stack:
  - Ownership of the DVIPA remains with the backup stack. The DVIPA on the restarting stack is placed in backup status at the head of the backup list for the DVIPA.
  - The backup stack periodically checks to see if it has any active connections to the DVIPA.

When or if it appears that there are no active connections for the DVIPA, the following events occur:

- The DVIPA is removed from the HOME list on the backup stack and reverts to backup status.
- The restarted stack assumes ownership of the DVIPA by adding it to its HOME list and notifying the routers.

**Notes:**

1. WHENIDLE is supported only for IPv4 DVIPAs.
2. A small period of time exists between the check for connections and the movement of the dynamic VIPA to the restarted stack. If connections are made to the old host (the backup stack) in this interval, they will be broken.
3. During the time that TCP/IP is periodically checking for connections, TCP/IP does not refuse new connections because this would be the same as an outage. If moving the work back to the restarted stack is more important than maintaining uninterrupted service to all clients, then the system operator can use the VARY TCPIP,,OBEYFILE command to delete the dynamic VIPA on the backup stack with the VIPADELETE profile statement. This causes the restarted stack to immediately activate the DVIPA. Optionally, the data set specified on the command can contain a VIPABACKUP statement following the VIPADELETE statement. This will restore the stack as a backup stack.

## Movement of unique application-instance (BIND)

A dynamic VIPA is created when any application binds to a nonexistent, specific IP address falling within a configured VIPARANGE on that stack.

In the case of a stack failure, the same application could be started on another stack and (assuming the new stack also has an appropriate VIPARANGE configured) when the application binds to the same IP address, the dynamic VIPA is created on the second stack. Future client connections to that IP address are routed to the second stack where the application is now running.

However, if the same (or a different) application is started on a second stack and attempts to create the same dynamic VIPA using a `bind()` while it exists on the first stack, the end result is determined by how the VIPARANGE was configured on the stack where the first `bind()` occurred.

## VIPARANGE (DEFINE) MOVEABLE NONDISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE NONDISRUPTIVE, the following events occur:

- If the EZB.BINDDVIPARANGE.*sysname.tcpname* security profile is defined, or if the SAF parameter is specified on the VIPARANGE statement and the EZB.BINDDVIPARANGE.*sysname.tcpname.resname* security profile is defined, the application issuing the `bind()` call must have READ access to the appropriate resource. If the SAF parameter is specified but the corresponding resource profile is not defined, then the bind fails. If the security profile is not defined but the same VIPA range is configured on another stack, any application on that stack can cause the DVIPA to move there by issuing a `bind()` call to that DVIPA.
- The DVIPA ownership is immediately transferred to the second stack which adds the DVIPA to its HOME list and dynamically notifies the routers. This stack will now receive all new connections for the DVIPA.
- At the same time, the first stack notifies the routers that it no longer is the owner of the DVIPA, and puts the DVIPA into moving status. The DVIPA remains in moving status (and in the first stack's HOME list) until the application closes the socket.
- Existing connections on the first stack are preserved. If the second stack receives packets intended for existing connections, it routes the packets to the first stack.

### Notes:

1. To ensure preservation of existing connections on the prior owning stack, you must define DYNAMICXCF on both stacks, on the IPCONFIG statement for IPv4 dynamic VIPAs or on the IPCONFIG6 statement for IPv6 dynamic VIPAs.
2. NONDISRUPTIVE is the default for V2R10 and later, and is the only option supported for IPv6.
3. Both stacks must be running V2R10 or later to get non-disruptive behavior. If either stack is running V2R8, the result will be as described in [“VIPARANGE \(DEFINE\) MOVEABLE DISRUPTIVE ” on page 430](#).

## VIPARANGE (DEFINE) MOVEABLE DISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE DISRUPTIVE (or if either stack is running V2R8), the following events occur:

- The `bind()` request for the application on the second stack will fail.
- The DVIPA on the first stack is not affected.

### Notes:

1. If movement of the application from the first to the second stack is intended, the application must be ended on the first stack before it is started on the second stack.
2. DISRUPTIVE is supported only for IPv4 DVIPAs.

## Defining a security profile for binding to DVIPAs in the VIPARANGE statement

You can define a System Authorization Facility (SAF) resource profile in the SERVAUTH class to control access to dynamic VIPAs (DVIPAs) in a VIPARANGE statement in the following ways:

- Control which applications can bind to create a DVIPA
- Control whether an application can bind to create a DVIPA within a specific VIPARANGE subnet

**Rule:** If you use the BIND parameter on the PORT statement to create a DVIPA within a VIPARANGE subnet, and you include the SAF parameter on the PORT statement, creation of the DVIPA is controlled by both the SAF resource profile associated with the VIPARANGE statement and the SAF resource

profile associated with the PORT statement. For more information about the SAF parameter on the [PORT](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

For information about controlling which applications can issue a SIOCSVIPA ioctl call, a SIOCSVIPA6 ioctl call, or call the MODDVIPA utility to create a DVIPA, see [“Defining a security profile for SIOCSVIPA, SIOCSVIPA6, and MODDVIPA”](#) on page 405.

This information includes examples that use RACF. If you are using another security product, see the documentation for that product for the equivalent commands. For more information about RACF, see [z/OS Security Server RACF Security Administrator's Guide](#).

### ***Steps for controlling which applications can bind to create a DVIPA***

You can define a System Authorization Facility (SAF) resource profile in the SERVAUTH class to control which applications can bind to create dynamic VIPAs (DVIPAs) in a VIPARANGE statement.

## **Procedure**

Perform the following steps to control whether an application can bind to create a DVIPA:

1. Define the EZB.BINDDVIPARANGE.*sysname.tcpname* resource profile in the SERVAUTH class.

For example, you can define the resource profile using the following RACF command:

```
RDEFINE SERVAUTH (EZB.BINDDVIPARANGE.sysname.tcpname) UACC(NONE)
```

2. Give the user ID that is associated with the application READ access to the resource by issuing the following RACF command:

```
PERMIT EZB.BINDDVIPARANGE.sysname.tcpname ACCESS(READ) CLASS(SERVAUTH) ID(userid)
```

3. Refresh the profile by issuing the following RACF command:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

## **Results**

In this example, *sysname* is the name of the MVS system, *userid* is the user ID that is associated with the application, and *tcpname* is the job name of the TCP/IP started task.

The job name for started tasks, such as TCP/IP, is derived depending on how it is started:

- If the START command is issued with the name of a member in a cataloged procedure library (for example, S TCPIPX), the job name will be the member name (for example, TCPIPX).
- If the member name on the START command is qualified by a started task identifier (for example, S TCPIPX.ABC), the job name will be the started task identifier (for example, ABC). The started task identifier is not visible to all MVS components, but TCP/IP uses it to build the RACF resource name.
- The JOBNAME parameter can also be used on the START command to identify the job name (for example, S TCPIPX,JOBNAME=XYZ).
- The JOBNAME can also be included on the JOB card.

### **Results:**

- If this resource profile is not defined, then the bind is processed.
- If this resource profile is defined and the user ID has READ access to the resource, then the bind is processed.
- If this resource profile is defined and the user ID does not have READ access to the resource, then the bind fails with a permission denied error, regardless of whether the user is a superuser.

## Steps for controlling whether an application can bind to create a DVIPA within a specific VIPARANGE subnet

You can define a System Authorization Facility (SAF) resource profile in the SERVAUTH class to control which applications can bind to create dynamic VIPAs (DVIPAs) within a specific VIPARANGE subnet.

### Procedure

Perform the following steps to control whether an application can bind to create a DVIPA within a specific VIPARANGE subnet for use by only that application:

1. Define the EZB.BINDDVIPARANGE.*sysname.tcpname.resname* resource profile in the SERVAUTH class. For example, to protect a VIPARANGE subnet for application APPL1, you can define the EZB.BINDDVIPARANGE.*sysname.tcpname*.APPL1 resource profile using the following command:

```
RDEFINE SERVAUTH (EZB.BINDDVIPARANGE.sysname.tcpname.APPL1) UACC(NONE)
```

2. On the VIPARANGE statement, include the SAF parameter with a *resname* value that matches the *resname* value of the EZB.BINDDVIPARANGE.*sysname.tcpname.resname* resource profile.

For example:

```
VIPARANGE DEFINE 255.255.255.255 10.10.10.1 SAF APPL1
```

For more information about the SAF parameter on the [VIPARANGE statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

3. Give the user ID that is associated with the application READ access to the EZB.BINDDVIPARANGE.*sysname.tcpname.resname* resource.

For example:

```
PERMIT EZB.BINDDVIPARANGE.sysname.tcpname.APPL1 ACCESS(READ) CLASS(SERVAUTH)
ID(userid)
```

4. Refresh the resource profile by issuing the following RACF command:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

### Results

In this example, *sysname* is the name of the MVS system, *userid* is the user ID that is associated with the application, and *tcpname* is the job name of the TCP/IP started task. For information about how the job name for a started task, such as TCP/IP, is determined, see [“Steps for controlling which applications can bind to create a DVIPA” on page 431](#).

#### Results:

- If the SAF parameter is specified and the user ID has READ access to the resource, then the bind is processed.
- If the SAF parameter is specified and the user ID does not have READ access to the resource, then the bind fails.
- If the SAF parameter is specified but the resource profile is not defined, then the bind fails.
- All of the following profile specifications that include wildcard values match the EZB.BINDDVIPARANGE.*sysname.tcpname.resname* resource profile name:
  - EZB.BINDDVIPARANGE.\*\*
  - EZB.BINDDVIPARANGE.\*\*
  - EZB.BINDDVIPARANGE.\*\*.

The most specific match to a resource profile is always used.

## Movement of a unique APF-authorized application instance (ioctl)

APF-authorized applications running under a user ID with superuser authority (or that have access through the MODDVIPA security profile) have the ability to activate a dynamic VIPA with the SIOCSVIPA or SIOCSVIPA6 ioctl command, either within the application itself or by invoking the MODDVIPA utility. Because this is a controlled environment, it is assumed configuration errors are minimized or avoided and the usage is correct. Thus, even if the requested DVIPA is currently active on another TCP/IP stack via BIND() or ioctl(), the DVIPA will be immediately activated on this stack. What happens on the other stack is determined by how the VIPARANGE was configured on that stack.

### VIPARANGE (DEFINE) MOVEABLE NONDISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE NONDISRUPTIVE, the following events occur:

- The DVIPA ownership is immediately transferred to the second stack which adds the DVIPA to its HOME list and dynamically notifies the routers.
- At the same time, the first stack notifies the routers that it no longer is the owner of the DVIPA, and puts the DVIPA into moving status. The DVIPA remains in moving status (and in the first stack's HOME list) until the DVIPA is deleted on that stack with the VIPADELETE profile statement or the SIOCSVIPA or SIOCSVIPA6 ioctl DELETE option.
- Existing connections on the first stack are preserved. If the second stack receives packets intended for existing connections, it will route the packets to the first stack.

#### Notes:

1. To ensure preservation of existing connections on the prior owning stack, you must define DYNAMICXCF on both stacks, on the IPCONFIG statement for IPv4 dynamic VIPAs or on the IPCONFIG6 statement for IPv6 dynamic VIPAs.
2. NONDISRUPTIVE is the default for V2R10 and later.
3. Both stacks must be running V2R10 or later to get non-disruptive behavior. If either stack is running V2R8, the result will be as described in [“VIPARANGE \(DEFINE\) MOVEABLE DISRUPTIVE” on page 433](#).

### VIPARANGE (DEFINE) MOVEABLE DISRUPTIVE

If the first stack is configured with VIPARANGE MOVEABLE DISRUPTIVE (or if either stack is running V2R8), the following events occur:

- The ioctl request for the application on the second stack succeeds. The DVIPA is added to the HOME list on the second stack, and the routers are dynamically notified.
- The DVIPA on the first stack is deleted.

#### Notes:

1. Any existing connections to the DVIPA on the first stack are broken.
2. DISRUPTIVE is IPv4 only.

## Same dynamic VIPA for VIPADEFINE and BIND(), SIOCSVIPA or SIOCSVIPA6 ioctl, or MODDVIPA utility

Regardless of careful implementation, it is possible that the same IP address is inadvertently selected for VIPADEFINE and for use with BIND(), SIOCSVIPA or SIOCSVIPA6 ioctl, or the MODDVIPA utility. Because the application scenarios are quite different, this must be an error.

If this duplicate DVIPA address conflict occurs on the same TCP/IP, the second attempt might fail. If an IP address is specified in a VIPADEFINE, and that same IP address has already been activated on the TCP/IP by an application using BIND(), the SIOCSVIPA or SIOCSVIPA6 ioctl, or the MODDVIPA utility, the VIPADEFINE will be rejected during VARY TCPIP,,OBEYFILE command processing. If an IP address is activated with VIPADEFINE, and the application does a BIND(), ioctl(), or the MODDVIPA utility is used,

the BIND() will succeed, but the ioctl() will fail with a nonzero errno and the MODDVIPA utility will set a nonzero condition to indicate that the IP address already exists.

The same situation could also occur on two different TCP/IPs in the sysplex. Because the TCP/IPs are exchanging information among themselves, if the two attempts are far enough apart in time, the second attempt will be caught immediately and rejected. However, it is possible that the attempt will be made almost simultaneously on two different TCP/IPs, such that neither TCP/IP is yet aware of the attempt on the other TCP/IP. If both attempt such an activation, and the exchange of information then shows a conflict, the internal sysplex time stamps are used to determine which attempt was really first. The one that appears to be first is allowed to continue, and the dynamic VIPA is deleted from the later TCP/IP. While such a simultaneous attempt is somewhat unpredictable in respect to which one will succeed, the dynamic VIPA will remain active on only one TCP/IP, and examination of messages will indicate which TCP/IP successfully created the DVIPA and on which TCP/IP it was rejected.

## Dynamic VIPA creation results

Table 21 on page 434 summarizes the results of attempting to create a dynamic VIPA when it (or the same IP address for HOME statement) already exists in the sysplex.

| Table 21. Summary of dynamic VIPA creation results |               |                                                                                                                                 |                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|----------------------------------------------------|---------------|---------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| First action                                       | Second action | Result if second action is on the same stack                                                                                    | Result if the second action is on a different stack within the sysplex                                                                                                                                                                                                                                                                                                                                                                     |
| bind()                                             | bind()        | Second bind() succeeds, but no new VIPA is created.                                                                             | <p>If both stacks are running V2R10 or later, and the first BIND DVIPA was created with MOVEABLE NONDISRUPTIVE:</p> <ul style="list-style-type: none"> <li>On stack 2, bind() succeeds</li> <li>On stack 1, the BIND VIPA remains in the HOME list (unadvertised) and any existing connections are preserved</li> <li>New connections to that IP address go to the application on stack 2.</li> </ul> <p>Otherwise, second bind fails.</p> |
| bind()                                             | ioctl()       | ioctl() fails with warning condition code, but the application associated with the ioctl is still able to use the dynamic VIPA. | ioctl() succeeds, bind is deleted (even if BIND DVIPA was created as MOVEABLE NONDISRUPTIVE)                                                                                                                                                                                                                                                                                                                                               |
| bind()                                             | VIPADefine    | VIPADefine fails.                                                                                                               | VIPADefine fails.                                                                                                                                                                                                                                                                                                                                                                                                                          |
| bind()                                             | VIPABackup    | VIPABackup fails.                                                                                                               | VIPABackup fails.                                                                                                                                                                                                                                                                                                                                                                                                                          |
| bind()                                             | HOME          | See note at end of table.                                                                                                       | See note at end of table.                                                                                                                                                                                                                                                                                                                                                                                                                  |
| ioctl()                                            | bind()        | bind() succeeds, no new VIPA is created.                                                                                        | bind() fails.                                                                                                                                                                                                                                                                                                                                                                                                                              |

Table 21. Summary of dynamic VIPA creation results (continued)

| First action | Second action | Result if second action is on the same stack                                                                                           | Result if the second action is on a different stack within the sysplex                                                                                                                                                                                                                                                                                |
|--------------|---------------|----------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ioctl()      | ioctl()       | Second ioctl() fails with warning condition code, but the application associated with the ioctl is still able to use the dynamic VIPA. | Second ioctl() succeeds.<br><br>If both stacks are running V2R10 or later, and the ioctl DVIPA on stack 1 was created with MOVEABLE NONDISRUPTIVE, the DVIPA on stack 1 remains in the HOME list (unadvertised) and any existing connections are preserved. Otherwise, the ioctl DVIPA on stack 1 is deleted and any existing connections are broken. |
| ioctl()      | VIPADefine    | VIPADefine fails.                                                                                                                      | VIPADefine fails.                                                                                                                                                                                                                                                                                                                                     |
| ioctl()      | VIPABackup    | VIPABackup fails.                                                                                                                      | VIPABackup fails.                                                                                                                                                                                                                                                                                                                                     |

| Note: Defining the same IP address in the HOME list as an existing dynamic VIPA will not be rejected by the TCP/IP stack, but it is likely to cause routing problems. |               |                                              |                                                                        |

## TIER1, TIER2, and CPCSCOPE keyword DVIPA contention resolution

Sysplex distributor supports load balancing across z/OS images in a sysplex, as described in “[Sysplex distribution optimizations for multi-tier z/OS workloads](#)” on page 515; the TIER1, TIER2, and CPCSCOPE keywords are used with this support. Use the following guidelines to define dynamic VIPAs (DVIPAs) that use these keywords.

### Guidelines:

- If you want to change the TIER1, TIER2, or CPCSCOPE definition for a DVIPA, delete the existing definition of the DVIPA from the sysplex first; the keyword usage for a DVIPA must be the same throughout the sysplex. For example:
  - If there is an existing VIPADefine or VIPABackup statement for DVIPA1 using the TIER2 keyword, use a VIPADelete statement to remove this DVIPA before using a VIPADefine TIER1 statement for DVIPA1.
  - If there is an existing VIPADefine or VIPABackup statement for DVIPA1 that does not use the TIER1, TIER2, or CPCSCOPE keywords, use a VIPADelete statement to remove this DVIPA before defining DVIPA1 with one of these keywords.
- When you are defining a DVIPA with the CPCSCOPE keyword, and the DVIPA exists in a different central processor complex (CPC), delete it from that CPC first; a DVIPA with the CPCSCOPE keyword can exist only on stacks in the same CPC. For example, if DVIPA1 was defined using a VIPABackup CPCSCOPE statement on a stack in CPC1, use a VIPADelete statement to remove this DVIPA before using a VIPABackup CPCSCOPE statement for a stack in CPC2.

If you do not follow these guidelines, the changes to DVIPA creation results that occur when the TIER1, TIER2, or CPCSCOPE keyword is changed, added, or removed from a DVIPA that already exists in the sysplex are described in [Table 22 on page 439](#), [Table 23 on page 440](#), and [Table 24 on page 441](#).

If you create a new definition for an existing DVIPA on the same stack, either in the same profile or later using the VARY TCPIP,OBeyFILE command, see [Table 22 on page 439](#). When the new definition is processed, it cannot change the TIER1, TIER2, or CPCSCOPE usage; if this is attempted, the new definition is rejected.

| Table 22. DVIPA contention resolution for DVIPA definitions on the same stack |                                                           |                                                        |
|-------------------------------------------------------------------------------|-----------------------------------------------------------|--------------------------------------------------------|
| Original definition                                                           | Later definition                                          | Result                                                 |
| VIPADefine or VIPABackup DVIPA1 TIER1                                         | VIPADefine or VIPABackup DVIPA1 TIER1                     | Later definition replaces the original definition      |
| VIPADefine or VIPABackup DVIPA1 TIER2                                         | VIPADefine or VIPABackup DVIPA1 TIER2                     |                                                        |
| VIPADefine or VIPABackup DVIPA1 TIER2 CPCSCOPE                                | VIPADefine or VIPABackup DVIPA1 TIER2 CPCSCOPE            |                                                        |
| VIPADefine or VIPABackup DVIPA1 CPCSCOPE                                      | VIPADefine or VIPABackup DVIPA1 CPCSCOPE                  |                                                        |
| VIPADefine or VIPABackup DVIPA1 TIER1                                         | VIPADefine or VIPABackup DVIPA1 TIER2 or CPCSCOPE         | Configuration mismatch; later definitions are rejected |
| VIPADefine or VIPABackup DVIPA1 TIER2                                         | VIPADefine or VIPABackup DVIPA1 TIER1 or CPCSCOPE         |                                                        |
| VIPADefine or VIPABackup DVIPA1 CPCSCOPE                                      | VIPADefine or VIPABackup DVIPA1 TIER1 or TIER2            |                                                        |
| VIPADefine or VIPABackup DVIPA1                                               | VIPADefine or VIPABackup DVIPA1 TIER1, TIER2, or CPCSCOPE |                                                        |
| VIPADefine or VIPABackup DVIPA1 TIER1, TIER2, or CPCSCOPE                     | VIPADefine or VIPABackup DVIPA1                           |                                                        |

When two stacks define the same DVIPA, contention resolution is as follows:

- If there is a TIER1, TIER2, or CPCSCOPE mismatch for the DVIPA, the stack with the later timestamp cannot change the keyword usage, and either rejects its own definition during profile processing or deletes its definition when it learns of the DVIPA definition with the earlier timestamp.
- If there is a mismatch between a DVIPA definition that uses a TIER1, TIER2, or CPCSCOPE keyword and a DVIPA definition that does not use any of these keywords, possible outcomes are as follows:
  - If the second stack has already received the mismatched DVIPA definition from the first stack prior to profile processing, contention resolution depends on the release level of stack 2:
    - If stack 2 is V1R11 or later, the earlier timestamp wins and stack 2 rejects all DVIPA1 definitions (including the VIPADISTRIBUTE statement)
    - If stack 2 is V1R10 or earlier, it is not aware of the new keywords and the mismatch and it defines the DVIPA; stack 1 deletes its definition when it learns that stack 2 defined the DVIPA
  - After two stacks have successfully defined DVIPAs with mismatching definitions, the stack that uses the keywords deletes all of its definitions for that DVIPA, because the stack that uses no keywords might be using V1R10 or earlier.

Table 23 on page 440 summarizes DVIPA contention resolution between stacks in the same CPC.

| <i>Table 23. DVIPA contention resolution between stacks in the same CPC</i> |                                                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

## IPv6 considerations

This topic discusses special considerations for IPv6.

### VIPARANGE

The MOVEable DISTRUPTive parameter is not supported for IPv6. To prevent an unauthorized application from creating a dynamic VIPA with a bind() call, you can add the EZB.BINDDVIPARANGE.sysname.tcpname resource profile, or you can use the SAF parameter along with the EZB.BINDDVIPARANGE.sysname.tcpname.resname resource profile. If the security check fails, the bind() request fails, and if the security check is successful, the bind() request is accepted.

### VIPADefine and VIPABackup

VIPABackup must specify an interface name and IPv6 address. The interface name and IPv6 address pair must match any preexisting dynamic VIPA definitions for either that interface name or IPv6 address. If using VIPABackup for an initial DVIPA activation, neither the interface name nor the IPv6 address can preexist. Furthermore, for the takeover and backup functions to succeed, if a corresponding VIPADefine is to be subsequently activated, the interface name and IPv6 address on the VIPADefine statement must match the VIPABackup statement.

## Unique application-instance scenario and IPv6-enabled applications

A single instance of an IPv6-enabled TCP application can typically handle communications with IPv4 or IPv6 partner applications. IPv6-enabled TCP server applications usually accomplish these communications by using a single AF\_INET6 socket to accept connections from both IPv4 and IPv6 clients. As a result, IPv6-enabled applications have some additional configuration considerations when compared to IPv4-only applications, as they require both an IPv4 DVIPA and an IPv6 DVIPA to be configured. If the application is using the MODDVIPA utility or the SIOCSVIPA IOCTL to define the DVIPA, it must be modified as follows:

- If you are using the MODDVIPA utility, an additional set of invocations for this utility is needed to define and delete the IPv6 DVIPA to be associated with the application.
- If the application is using the SIOCSVIPA IOCTL, it must be modified to also issue the SIOCSVIPA6 IOCTL to define and delete the IPv6 DVIPA to be associated with the application.

Applications that are currently relying on defining the DVIPA dynamically by using the bind() socket API or the BIND parameter on the PORT reservation statement have some additional considerations, as a single socket cannot be bound to more than one IP address.

The following options can help alleviate this issue:

- Instead of relying on the bind to trigger the DVIPA definition, the application or configuration can be modified to allow the application to bind to the IPv6 unspecified address (in6addr\_any). The MODDVIPA

utility can then be used to define and delete both the IPv4 and IPv6 DVIPAs associated with the application.

Another similar alternative is for the application to issue the SIOCSVIPA or SIOCSVIPA6 IOCTL for both of these DVIPAs. If two or more application instances are to bind their listeners to the same port and the IPv6 unspecified address, each DVIPA can be created with affinity to the application instance that created it. Such affinity ensures that a connection request is sent to the correct listener. A connection request for a DVIPA that is created with affinity is sent to a TCP Listener if the application instance that created the DVIPA issues the bind() call. If no matching listener is available, normal shareport load balancing is used to choose the best available listener. See [“Configuring the unique application-instance scenario” on page 401](#) for information about creating a DVIPA with affinity.

- Start two instances of the application, one binding to the IPv4 DVIPA and the other binding to the IPv6 DVIPA, assuming that multiple instances of the same application can be started within the same MVS image or across different images in the sysplex. This configuration allows IPv4 clients to reach the application instance that is bound to the IPv4 DVIPA and IPv6 clients to reach the application instance that is bound to the IPv6 DVIPA.
- In some cases, it might be possible to modify the application so that it can create two sockets, one for IPv6 communications and one for IPv4 communications. Each socket can then be bound to the IPv4 or IPv6 DVIPA as appropriate, and a single instance of the application can handle both IPv4 and IPv6 clients. This solution might be less desirable because it also involves application code changes.

## VIPAs, OSA, and Spanning Tree Protocol

---

Spanning Tree Protocol (STP) can potentially impact environments where both OSA and VIPA are deployed.

With dynamic VIPA, a TCP/IP address takeover occurs when a TCP/IP stack fails, or a static or dynamic VIPA is manually moved by operator intervention. In either case, when a static or dynamic VIPA moves, the IP address and respective workloads are taken over by another TCP/IP stack through other OSA Ethernet devices running on a different server. When the original TCP/IP stack and respective OSA devices are returned to operation, both the IP address and respective workload traffic are taken back by the recovered TCP/IP stack.

If the network bridge or switch is not configured properly, packets can get lost in the network or be blocked by the networking equipment. This is a result of a physical looping condition identified by the STP, or expired OSA timers due to the increased latencies associated with blocked ports or delayed packets. In these cases, static or dynamic VIPA connectivity can fail.

When configuring STP, use care in the bridge or switch configuration to avoid or minimize potential loop conditions. For example, if the STP is not an integral component of the overall network, disabling the STP on all of the Virtual LANs (VLANs) that connect to OSA devices will help avoid the problem.

Also, some networking switches provide a mechanism for suppressing the STP's listening and learning states on specific switch ports. For example, Cisco Systems provides an STP configuration feature called PortFast that can place specific switch ports into forwarding state as soon as a link is detected. Without PortFast enabled, a switch port has to transition through the listening and learning stages (30 seconds total) of Spanning Tree reconvergence before the switch port can actually pass valid traffic. For PortFast capable Cisco switches, enabling PortFast on all switch ports that OSA is connected into allows network administrators to both preserve their original Spanning Tree configuration by not having to change it, while also providing a viable mechanism to avoid potential static or dynamic VIPA problems.

For more information on configuring STP and immediate port forwarding, see the bridge or switch operational manual.

## Mixture of types of dynamic VIPAs within subnets

---

Any particular IP address can be used in only one way as a dynamic VIPA. A dynamic VIPA can be defined either with VIPADEFINE or by application action within a valid VIPARANGE, but not both. However, within a subnet defined as a VIPARANGE, some IP addresses can be used for VIPADEFINE, and others may be

assigned to unique application instances, without conflict, as long as the limit of a total of 1024 active and backup dynamic VIPAs on a single TCP/IP is not exceeded. TCP/IP will make no attempt to reject a VIPADefine dynamic VIPA that also falls within a VIPARANGE. This allows installations with limited availability of IP addresses to assign individual addresses to either application scenario, without having to define separate subnets and use up additional IP addresses in that manner.

## MVS failure and sysplex failure management

---

The TCP/IPs in a sysplex use MVS XCF messaging to exchange information about dynamic VIPAs. When a TCP/IP fails or is ended by operator command, but the underlying MVS remains active, the other TCP/IPs are immediately notified, and takeover of VIPADefine dynamic VIPAs is automated and very fast. In addition, each TCP/IP stack monitors for local problem conditions that might cause it to leave the TCP/IP sysplex group, at which point the other TCP/IPs will be immediately notified. For more information, see [“Sysplex problem detection and recovery”](#) on page 480.

However, when an MVS fails, there is normally an operator message on the console requiring a response (WTOR). Until this response is made by an operator or automation, the other MVS systems do not notify the remaining TCP/IPs in the sysplex of the failure of the TCP/IP on the failing MVS. This can delay automated backup of dynamic VIPAs defined with VIPADefine. Sysplex Failure Management (SFM) can be used to automate the required response to the console message of the failing MVS. See [z/OS MVS Setting Up a Sysplex](#) for information on how to set up SFM to avoid the requirement for a manual response and speed backup of dynamic VIPAs defined with VIPADefine.

For more information, see [z/OS Communications Server: IP Diagnosis Guide](#).

## Applications and dynamic VIPAs

---

While most applications support multiple instances in a sysplex, very few applications expect IP addresses to move around under them. TCP applications use TCP connections to form a relationship between particular client and server instances to exchange data over an extended period. They rely on notification of TCP connection termination to initiate recovery and to reestablish a new relationship (possibly from a client to a different server). Conversely, most UDP applications do the equivalent function at the application layer. Movement of an IP address to a different server could be confusing to the client, unless the new server also is aware of the state of the client work.

UDP applications whose interactions consist of atomic interactions (a single request followed by one or more responses, with no state information maintained at the server between requests) can use dynamic VIPAs in the multiple application-instance scenario. However, if the server application maintains state information between interactions (for example, NFS), then moving a dynamic VIPA to another server might not work unless the client/server application protocol can detect the discontinuity. In that case, the unique application-instance scenario might apply, which would require the restart of the server instance on another TCP/IP.

In addition, the following types of work are not appropriate for distribution with distributed dynamic VIPA:

- Applications that establish affinity with a particular TCP/IP stack, such as SNMP.
- FTP servers that receive the PASV or EPSV command for a distributed DVIPA that did not specify SYSPLEXPORTS. The PASV and EPSV commands are supported when SYSPLEXPORTS was specified on the VIPADISTRIBUTE statement of the distributed DVIPA that is the destination IP address being used by the FTP server. These commands request that the FTP server bind() on a data port that is not the default data port, or the one specified on the VIPADISTRIBUTE statement, and to wait for a connection rather than initiate one on receipt of a transfer command (for example, RETR). Because SYSPLEXPORTS cannot be specified for a non-distributed dynamic VIPA, passive mode FTP connections made to a non-distributed dynamic VIPA cannot be recovered when the VIPA is moved through a planned takeover. The control connection remains on the original stack, but attempts to create new data connections for control connections that existed prior to the move will fail. When SYSPLEXPORTS is used with a distributed dynamic VIPA, new data connections are always sent to the same stack containing their control connection. For more information on using the SYSPLEXPORTS parameter in the VIPADYNAMIC statement summary block, see [z/OS Communications Server: IP Configuration Reference](#).

- FTP servers that accept connections on an IPv6 distributed DVIPA that does not have SYSPLEXPORTS specified. The FTP server expects an EPSV command for data transfers to or from an IPv6 address, and use of the EPSV command is supported only when SYSPLEXPORTS was specified on the VIPADISTRIBUTE statement of the distributed DVIPA that is the destination IP address being used by the FTP server.

## Configuring VIPAs for activation with VIPABACKUP

When adding a dynamic VIPA to a functioning sysplex, the normal order is to add VIPABACKUP statements to backup stacks, and then add a VIPADEFINE statement to the TCP/IP stack where the VIPA should normally be, at which time the VIPA would be activated and ready for use. A VIPADISTRIBUTE statement could be added at the same time. The VIPA would be activated only when the VIPADEFINE was processed on the TCP/IP that would normally own it, and not when a VIPABACKUP is processed on another stack. This is, in part, because parameters on the VIPADEFINE that are needed to activate the VIPA were not found on the VIPABACKUP statement.

However, on the rare occasion that a disaster occurs, it might be necessary to IPL all of the systems in a sysplex. Assuming that many dynamic VIPAs are in use and the VIPADEFINE statements are throughout the available TCP/IP stacks in the sysplex, most of the dynamic VIPAs have a lengthy wait before the owning operating system, TCP/IP, and application are started and fully operational. The intent of dynamic VIPAs defined with VIPADEFINE and VIPABACKUP is to move the dynamic VIPAs under a functioning application as soon as possible. Therefore, optional parameters have been added to the VIPABACKUP statement to allow the dynamic VIPA to be activated when the VIPABACKUP is processed at TCP/IP initialization or VARY TCPIP, OBEYFILE command processing. If the MOVEABLE IMMEDIATE or MOVEABLE WHENIDLE parameter is specified on a VIPABACKUP profile statement, along with required address mask and optional SERVICEMGR parameters for an IPv4 DVIPA, the dynamic VIPA will be activated when the profile statement is processed, if it is not active elsewhere in the sysplex already. The following notes apply to this case:

- If the MOVEABLE parameter is specified, the address mask must also be specified. The address mask and SERVICEMGR parameters can be specified on a VIPABACKUP statement only if the MOVEABLE parameter has also been specified.
- The first started VIPABACKUP TCP/IP stack that is configured to start a particular dynamic VIPA with VIPABACKUP will activate the dynamic VIPA and own it until the VIPADEFINE stack is started. As long as the first activating VIPABACKUP stack remains operational, starting another stack with a VIPABACKUP statement will not cause the dynamic VIPA to move, even if the second stack has a higher backup rank. Only the initialization of the VIPADEFINE stack will cause the VIPA to move automatically.
- When the VIPADEFINE is eventually processed, its parameters will override the values specified on the VIPABACKUP that activated the dynamic VIPA, if the VIPADEFINE has parameters that are different from those specified on the VIPABACKUP.

It is always a good idea, when able to specify a parameter on both primary and backup, to specify exactly the same values for each. When all the parameters common to VIPADEFINE and VIPABACKUP are specified the same on both for a particular DVIPA, the behavior exhibited when the VIPADEFINE stack comes up will be the same as when the DVIPA is activated first by a VIPABACKUP stack. However, for IPv4, there are several parameters that could be specified inconsistently on the VIPABACKUP and VIPADEFINE statements. If they are specified inconsistently, the following implications are some of the implications by parameter:

- **MOVEABLE:** If there is any doubt, this parameter should be coded as MOVEABLE IMMEDIATE on the VIPABACKUP stack, so that the stack will maintain connection information to be sent to the VIPADEFINE stack when it comes up. Subsequent operation in the sysplex will be determined by the coding (or defaulting) of MOVEABLE on the VIPADEFINE statement, regardless of what was coded on the VIPABACKUP of the stack that first activated the DVIPA. This is true even if that same stack later takes over the DVIPA from the VIPADEFINE or another stack. (This is the reason MOVEABLE was chosen as the way to activate the new function on VIPABACKUP stacks, rather than a new keyword, to force consideration of the setting of the MOVEABLE parameter for VIPABACKUP stacks.)

- **address\_mask:** The `address_mask` is used to build `BSDROUTINGPARMS` statements. If the attached routing daemon is `OMPROUTE` and there is no corresponding interface definition with the subnet mask parameter in `OMPROUTE` configuration, `OMPROUTE` might send a different address mask from the `VIPADefine` stack than it will for the `VIPABackup` stack, which might confuse the routing network. The `address_mask` should be the same on `VIPABackup` and `VIPADefine` statements for a particular `DVIPA`.

**Result:** Incorrect `OMPROUTE` configuration, such as missing interface definitions for `RIPv1`, `RIPv2`, or `OSPF`, can lead to unexpected results, especially if `OMPROUTE` uses defaults for the address mask.

Assuming that dynamic VIPAs are throughout the sysplex, and that critical applications are as well, the first stack to be activated might activate most, if not all, `DVIPAs`, and might therefore assume a considerable amount of the workload. For any particular application, all of the workload is directed to the first stack supporting that application to be activated, regardless of what other workload will be executing on that same stack or `LPAR`.

**Guideline:** Consider the planned sysplex TCP/IP activation sequence, and have only those `DVIPAs` for critical applications activating on TCP/IP stacks early in the sequence, so that less important work does not interfere with the business-critical applications during sysplex startups.

## Example of configuring dynamic and distributed VIPAs

The TCP/IP profiles needed to implement dynamic VIPA (`DVIPA`) on multiple systems in a sysplex are shown in the following examples. The `VIPADefine` and `VIPABackup` statements allow automatic dynamic VIPA takeover to occur if needed (see “Configuring the multiple application-instance scenario” on page 400), and the `VIPARange` statements allow dynamic VIPAs to be dynamically created by an application or by the `MODDVIPA` utility (see “Configuring the unique application-instance scenario” on page 401). The `VIPADistribute` statements allow a single VIPA to be shared among several TCP/IP stacks. Including the `SOURCEVIPA` and `TCPSTACKSOURCEVIPA` parameters on the `IPCONFIG` and `IPCONFIG6` statements, on each target stack with the same dynamic VIPA specified, enables a single `DVIPA` address to be used as a sysplex-wide source `DVIPA` address for outbound TCP connections. The following examples show both IPv4 and IPv6 `DVIPAs`, and the output is shown in the IPv6-enabled, or long, format.

TCPCS6 does not have dynamic VIPAs defined so it does not contain a VIPADYNAMIC definition. It has DYNAMICXCF specified for IPv4 and IPv6 to enable XCF dynamic support and to allow TCPCS6 to be a target for dynamic VIPA distribution.

Start TCP/IP on each system as shown.

- On system1, start TCPCS and TCPCS2.
- On system2, start TCPCS3, on system3 start TCPCS6.
- On system1, run the MODDVIPA utility to define the DVIPA 201.2.10.193.

```

//TCPDVP PROC
//*
//*
//TCPDVP EXEC PGM=MODDVIPA ,REGION=0K,TIME=1440, x
// PARM='POSIX(ON) ALL31(ON)/-p TCPCS -c 201.2.10.193'
//SYSPRINT DD SYSOUT=*,DCB=(RECFM=FB,LRECL=132,BLKSIZE=132)
//SYSERR DD SYSOUT=*
//SYSERROR DD SYSOUT=*
//SYSDEBUG DD SYSOUT=*
//SYSUDUMP DD SYSOUT=A
//SYSABEND DD SYSOUT=*
//*
//*Run program here
//*
//TCPDVP EXEC PGM=MODDVIPA ,REGION=0K,TIME=1440, x
// PARM='POSIX(ON) ALL31(ON)/-p TCPCS -d
201.2.10.193'

```

The PARM field can be -c for create, -a for create with affinity, or -d for delete. This example creates DVIPA 201.2.10.193 for the TCP/IP named TCPCS. After intermediate program is completed (and the comment character is removed), the DVIPA is deleted.

- On system 1, deactivate DVIPA 201.2.10.23 by issuing the following command on the MVS console:

```
V TCPIP,TCPCS,SYSPLEX,DEACTIVATE,DVIPA=201.2.10.23
```

## Verifying the DVIPAs in a sysplex

The following display command can be used to display dynamic VIPAs in a sysplex:

```
d tcpip,tcpname,sysplex,vipadyn
```

In the following example taken from stack TCPCS, the ORIGIN lines show that 201.2.10.11, 201.2.10.12, 201.2.10.14, 201.2.10.15, DVIPA1, and DVIPA2 were all created by VIPADEFINE on this stack. 201.2.10.13, 201.2.10.21, and 201.2.10.22 were created by VIPABACKUP statements. (Note that the deactivated DVIPA 201.2.10.23 does not appear in this display.)

The ORIGIN line indicates how the DVIPA is configured on the stack specified by `tcpname`. Each stack (TCPNAME) for each system (MVSNAME) is shown with its status (STATUS). Two other status values not shown in the following example are:

### QUIESCING

This DVIPA has been deactivated, or it was a target for distribution and has been removed as a target. However, it is still servicing one or more connections for this DVIPA. The DVIPA will be removed when all connections complete.

### MOVING

This DVIPA was active on this stack and has been moved to another stack. Connections on this stack for this DVIPA prior to the move will still be serviced by this stack until completion.

The rank (RANK) indicates which of the stacks is eligible to take over if the stack on which the DVIPA is active stops. The stack with the highest rank is the one that will take over the DVIPA.

## Using Netstat support to verify dynamic VIPA configuration

You can use the Netstat VIPADCFG/-F report option to display the dynamic VIPA configuration for a particular TCP/IP stack. Use the DETAIL modifier on the distributing stack to verify all the options configured on the VIPADISTRIBUTE statements.

**Guideline:** Use the Netstat CONFIG/-f report option to verify the rest of the stack configuration, including SOURCEVIPA, TCPSTACKSOURCEVIPA, and SYSPLEXROUTING; use the Netstat SRCIP/-J report option to verify the SRCIP profile statement for particular jobs or destinations.

The dynamic VIPA information section is displayed only when there are DVIPAs configured on this stack. The VIPA Range section, displayed only if a VIPARANGE statement was processed in this stack's initial profile (or in a data set referenced by a VARY TCPIP,,OBEYFILE command), indicates only that a range was configured. It does not indicate whether any ioctl or BIND has actually created a DVIPA in the specified range. The VIPA distribute section is displayed only if there are VIPADISTRIBUTE statements configured on this stack. The deactivated dynamic VIPA information section is displayed only when there are DVIPAs that have been deactivated on this stack.

## Verifying sysplex distributor workload

You can use the Netstat VDPT/-O and VCRT/-V report options to verify sysplex distributor workload. See [z/OS Communications Server: IP System Administrator's Commands](#) for more information on these commands.

Use the Netstat VDPT/-O report option with the DETAIL modifier on the distributing stack to confirm that there are target stacks available with server applications ready. This display will show only target stacks that are currently up and have joined the sysplex. The RDY field indicates how many, if any, applications the target TCP/IP, identified by its DestXCF Addr, has bound to DPort. If none, then this target TCP/IP will not receive any connection workload. The TotalConn field indicates how many connections this distributing TCP/IP has forwarded to the target TCP/IP. The ActiveConn field indicates how many connections the distributing TCP/IP has forwarded to the target TCP/IP that are currently active.

**Tip:** TotalConn is an historical count and will wrap.

The following Netstat display command on the distributing stack, TCPCS, shows which target stacks are available with the server applications ready.

```

```

- The target stack is identified by its dynamic XCF address (DESTXCF).
- The RDY field indicates how many applications on that target stack have bound to the DEST port.
- TOTALCONN is the number of all connections the distributing stack, TCP/CS, has routed to the target stack.
- The ACTIVECONN value is the number of currently active connections that the distributing stack, TCP/CS, has routed to the target stack. The active connections include all TCP connections that the target TCP/IP stack is still aware of, even if the connections are in the process of terminating. For example, connections in FIN\_WAIT2 or TIMEWAIT states are also included in this count.

- The ABNORM value is the rate of abnormal terminations for this server. This field affects the WLM weight and the operation of the OPTLOCAL distributor setting.
- The HEALTH value is the health indicator for this server. This field affects the WLM weight and the operation of the OPTLOCAL distributor setting.
- WLM is the normalized workload manager weight value for the target TCP/IP stack.
- Weight is the raw composite weight for the target TCP/IP stack. The composite weight is based on the application's general CPU usage, the System z Application Assist Processor (zAAP) usage, and the System z Integrated Information Processor (zIIP) usage, as shown in [Table 25](#) on page 458.

| Table 25. Weight determination |                                                                                                                                                                                                                                     |                                                                                                                                                                                                                                                                                      |
|--------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Processor                      | DISTMETHOD BASEWLM                                                                                                                                                                                                                  | DISTMETHOD SERVERWLM                                                                                                                                                                                                                                                                 |
| CP                             | <p>The Raw value is the raw WLM system general CP weight.</p> <p>The Proportional value is the Raw value modified by the expected CP usage proportion configured on the VIPADISTRIBUTE PROCTYPE statement for this application.</p> | <p>The Raw value is the raw WLM server-specific general CP weight.</p> <p>The Proportional value is the Raw value modified by the proportion of CP capacity that is currently being consumed by the application's workload, as compared to the other processors (zIIP and zAAP).</p> |
| zAAP                           | <p>The Raw value is the raw WLM system zAAP weight.</p> <p>The Proportional value is the Raw value modified by the expected zAAP usage proportion configured on the VIPADISTRIBUTE PROCTYPE statement for this application.</p>     | <p>The Raw value is the raw WLM server-specific zAAP weight.</p> <p>The Proportional value is the Raw value modified by the proportion of zAAP capacity that is currently being consumed by the application's workload, as compared to the other processors (CP and zIIP).</p>       |
| zIIP                           | <p>The Raw value is the raw WLM system zIIP weight.</p> <p>The Proportional value is the Raw value modified by the expected zIIP usage proportion configured on the VIPADISTRIBUTE PROCTYPE statement for this application.</p>     | <p>The Raw value is the raw WLM server-specific zIIP weight.</p> <p>The Proportional value is the Raw value modified by the proportion of zIIP capacity that is currently being consumed by the application's workload, as compared to the other processors (CP and zAAP).</p>       |

- FLG is a flag field indicating how the connection was distributed. For example, the value DYNAMIC indicates this DVIPA is being distributed by the dynamic port assignment function.
- The target server responsiveness (TSR) field indicates how well a target server is accepting TCP connection setup requests. A value of 100 indicates that the target server is accepting all TCP connection setup requests successfully. A value of 0 indicates that the target server is accepting no TCP connection setup requests successfully. A value between 100 and 0 indicates the relative success rate of TCP connection setup requests for this target server.

When weighted active distribution is being used, the configured active connection weight for each target is shown as the WLM value in the Netstat VDPT/-O display. By using the DETAIL modifier on the display, the active connection counts (ActiveConn) are shown. The distributor balances incoming connection requests across the targets with a goal of having the number of active connections on each target proportionally equivalent to the configured active connection weight of each target.

## Dynamic VIPAs and routing protocols

With dynamic VIPAs, IP addresses may move from one stack to another. These changes need to be communicated to the network. Therefore, dynamic routing should be implemented when dynamic VIPAs are being used.

### IPv4 considerations for OMPROUTE

The names of dynamic VIPA interfaces are assigned dynamically by the stack when a dynamic VIPA interface is created. Therefore, the Name field that is set on the Interface or OSPF\_Interface statement for a dynamic VIPA is ignored by OMPROUTE.

Define an Interface or OSPF\_Interface definition for every dynamic VIPA address that a host might own. Because there could be many interfaces, more wildcard capabilities are added to OMPROUTE, for dynamic VIPA interfaces only.

Ranges of dynamic VIPA interfaces can be defined by using the subnet mask parameter on the OSPF\_Interface or Interface statement. The range that is defined is all the IP addresses that fall within the subnet that is defined by the mask and the IP address. The IP address parameter must be the subnet number of the range that is being defined, not a host address within that range. The following example defines a range of dynamic VIPA addresses from 10.138.165.81 to 10.138.165.94:

```
OSPF_Interface
 IP_address = 10.138.165.80
 Name = dummy_name (see tip)
 Subnet_mask = 255.255.255.240;
```

#### Tips:

- The Name parameter is required and must be unique, but it is not used for dynamic VIPAs.
- When you are defining ranges, it is not necessary or desirable to code a destination address. OMPROUTE automatically sets the destination address of a dynamic VIPA to its IP address.
- There is nothing in the interface definition statements that informs OMPROUTE that a particular interface definition statement is for a dynamic VIPA or a range of dynamic VIPAs. Rather, OMPROUTE learns this information from the stack when these interfaces are created or taken over.
- Because dynamic VIPAs can move between z/OS hosts, configure a router ID that specifies a physical interface or a static VIPA and not a dynamic VIPA.

OMPROUTE cannot build an advertisement with a size that exceeds the largest IP packet size, which is 64K. When this limit is reached, the following message is displayed:

```
EZZ7967I ADVERTISEMENT DISCARDED, OVERFLOWS BUFFER: LS
TYPE x ID x.x.x.x ORG y.y.y.y
```

**Result:** If this limit is reached with a router link-state advertisement (LSA), OMPROUTE cannot send the router LSA and other hosts cannot calculate routes to destinations (for example, VIPAs) owned by the stack on which OMPROUTE is running. OMPROUTE ends if it encounters this condition. If OMPROUTE cannot send its router LSA, it is useless as a router.

If an LSA exceeds the maximum transmission unit (MTU) size on its network, the LSA is fragmented. This fragmentation is not a problem for OMPROUTE, but some routers cannot accept fragmented LSAs.

**Tip:** If you are experiencing adjacency problems with routers and have many interfaces on your stack, check for fragmentation of the OMPROUTE router LSA.

Normally, large router LSAs are not a problem, as the size of LSAs seldom exceeds 64K, or even network MTU sizes. However, if many VIPA or dynamic VIPA interfaces are defined on a host, router LSA size can become a consideration. The size of the router LSA includes 52 bytes for headers, plus the number of bytes required to advertise the interfaces that the host owns. The number of bytes required for each interface is:

**VIPA**

12 bytes, plus 12 bytes for each VIPA subnet

**Tip:** If many VIPAs are in different subnets on the host, the size of the router LSA can be reduced by suppressing VIPA subnet routes by coding the `Advertise_VIPA_Routes` parameter on the `OSPF_INTERFACE` statement for the VIPA interfaces.

**Point-to-point**

24 bytes

**Point-to-multipoint**

12 bytes, plus 12 bytes for each neighbor on the interface

**All other types**

12 bytes

## IPv4 considerations for Routing Information Protocol

If using Routing Information Protocol (RIP) services and Host Route advertising is not supported by adjacent routers (that is, inability to learn host routes), the following restrictions for VIPA addresses must be applied to benefit from fault tolerance support:

- If you use subnetting and VIPA addresses are in the same network as the physical IP addresses, the subnetwork portion of any VIPA addresses must not be the subnetwork portion of any physical IP addresses in the network. In this case, assign a new subnetwork for the VIPA address.
- If subnetting is not used on any physical interface, the network portion of any VIPA addresses must not be the network portion of any physical IP addresses in the network. In this case, assign a new network for the VIPA address, preferably a class C network address.

If using RIP services and Host Route advertising is supported by adjacent routers, the network or subnetwork portions of VIPA addresses can be the same across multiple z/OS TCP/IP stacks in the network. To enable Host Route advertising in OMPROUTE, configure `RIP_Interface Send_Host_Routes=YES`.

## IPv6 considerations

For IPv6, all interfaces are defined to OMPROUTE by name only, and name wildcards are supported. This greatly simplifies definition considerations for OMPROUTE and VIPA interfaces.

To define IPv6 interfaces to OMPROUTE, you must know their names. Unlike IPv4, in which VIPA link names are generated by the stack, you specify link names to TCP/IP when defining IPv6 dynamic VIPA interfaces. These link names should be used when defining the same interfaces to OMPROUTE.

**Tip:** Using consistent naming conventions and name wildcards can make this task easier. For example, if you require that all IPv6 VIPA link names start with the letter V, and do not allow other interface types to have link names starting with V, a single definition can define all IPv6 VIPA interfaces to OMPROUTE as follows:

```
IPV6_OSPF_INTERFACE
 NAME=V*;
```

Unlike IPv4, there are no size limitations on the number of IPv6 dynamic VIPA addresses that OMPROUTE can advertise. In IPv6 OSPF, OMPROUTE will advertise all host and prefix addresses associated with owned interfaces, including VIPAs and dynamic VIPAs. In IPv6 RIP, sending and receiving of host routes should be turned on to allow host addresses associated with VIPAs to be advertised.

---

## Chapter 8. TCP/IP in a sysplex

The increasing demands of network servers, and in particular System z servers, has led to the creation of different techniques to address performance requirements when a single server is not capable of providing the availability and scalability demands placed on it by its clients. Specifically, network solutions make use of what is referred to as the clustering technique, whereby multiple servers are associated together into a cluster to provide sufficient processing power and availability characteristics to handle the demands of the clients.

In the scope of this topic, this cluster functionality is provided by the sysplex. That is, the sysplex provides the necessary capability to cluster together a number of System z servers that cooperate with one another to deliver the processing power needed to service the demands required of a particular service environment.

Solutions that use the clustering approach to increase server availability and processing capability attempt to provide mechanisms by which they ensure the viability of the cluster in an environment containing a large number of clients generating a potentially high number of requests. To do so, the cluster technique can provide for two main objectives, high availability and load balancing. In some cases, clustering techniques address only high availability, as is the case with dynamic VIPA that provides for availability in spite of potential TCP/IP stack or z/OS image failures. In other cases, the intent is to provide for both high availability and load balancing, as is done by sysplex distributor.

In general, load balancing refers to the ability to use different systems within the cluster simultaneously, thereby taking advantage of the additional computational function of each. Further, clustering techniques addressing load balancing lead to other system requirements, such as that of a single systemwide image (one identity by which clients access the system), horizontal growth, and ease of management.

The traditional view of a single server has been primarily a single machine with perhaps a few network interfaces (IP addresses). This tends to lead to many potential points of failure within the server: the machine itself (hardware), the operating system (including TCP/IP stack) kernel executing on the machine, or a network interface (and the IP address associated with it). Static Virtual IP Addresses (VIPAs) exclude the network interface as a point of failure while dynamic VIPAs additionally aid with server (image) or kernel failure. In this way, high availability is seen as the availability of the entire server cluster and the service it provides. Furthermore, VIPAs can be used in conjunction with the sysplex distributor load balancing solution.

Clustering techniques that address the load balancing of connections requests also typically provide for some high availability. That is, these techniques dispatch connections to target servers and can exclude failed servers from the list of target servers that can receive connections. In this way, the dispatching function avoids routing connections and requests to a server incapable of satisfying such requests.

Load balancing is the ability for a cluster to distribute workload evenly (or based on some policy) to target servers comprising the cluster. Usually, this load balancing is measured by some notion of perceived load on each of the target servers. This topic describes load balancing using the sysplex distributor, which identifies the target System z servers willing to receive client connections based on some specification.

By providing load balancing, clustering techniques must also provide for other system requirements in addition to the dispatching of connections. These include the ability to advertise some single systemwide image or identity so that clients can uniquely and easily identify the service. Additionally, clustering techniques should also provide for horizontal growth of the system and ease of management.

It is also sometimes useful to arrange the members in the sysplex into subsets of members that communicate through XCF only amongst themselves. This is called subplexing. Each member of a subplex joins a unique set of sysplex groups and communicates through XCF with only other members that have joined the same unique set of sysplex groups. Each TCP/IP stack can participate in one and only one subplex. For more information, see [“Sysplex subplexing” on page 464](#).

**Note:** This information applies to both IPv4 and IPv6, unless otherwise noted.

## Connectivity in a sysplex

---

With dynamic VIPAs, IP addresses may move from one stack to another. These changes need to be communicated to the network. Therefore, dynamic routing should be implemented when dynamic VIPAs are being used. See [“Dynamic VIPAs and routing protocols”](#) on page 460 for more detailed information.

### Sysplex subplexing

A subplex is a subset of a sysplex that consists of all the members in the sysplex that communicate through cross-system coupling facility (XCF) groups with each other, and not with members outside the subset.

Defining multiple subplex scopes within a sysplex can be useful in scenarios where multiple networks with different security or functional attributes are attached to specific systems in the sysplex. For example, consider the scenario where some systems in the sysplex are connected to an internal enterprise network and other systems in the sysplex are connected to external networks that have different security attributes. In this example, you might want to be able to partition the sysplex into two subplexes from a sysplex network function perspective; one that includes the systems connected to the internal network and another for the systems that are connected to the external networks. By defining these separate subplexes, users can still exploit some of the sysplex network functions while preserving the isolation of the networks (that is, without automatically enabling dynamic XCF connectivity across the entire sysplex).

### TCP/IP and VTAM subplex concepts and example

To enable partitioning of the TCP/IP stacks and VTAM nodes in a sysplex into subplexes, the values specified by the following VTAM start option and TCP/IP profile GLOBALCONFIG parameter are used as suffixes for XCF group names and coupling facility structure names.

- VTAM

Use the XCFGRPID start option. For a description of [subplexing](#) and how the XCFGRPID start option modifies VTAM group names and VTAM structure names, see [z/OS Communications Server: SNA Network Implementation Guide](#).

- TCP/IP

Use the XCFGRPID parameter on the GLOBALCONFIG statement in the TCP/IP profile.

For TCP/IP, both the VTAM group ID suffix and the TCP group ID suffix can be used to modify the group name that a TCP/IP stack uses when it joins the sysplex. The group name used is in the form EZBTvvtt, where vv is the 2-digit VTAM group ID suffix specified on the XCFGRPID start option, and tt is the TCP group ID suffix specified on the GLOBALCONFIG statement in the TCP/IP profile. By using these suffixes to modify the XCF group name, the sysplex is effectively partitioned into subsets referred to as subplexes.

Only those TCP/IP stacks joining the unique group name generated using the specified suffixes are aware of each other in the sysplex; they communicate with each other through dynamic XCF. If the VTAM node is stopped and restarted with a new value for its XCFGRPID start option, the TCP/IP stacks using that VTAM node must be stopped and restarted to access the new VTAM suffix.

[Figure 58 on page 465](#) shows an example of TCP/IP and VTAM subplexes.

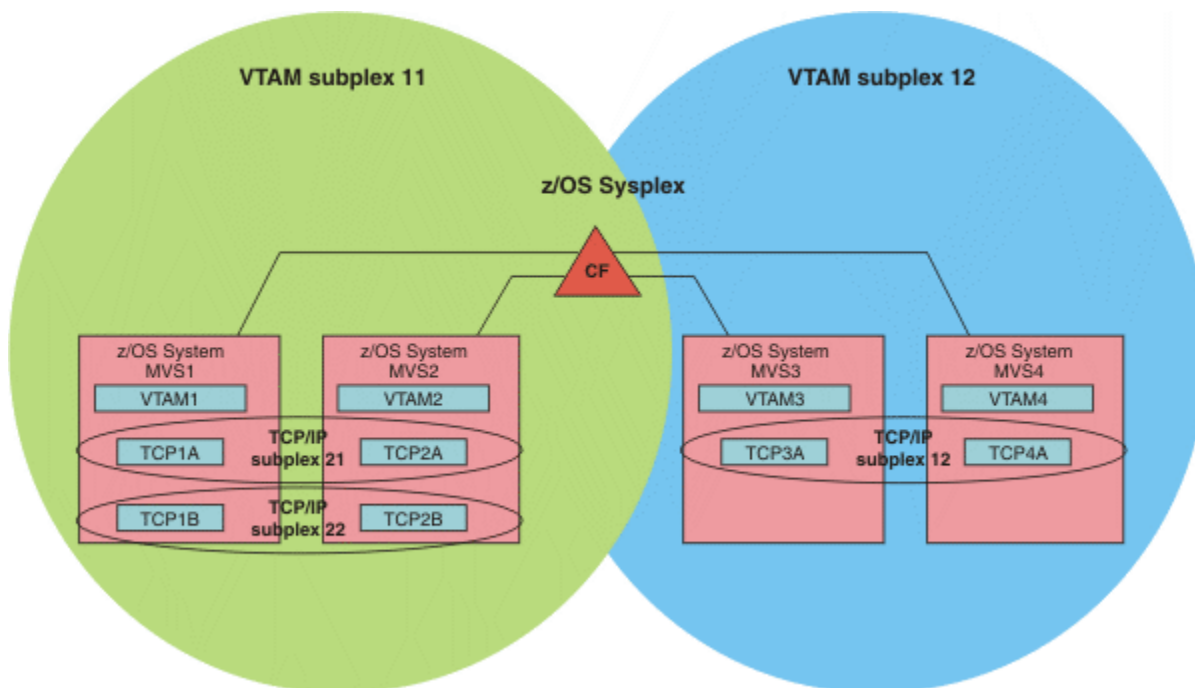

Figure 58. An example of TCP/IP and VTAM subplexes

In Figure 58 on page 465, the following subplexes are defined:

- Two VTAM subplexes (11 and 12) have been defined by starting VTAM1 and VTAM2 with a start option of XCFGRP1D 11, and starting VTAM3 and VTAM4 with a start option of XCFGRP1D 12.
- Three TCP/IP subplexes have been defined by starting TCP1A and TCP2A with the statement GLOBALCONFIG XCFGRP1D 21, TCP1B and TCP2B with the statement GLOBALCONFIG XCFGRP1D 22, and TCP3A and TCP4A with the statement GLOBALCONFIG XCFGRP1D 12.

The following conditions exist in the sysplex shown in Figure 58 on page 465:

- TCP/IP stacks TCP1A and TCP2A join XCF group EZBT1121. TCP1A is aware of only TCP2A in the sysplex, and TCP2A is aware of only TCP1A in the sysplex.
- TCP/IP stacks TCP1B and TCP2B join XCF group EZBT1122. TCP1B is aware of only TCP2B in the sysplex, and TCP2B is aware of only TCP1B in the sysplex.
- TCP/IP stacks TCP3A and TCP4A join XCF group EZBT1212. TCP3A is aware of only TCP4A in the sysplex, and TCP4A is aware of only TCP3A in the sysplex.

**Note:** Even if TCP3A and TCP4A had been started with a GLOBALCONFIG 21 value, they would still be in a separate group from TCP1A and TCP2A, because they are in different VTAM subplexes.

**Rule:** Because TCP/IP stacks use VTAM XCF support for their dynamic XCF connectivity, TCP/IP subplexes cannot span multiple VTAM subplexes.

To preserve separation between the subplexes, the TCP and VTAM coupling facility structures accessed must also be unique for each subplex. For the TCP structures EZBDVIPA, used for SWSA support, and EZBEPOR, used for SYSPLEXPORTS support, this is accomplished by appending the VTAM and TCP XCF group ID suffixes to the end of the structure names, or EZBDVIPA $vvtt$  and EZBEPOR $vvtt$  respectively. Thus, in the example, TCP1A and TCP2A access EZBDVIPA1121 and EZBEPOR1121, while TCP1B and TCP2B access EZBDVIPA1122 and EZBEPOR1122.

To access the TCP structures, the structure names, including the suffixes, must be defined in the sysplex CFRM policy. In Figure 58 on page 465, the CFRM policy for the sysplex must have structure definitions for EZBDVIPA1121, EZBDVIPA1122, EZBDVIPA1212, EZBEPOR1121, EZBEPOR1122, and EZBEPOR1212, if all of the stacks expect to access these structures.

- If no VTAM suffix is specified, a value of CP is used for  $vv$  when creating the TCP sysplex group name, and a value of 01 is used for  $vv$  when creating the structure names.

- If a VTAM suffix is specified, but no TCP suffix is specified, a value of CS is used for *tt* when creating the TCP sysplex group name, and a null value is used for *tt* when creating the structure names. Thus, in Figure 58 on page 465, if TCP1B and TCP2B are started without an XCFGRPID parameter on their GLOBALCONFIG statements, the sysplex group they join is EZBT11CS, and the structures they can access are EZBDVIPA11 and EZBEPOR11.

To estimate the coupling facility size requirements for each of these structures, use the CFSizer website at <http://www.ibm.com/systems/support/z/cfsizer/>.

To isolate communication between different subplexes within a sysplex, dynamic XCF connectivity between TCP/IP stacks in different subplexes on separate MVS images is blocked. In addition, IUTSAMEH connectivity for dynamic XCF between stacks in different subplexes on the same MVS image is also blocked.

When using HiperSockets to establish dynamic XCF connectivity between TCP/IP stacks in the same CPC using the same HiperSockets CHPID, to preserve subplex isolation, specify the IQDVLANID parameter on the GLOBALCONFIG statement as follows:

- TCP/IP stacks in the same subplex that share the same CPC and specify the same HiperSockets CHPID must specify the same VLAN ID value on the IQDVLANID parameter.
- TCP/IP stacks in different subplexes that share the same CPC and specify the same HiperSockets CHPID must specify different VLAN ID values on the IQDVLANID parameter.
- If subplexing is not being used within the sysplex, do not specify the IQDVLANID parameter on the GLOBALCONFIG statement.

Static XCF, user-defined IUTSAMEH, or user-defined HiperSockets connectivity between TCP stacks in different TCP subplexes within the same VTAM subplex are not blocked, because you have control over the definition and activation of these connections.

No steps are explicitly taken to block any other network connectivity available through LANs and WANs that might be shared by different subplexes, including scenarios where the same OSA adapter is shared across systems in different subplexes. If complete network isolation between subplexes is required, other mechanisms, such as physical network isolation or logical separation through firewall technologies, should be deployed.

Subplex support applies to TCP/IP and VTAM sysplex functions that make explicit use of XCF communications and coupling facility structures. For TCP/IP, this includes functions such as dynamic XCF, dynamic VIPAs, sysplex distributor, SYSPLEXPORTS, and SWSA. The scope of these functions is typically the entire sysplex. Automated domain name registration (ADNR) does not have explicit support for subplexing, but if ADNR is used in a subplexing environment, the scope of ADNR might be restricted to a subplex when the different subplexes are used to isolate network connectivity. In this case, an instance of ADNR must be started for each subplex in the sysplex that will use ADNR functions. ADNR needs to have affinity to one of the stacks in the subplex when ADNR is started on a system that is running multiple stacks. See *adnrproc.sample* for an example of the JCL.

In the remainder of this information, references to the sysplex or the sysplex group can refer to the entire sysplex and sysplex group EZBTCPCS, if subplexing is not being used, or to a specific subplex and a specific instance of the sysplex group EZBTVvtt, if subplexing is in effect.

## Setting up a subplex

Setting up TCP/IP and VTAM subplexes within a sysplex requires some preparation.

### ***Steps for preparing your sysplex for subplexing***

You need to plan how many subplexes are needed, assign group IDs, ensure that all TCP/IP stacks and VTAM nodes in the sysplex are at z/OS V1R8 or later, and assign VLAN IDs as needed.

### **Before you begin**

Steps 2 and 3 depend on the level of isolation you require for your subplexes within the sysplex. Those two steps are not needed when the following conditions are true:

- You do not use HiperSockets in support of dynamic XCF connectivity
- You do not need to isolate the subplexes for HiperSockets connectivity (if, for example, you need only to restrict sysplex distributor distribution between subplexes)
- You can configure your systems such that TCP/IP stacks that are in separate subplexes and are on the same CPC use a CHPID that is unique to the subplex

**Requirement:** A z890 GA2 or z990 GA2 hardware level is required to support VLAN IDs on HiperSockets.

## Procedure

Perform the following steps to prepare your sysplex for subplexing.

1. Plan how many subplexes are needed and assign a TCP/IP XCF group ID and a VTAM XCF group ID for each anticipated subplex in the sysplex:
  - All TCP/IP stacks in the same TCP/IP subplex must have the same TCP/IP XCF group ID.
  - All VTAM nodes in the same VTAM subplex must have the same VTAM XCF group ID.
2. Ensure that all TCP/IP stacks and VTAM nodes in the sysplex are at z/OS V1R8 or later.
3. If HiperSockets is enabled and there are TCP/IP stacks in the sysplex that are on the same CPC and use the same HiperSockets CHPID, assign a VLAN ID to each anticipated subplex in the sysplex. Also, assign a VLAN ID to the default subplex (that is, the subset of sysplex TCP/IP stacks that uses the default sysplex group name, EZBTCPCS). All TCP/IP stacks in the same subplex must have the same VLAN ID, if they are on the same CPC and use the same HiperSockets CHPID.

## ***Steps for partitioning a set of TCP/IP stacks in a sysplex into a subplex***

You can partition a set of TCP/IP stacks in a sysplex into a subplex that is functionally isolated from the other TCP/IP stacks in the sysplex.

## Procedure

Perform the following steps to partition a set of TCP/IP stacks in a sysplex into a subplex:

1. If TCP/IP coupling facility structures for SYSPLEXPORTS or sysplex-wide security associations (SWSA) are to be used, ensure that all the structures are defined to MVS and are specified in the active CFRM policy using their fully suffixed names. For example, if SYSPLEXPORTS is to be used with the base structure name of EZBEPOR, two VTAM subplexes are to be configured (11 and 12), and within each VTAM subplex, two TCP/IP subplexes are defined (21 and 22), ensure that the EZBEPOR1121, EZBEPOR1122, EZBEPOR1221, and EZBEPOR1222 structures are defined to MVS and specified in the active CFRM policy.
2. If the VTAM nodes are to be partitioned into subplexes, reconfigure each VTAM node in the VTAM subplex that will support the new TCP/IP subplex. For a description of how to set up VTAM subplexing, see [z/OS Communications Server: SNA Network Implementation Guide](#).
3. As each VTAM is being reconfigured, for each TCP/IP stack that you want to place in a new subplex, perform the following steps:
  - a) Stop the stack.
  - b) Change the GLOBALCONFIG statement in the TCP/IP profile to include the XCFGRPID parameter with the group ID for the new subplex.
  - c) If HiperSockets is enabled and there are TCP/IP stacks that are on the same CPC as this stack and that use the same HiperSockets CHPID, change the GLOBALCONFIG statement in the TCP/IP profile to include the IQDVLANID parameter with the selected VLAN ID for the new subplex.
 

**Tip:** This step depends on the level of isolation you require for your subplexes within the sysplex. If you do not need to isolate the subplexes for HiperSockets connectivity (if, for example, you need only to restrict sysplex distributor distribution between subplexes), you do not need to perform this step.
  - d) Start the TCP/IP stack, specifying the updated TCP/IP profile.
  - e) Continue until all the TCP/IP stacks in the new subplex have been reconfigured.

## Dynamic XCF

For most point-to-point links, a unique pair of IP addresses is needed for each stack within a sysplex. This requirement tends to use more IP addresses, and IP addresses can be saved by using dynamic XCF. Dynamic XCF creates a single IP address by which all other stacks in a sysplex can reach a stack. Dynamic XCF creates trusted, internal links to other stacks within a sysplex, generating dynamic definitions for TCP/IP stacks that are on another z/OS host in a sysplex or for TCP/IP stacks that are on the same z/OS host.

Dynamic XCF automatically generates the appropriate DEVICE, LINK, HOME, INTERFACE, BSDROUTINGPARMS, and BEGINROUTES definitions, and activates the devices to enable a stack to communicate with other stacks in the sysplex. Dynamic XCF devices and links, when activated, appear to the stack as though they had been defined in the TCP/IP profile, and can be displayed using standard commands.

Dynamic XCF support is available for both IPv4 and IPv6, and is enabled with the DYNAMICXCF parameter on the IPCONFIG or IPCONFIG6 statement, respectively. Though not specifically mentioned throughout this topic, unless otherwise noted, this information applies to IPv6 as well as IPv4.

### Notes:

1. Dynamic XCF (non-IUTSAMEH and non-IQDIO) interface definitions to a particular LPAR are stopped and deleted when the last stack on a given LPAR is removed from the sysplex.
2. If you are using policy-based routing, by default dynamic XCF does not generate the corresponding policy-based routing RouteTable definitions. Determine whether it is appropriate for these routes to be added to each of your policy-based route tables. Use the DynamicXCFRoutes parameter on the RouteTable statement that defines a policy-based route table to indicate whether the routes should be added to that table. For information about the [Policy-based routing policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Getting started with dynamic XCF

The minimum requirements for TCP/IP stacks to use dynamic XCF differ based on whether same host or inter-host communication is being used. To generate definitions for two TCP/IP stacks that reside on different MVS hosts:

- Both MVS hosts must belong to the same sysplex.
- VTAM must have XCF communications enabled by specifying the XCFINIT=YES or XCFINIT=DEFINE start option, or by activating the VTAM XCF local SNA major node, ISTLSXCF. For details about configuration, see [z/OS Communications Server: SNA Network Implementation Guide](#).
- DYNAMICXCF must be specified in the TCP/IP profile of each stack.

With this configuration, both same host and inter-host communication can be performed using dynamic XCF.

To generate definitions for two TCP/IP stacks that are on the same MVS host, you must specify DYNAMICXCF in the TCP/IP profile of each stack.

At initialization, each TCP/IP stack configured for XCF joins a well-known XCF group. When other stacks in the group discover the new stack, the definitions are created automatically, the links are activated, and the remote IP address for each link is added to the routing table. After the remote IP address has been added, IP traffic proceeds as usual.

In VTAM, you must activate the XCF local SNA major node. You can do this using the start option XCFINIT=YES or XCFINIT=DEFINE. If dynamically defined XCF definitions have been created for another VTAM in the sysplex that has since stopped and restarted with a different CPName, dynamic XCF recognizes this situation and automatically modifies existing definitions to accommodate the CPName change. If the XCF local SNA major node is inactive when TCP/IP is started and is not activated until after TCP/IP has finished initialization, TCP/IP does not generate any dynamic definitions for other TCP/IP hosts already started in the sysplex until either:

- A new TCP/IP host is detected

- A profile related operator command is issued (such as the VARY TCPIP,,OBEYFILE, VARY TCPIP,,START, or VARY TCPIP,,STOP commands)

### ***Dynamic XCF for IPv4 addresses***

To request dynamics for XCF or same host connections, enter the following definition in the IPCONFIG statement:

```
DYNAMICXCF IPAddress SubnetMask CostMetric
```

The internal definitions that are created depend on your configuration.

#### *Scenario number 1*

- TCP/IP detects another instance of TCP/IP on the same z/OS
- No device exists with the name IUTSAMEH
- No link exists with the name EZASAMEMVS

This scenario creates internal definitions equivalent to the following definitions:

#### **DEVICE IUTSAMEH MPCPTP AUTORESTART**

Device definition to obtain the most efficient stack-to-stack communications within the same MVS image.

#### **LINK EZASAMEMVS MPCPTP IUTSAMEH**

Link definition for the IUTSAMEH device.

#### **HOME IPAddress EZASAMEMVS**

Associates the IP address with the IUTSAMEH link.

#### **BSDROUTINGPARMS EZASAMEMVS 65535 CostMetric SubnetMask DestIPAddress**

Defines the link characteristics for EZASAMEMVS.

**Note:** The DestIPAddress is always 0.

#### **START IUTSAMEH**

Starts the IUTSAMEH device.

For details about XCF-related statements, see [z/OS Communications Server: IP Configuration Reference](#). For information about changes to Netstat displays of dynamic XCF settings, see [z/OS Communications Server: IP System Administrator's Commands](#).

#### *Scenario number 2*

- TCP/IP detects another instance of TCP/IP in the sysplex
- No device with the name of the CPName of the remote VTAM exists
- No HiperSockets connectivity between the two images exists
- No link exists with the name EZAXCFnn, where nn is the value of the MVS system symbol (SYSCONE) for the MVS hosting the VTAM with the device name

This scenario creates internal definitions equivalent to the following definitions:

#### **DEVICE CPName MPCPTP AUTORESTART**

Device definition to communicate with TCP/IP stacks hosted by the remote VTAM.

#### **LINK EZAXCFnn MPCPTP CPName**

Link definition for the device, where nn is the SYSCONE value for the remote VTAM and MVS.

#### **HOME IPAddress EZAXCFnn**

Associates the IP address with the dynamic XCF link.

#### **BSDROUTINGPARMS EZAXCFnn 55296 CostMetric SubnetMask DestIPAddress**

Defines the link characteristics for EZAXCFnn.

#### **START CPName**

Starts the specified device.

**Notes:**

1. If EZAXCFnn is already defined as a link name, or the CP name is already defined as a device name, then dynamic XCF definition EZAXCFnn and the CP name are not generated for discovery of another stack in the same sysplex.
2. The DestIPAddress is always zero.

For details about XCF-related statements, see [z/OS Communications Server: IP Configuration Reference](#). For information about changes to Netstat displays of dynamic XCF settings, see [z/OS Communications Server: IP System Administrator's Commands](#).

*Scenario number 3*

- TCP/IP detects another instance of TCP/IP in the sysplex
- The images are on the same CPC
- HiperSockets connectivity between the two images exists
- The host processor supports HiperSockets and z/OS Communications Server is properly configured
- No link exists with the name IQDIOLNKnnnnnnnn (where nnnnnnnn is the hexadecimal representation of the IP address specified on the IPCONFIG DYNAMICXCF statement)

This scenario creates internal definitions equivalent to the following definitions:

**DEVICE IUTIQDIO MPCIPA AUTORESTART**

Device definition to communicate with TCP/IP stacks hosted by the remote VTAM.

**LINK IQDIOLNKnnnnnnnn IPAQIDIO IUTIQDIO**

Link definition for the device, where nnnnnnnn is the hexadecimal representation of the IP address specified on the IPCONFIG DYNAMICXCF statement (that is, IPAddress).

**HOME IPAddress IQDIOLNKnnnnnnnn**

Associates the IP address with the dynamic XCF link.

**BSDROUTINGPARMS IQDIOLNKnnnnnnnn 57344 CostMetric SubnetMask DestIPAddress**

Defines the link characteristics for IQDIOLNKnnnnnnnn.

**START IUTIQDIO**

Starts the specified device.

**Notes:**

1. If IQDIOLNKnnnnnnnn is already defined as a link name, or IUTIQDxx (where xx is the CHPID of the HiperSockets LAN that is defined or specified by default on the VTAM start option IQDCHPID) is already defined as a device name, dynamic XCF IQDIOLNKnnnnnnnn and IUTIQDIO definitions are not generated for discovery of another stack in the same CPC.
2. The DestIPAddress is always zero.

For details about XCF-related statements, see [z/OS Communications Server: IP Configuration Reference](#). For information about changes to Netstat displays of dynamic XCF settings, see [z/OS Communications Server: IP System Administrator's Commands](#).

**Dynamic XCF for IPv6 addresses**

To request dynamics for XCF or same host connections, enter the following definition in the IPCONFIG6 statement:

```
DYNAMICXCF IP6Address
```

The internal definitions that are created depend on your configuration.

*Scenario number 1*

- TCP/IP detects another instance of TCP/IP on the same z/OS
- No device exists with the name IUTSAMEH

- No link exists with the name EZ6SAMEMVS

This scenario creates internal definitions equivalent to the following definitions:

#### **INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAM IUTSAMEH IPADDR IP6Address**

Interface definition for EZ6SAMEMVS.

#### **START EZ6SAMEMVS**

Starts the EZ6SAMEMVS interface.

For details about XCF-related statements, see [z/OS Communications Server: IP Configuration Reference](#).

For information about changes to Netstat displays of dynamic XCF settings, see [z/OS Communications Server: IP System Administrator's Commands](#).

#### *Scenario number 2*

- TCP/IP detects another instance of TCP/IP in the sysplex
- No device with the name of the CPName of the remote VTAM exists
- No HiperSockets connectivity between the two images exists
- No link exists with the name EZ6XCFnn, where nn is the value of the MVS system symbol (SYSCONE) for the MVS hosting the VTAM with the device name

This scenario creates internal definitions equivalent to the following definitions:

#### **INTERFACE EZ6XCFnn DEFINE MPCPTP6 TRLENAM CPName IPADDR IP6Address**

Interface definition, where nn is the SYSCONE value for the remote VTAM and MVS.

#### **START EZ6XCFnn**

Starts the specified interface.

#### **Notes:**

1. If EZ6XCFnn is already defined as a link name, or the CP name is already defined as a device name, then dynamic XCF definition EZ6XCFnn and CP name are not generated for discovery of another stack in the same sysplex.
2. The DestIPAddress is always zero.

For details about XCF-related statements, see [z/OS Communications Server: IP Configuration Reference](#).

For information about changes to Netstat displays of dynamic XCF settings, see [z/OS Communications Server: IP System Administrator's Commands](#).

## **IUTSAMEH**

Communications Server provides internal links between TCP/IP stacks that are running within the same MVS image. This support is referred to as a Same Host (IUTSAMEH) link. If DYNAMICXCF is defined, TCP/IP always creates and activates a same host (IUTSAMEH) device and link (unless a static IUTSAMEH device is already defined) even if this is the only stack on the MVS image. When TCP/IP activates the IUTSAMEH device, VTAM dynamically builds the IUTSAMEH TRLE. The generated device name is IUTSAMEH, the generated link name is EZASAMEMVS (IPv4), and the generated interface name is EZ6SAMEMVS (IPv6). As other stacks are brought up within the same MVS image, a host route is created to each of these stacks across the same host link. It is recommended that users do not configure a static device for IUTSAMEH (allow TCP/IP to dynamically create the device and link). Communications Server also uses the IUTSAMEH link for Enterprise Extender support.

The IUTSAMEH device and link (IPv4) or interface (IPv6) do not become active and remain in SENT SETUP status until either another TCP/IP stack or Enterprise Extender connection is activated on this MVS image.

|                       |                   |                        |
|-----------------------|-------------------|------------------------|
| DEVNAME: IUTSAMEH     | DEVTYPE: MPCPTP   |                        |
| DEVSTATUS: SENT SETUP |                   |                        |
| LNKNAME: EZASAMEMVS   | LNKTYPE: MPCPTP   | LNKSTATUS: NOT ACTIVE  |
| :                     |                   |                        |
| INTFNAME: EZ6SAMEMVS  | INTFTYPE: MPCPTP6 | INTFSTATUS: NOT ACTIVE |

In the case where IUTSAMEH is active solely because of Enterprise Extender and the IUTSAMEH is subsequently stopped, to restart the IUTSAMEH for Enterprise Extender, the XCA major node must be recycled. Otherwise, it might require manual reactivation of the Enterprise Extender LINEs and PUs, and manual redials.

## XCF

When a subsequent stack within the sysplex is started that is not within the same MVS image, TCP/IP creates and activates an XCF device and link (unless an XCF device is already defined). The XCF links connect using the sysplex coupling facility or CTC links. A new device and link are created for every other VTAM node in the sysplex with at least one TCP/IP stack active on the same system with DYNAMICXCF specified. The generated device name is the CP name (for APPN) or SSCP name (for subarea-only nodes) of the remote VTAM. The generated link name is EZAXCF $nn$  (IPv4), and the generated interface name is EZ6XCF $nn$  (IPv6), where  $nn$  is the 2-character &SYSCONE value. A host route across the XCF link is created when the XCF link is successfully activated.

## Examples of definitions generated by dynamic XCF

This topic contains examples of definitions generated by dynamic XCF in both IPv4 and IPv6 environments. The notes following the examples pertain to both environments.

- IPv4 example 1:

This configuration consists of two MVS systems (MVS1,MVS2) that are members of the same sysplex. Each MVS host has one TCP/IP stack (TCPIP1 and TCPIP2, respectively). From the syntax descriptions, the following information is needed to generate the dynamic definitions:

- MVS sysclone value
- VTAM CPName
- Status of XCF in VTAM
- The values specified on the IPCONFIG DYNAMICXCF keyword

Using the following user definitions:

```
MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.1 255.255.255.248 3

MVS2:
Sysclone = B2 VTAM
Cpname = VTAM2
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.2 255.255.255.248 2
```

After both TCPIP1 and TCPIP2 have been started, the following definitions will be generated.

TCPIP1 will generate the equivalent of these definitions:.

```
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.1 EZAXCFB2
BSDROUTINGPARMS EZAXCFB2 55296 3 255.255.255.248 0
START VTAM2
```

TCPIP2 will generate:

```
DEVICE VTAM1 MPCPTP AUTORESTART
LINK EZAXCFA1 MPCPTP VTAM1
HOME 9.1.1.2 EZAXCFA1
BSDROUTINGPARMS EZAXCFA1 55296 2 255.255.255.248 0
START VTAM1
```

When an XCF link becomes active, each TCPIP will generate a route to the other TCPIP over the XCF link. In this example, when the XCF link becomes active, TCPIP1 will generate a route to TCPIP2 over the XCF link and vice versa.

- IPv4 example 2:

The configuration is the same as Example 1 except a second TCP/IP stack (TCPIP1A) was added to MVS1.

Using the following user definitions:

```
MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.1 255.255.255.248 3
TCPIP1A: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.3 255.255.255.248 0

MVS2:
Sysclone = B2
VTAM Cpname = VTAM2
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.2 255.255.255.248 2
```

After both TCPIP1 and TCPIP2 have been started, the following definitions will be generated, as in Example 1.

TCPIP1 will generate the equivalent of these definitions:

```
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.1 EZAXCFB2
BSDROUTINGPARMS EZAXCFB2 55296 3 255.255.255.248 0
START VTAM2
```

TCPIP2 will generate:

```
DEVICE VTAM1 MPCPTP AUTORESTART
LINK EZAXCFA1 MPCPTP VTAM1
HOME 9.1.1.2 EZAXCFA1
BSDROUTINGPARMS EZAXCFA1 55296 2 255.255.255.248 0
START VTAM1
```

Now, TCPIP1A is started. TCPIP1 and TCPIP2 recognize that TCPIP1A has started. TCPIP1A will generate definitions for both TCPIP1 and TCPIP2. TCPIP1 will generate IUTSAMEH definitions for TCPIP1A. However, TCPIP2 does not need to generate and will not generate any new definitions except for routing information for TCPIP1A. New definitions do not need to be created because the DEVICE and LINK definitions are based on the discovery of a new VTAM node in the sysplex. (The DEVICE name is the VTAM CPName.)

TCPIP1 will generate the equivalent of these definitions:

```
DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
HOME 9.1.1.1 EZASAMEMVS
BSDROUTINGPARMS EZASAMEMVS 65535 3 255.255.255.248 0
START IUTSAMEH
```

When the IUTSAMEH connection becomes active, each TCPIP will generate a route to the other TCPIP over the IUTSAMEH connection.

TCPIP2 does not generate anything.

TCPIP1A will generate:

```
DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.3 EZAXCFB2
HOME 9.1.1.3 EZASAMEMVS
BSDROUTINGPARMS EZAXCFB2 55296 0 255.255.255.248 0
```

```
BSDROUTINGPARMS EZASAMEMVS 65535 0 255.255.255.248 0
START IUTSAMEH
START VTAM2
```

When the IUTSAMEH connection becomes active, each TCPIP will generate a route to the other TCPIP over the IUTSAMEH connection.

- IPv4 example 3:

To continue Example 2, add another MVS host (MVS3) with a VTAM node (VTAM3) with one TCP/IP stack (TCPIP3).

```
MVS3:
Sysclone = C3
VTAM Cpname = VTAM3
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP3: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.3 255.255.255.248 0
```

In this example, the previously active TCP/IP stacks will generate definitions for TCPIP3 because a new VTAM stack has become active in the sysplex. TCPIP3 will generate definitions for definitions for TCPIP1/TCPIP1A and TCPIP2.

TCPIP1 will generate the equivalent of these definitions:

```
DEVICE VTAM3 MPCPTP AUTORESTART
LINK EZAXCFC3 MPCPTP VTAM3
HOME 9.1.1.1 EZAXCFC3
BSDROUTINGPARMS EZAXCFC3 55296 3 255.255.255.248 0
START VTAM3
```

TCPIP2 will generate:

```
DEVICE VTAM3 MPCPTP AUTORESTART
LINK EZAXCFC3 MPCPTP VTAM3
HOME 9.1.1.2 EZAXCFC3
BSDROUTINGPARMS EZAXCFC3 55296 2 255.255.255.248 0
START VTAM3
```

TCPIP1A will generate:

```
DEVICE VTAM3 MPCPTP AUTORESTART
LINK EZAXCFC3 MPCPTP VTAM3
HOME 9.1.1.3 EZAXCFC3
BSDROUTINGPARMS EZAXCFC3 55296 0 255.255.255.248 0
START VTAM3
```

TCPIP3 will generate:

```
DEVICE VTAM1 MPCPTP AUTORESTART
LINK EZAXCFA1 MPCPTP VTAM1
DEVICE VTAM2 MPCPTP AUTORESTART
LINK EZAXCFB2 MPCPTP VTAM2
HOME 9.1.1.3 EZAXCFA1
HOME 9.1.1.3 EZAXCFB2
BSDROUTINGPARMS EZAXCFA1 55296 0 255.255.255.248 0
BSDROUTINGPARMS EZAXCFB2 55296 0 255.255.255.248 0
START VTAM1
START VTAM2
```

- IPv4 example 4:

This example illustrates how dynamic XCF can generate IUTSAMEH definitions without VTAM having its XCF enabled.

```
MVS1:
Sysclone = A1 (not used in this example)
VTAM Cpname = VTAM1 (not used in this example)
VTAM has XCFINIT=NO specified and has not activated the major node ISTLSXCF.
TCPIP1: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.1 255.255.255.248 3
TCPIP1A: PROFILE.TCPIP contains IPCONFIG DYNAMICXCF 9.1.1.3 255.255.255.248 0
```

TCPIP1 will generate the equivalent of these definitions:

```

DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
HOME 9.1.1.1 EZASAMEMVS
BSDROUTINGPARMS EZASAMEMVS 65535 3 255.255.255.248 0
START IUTSAMEH

```

TCPIP1A will generate:

```

DEVICE IUTSAMEH MPCPTP AUTORESTART
LINK EZASAMEMVS MPCPTP IUTSAMEH
HOME 9.1.1.3 EZASAMEMVS
BSDROUTINGPARMS EZASAMEMVS 65535 0 255.255.255.248 0
START IUTSAMEH

```

- IPv6 example 1:

This configuration consists of two MVS systems (MVS1,MVS2) that are members of the same sysplex. Each MVS host has one TCP/IP stack (TCPIP1 and TCPIP2, respectively). From the syntax descriptions, the following information is needed to generate the dynamic definitions:

- MVS sysclone value
- VTAM CPName
- Status of XCF in VTAM
- The values specified on the IPCONFIG6 DYNAMICXCF keyword

Using the following user definitions:

```

MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f001
MVS2:
Sysclone = B2
Cpname = VTAM2
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::222:f001

```

After both TCPIP1 and TCPIP2 are started, the following definitions are generated.

TCPIP1 generates the equivalent of these definitions:

```

INTERFACE EZ6XCFB2 DEFINE MPCPTP6 TRLENAM VTAM2 IPADDR 2001:0DB8::111:f001
START EZ6XCFB2

```

TCPIP2 generates:

```

INTERFACE EZ6XCFA1 DEFINE MPCPTP6 TRLENAM VTAM1 IPADDR 2001:0DB8::222:f001
START EZ6XCFA1

```

The INTERFACE statement combines the definitions of DEVICE, LINK, and HOME into a single statement for IPv6. When an XCF interface becomes active, each TCP/IP generates a route to the other TCP/IP over the XCF interface. In this example, when the XCF interface becomes active, TCPIP1 generates a route to TCPIP2 over the XCF interface, and TCPIP2 generates a route to TCPIP1 over the XCF interface.

- IPv6 example 2:

The configuration is the same as Example 1 except a second TCP/IP stack (TCPIP1A) is added to MVS1.

Using the following user definitions:

```

MVS1:
Sysclone = A1
VTAM Cpname = VTAM1
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP1: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f001
TCPIP1A: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f002
MVS2:
Sysclone = B2
VTAM Cpname = VTAM2

```

```
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP2: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::222:f001
```

After both TCPIP1 and TCPIP2 are started, the following definitions are generated, as in Example 1.

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE EZ6XCFB2 DEFINE MPCPTP6 TRLENAM VTAM2 IPADDR 2001:0DB8::111:f001
START EZ6XCFB2
```

TCPIP2 generates:

```
INTERFACE EZ6XCFA1 DEFINE MPCPTP6 TRLENAM VTAM1 IPADDR 2001:0DB8::222:f001
START EZ6XCFA1
```

Now, TCPIP1A is started. TCPIP1 and TCPIP2 recognize that TCPIP1A has started. TCPIP1A generates definitions for both TCPIP1 and TCPIP2. TCPIP1 generates IUTSAMEH definitions for TCPIP1A. However, TCPIP2 does not need to generate and does not generate any new definitions, except for routing information, for TCPIP1A. New definitions do not need to be created because the INTERFACE definition is based on the discovery of a new VTAM node in the sysplex. (The TRLENAM is the VTAM CPName.)

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAM IUTSAMEH IPADDR 2001:0DB8::111:f001
START EZ6SAMEMVS
```

When the IUTSAMEH connection becomes active, each TCP/IP generates a route to the other TCP/IP over the IUTSAMEH connection.

TCPIP2 does not generate anything.

TCPIP1A generates:

```
INTERFACE EZ6XCFB2 DEFINE MPCPTP6 TRLENAM VTAM2 IPADDR 2001:0DB8::111:f002
START EZ6XCFB2
INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAM IUTSAMEH IPADDR 2001:0DB8::111:f002
START EZ6SAMEMVS
```

When an XCF interface becomes active, each TCP/IP generates a route to the other TCP/IP over the XCF interface. In this example, when the XCF interface becomes active, TCPIP1A generates a route to TCPIP2 over the XCF interface, and TCPIP2 generates a route to TCPIP1A over the XCF interface. When the IUTSAMEH connection becomes active, each TCP/IP generates a route to the other TCP/IP over the IUTSAMEH connection.

- IPv6 example 3:

To continue Example 2, add another MVS host (MVS3) with a VTAM node (VTAM3) with one TCP/IP stack (TCPIP3).

```
MVS3:
Sysclone = C3
VTAM Cpname = VTAM3
VTAM has either specified XCFINIT=YES, XCFINIT=DEFINE, or the major node ISTLSXCF is active
TCPIP3: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::333:f001
```

In this example, the previously active TCP/IP stacks generate definitions for TCPIP3 because a new VTAM stack has become active in the sysplex. TCPIP3 generates definitions for TCPIP1, TCPIP1A, and TCPIP2.

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE EZ6XCFC3 DEFINE MPCPTP6 TRLENAM VTAM3 IPADDR 2001:0DB8::111:f001
START EZ6XCFC3
```

TCPIP2 generates:

```
INTERFACE EZ6XCFC3 DEFINE MPCPTP6 TRLENAM VTAM3 IPADDR 2001:0DB8::222:f001
START EZ6XCFC3
```

TCPIP1A generates:

```
INTERFACE EZ6XCFC3 DEFINE MPCPTP6 TRLENAM VTAM3 IPADDR 2001:0DB8::111:f002
START EZ6XCFC3
```

TCPIP3 generates:

```
INTERFACE EZ6XCFA1 DEFINE MPCPTP6 TRLENAM VTAM1 IPADDR 2001:0DB8::333:f001
START EZ6XCFA1
INTERFACE EZ6XCFB2 DEFINE MPCPTP6 TRLENAM VTAM2 IPADDR 2001:0DB8::333:f001
START EZ6XCFB2
```

- IPv6 example 4:

This example illustrates how dynamic XCF can generate IUTSAMEH definitions without VTAM having its XCF enabled.

```
MVS1:
Sysclone = A1 (not used in this example)
VTAM Cpname = VTAM1 (not used in this example)
VTAM has XCFINIT=NO specified and has not activated the major node ISTLSXCF.
TCPIP1: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f001
TCPIP1A: PROFILE.TCPIP contains IPCONFIG6 DYNAMICXCF 2001:0DB8::111:f002
```

TCPIP1 generates the equivalent of these definitions:

```
INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAM IUTSAMEH IPADDR 2001:0DB8::111:f001
START EZ6SAMEMVS
```

TCPIP1A generates:

```
INTERFACE EZ6SAMEMVS DEFINE MPCPTP6 TRLENAM IUTSAMEH IPADDR 2001:0DB8::111:f002
START EZ6SAMEMVS
```

### Notes:

1. Because the interfaces generated by dynamic XCF use a single IP address, the output of the SIOCGIFCONF ioctl() contains multiple entries with the same IP address. If an application is using the SIOCGIFCONF output to issue bind() to all the entries returned, the application could receive EADDRINUSE on a bind() if there are multiple XCF devices defined by dynamic XCF in the list.
2. If you want to define a static route to a link which is generated by dynamic XCF, you must wait until the dynamic devices are started and then use the VARY TCPIP,,OBEYFILE command. The BEGINROUTES statement that refers to a dynamically defined link name or interface name must be in a separate data set from the data set that is used to define the dynamic devices (either the initial profile data set or the data set referenced by a VARY TCPIP,,OBEYFILE command).
3. Even though the HOME, BSDROUTINGPARMS and BEGINROUTES definitions are full replacement statements, the definitions generated by dynamic XCF will not replace any existing definitions. Likewise, user-defined HOME, BSDROUTINGPARMS and BEGINROUTES definitions will not affect existing or future definitions generated by dynamic XCF.
4. A mix of static and dynamic IPv4 and IPv6 definitions for a device is not allowed. For example, if a static IUTSAMEH IPv4 device and link is defined, an IPv6 dynamic definition for IUTSAMEH will not be created. If a static IUTSAMEH IPv6 interface is defined, an IPv4 dynamic definition for IUTSAMEH will not be created. The same logic also applies for XCF links; a mix of static and dynamic IPv4 and IPv6 definitions is not allowed for an XCF link.
5. The address specified on the IPCONFIG6 DYNAMICXCF statement cannot be an existing, statically defined, interface address. If a profile contains an IPv6 interface statement for an address that is also used in the IPCONFIG6 DYNAMICXCF statement, the IPCONFIG6 DYNAMICXCF statement is ignored.

## Deleting dynamically defined XCF devices

You can delete dynamically defined XCF devices and links by first stopping the devices to be deleted and then issuing a VARY TCPIP,,OBEYFILE command that references a data set containing a DELETE LINK EZAXCFnn and DELETE DEVICE. Because the HOME statement processing does not affect dynamically defined XCF HOME list entries, the HOME xx.xx.xx.xx EZAXCFnn entry is automatically deleted by DELETE LINK.

For IPv6, you can delete dynamically defined XCF interfaces by first stopping the interface previously defined in an INTERFACE statement and then issuing a VARY TCPIP,,OBEYFILE command that references a data set containing an INTERFACE *interfacename* DELETE statement.

## HiperSockets

HiperSockets is a System z hardware feature that provides high performance internal communications between LPARs within the same central processor complex (CPC) without the use of any additional or external hardware equipment (for example, channel adapters, LANs, and so on).

If the host processor supports HiperSockets and Communications Server is properly configured, Communications Server will attempt to create XCF connectivity between LPARs in the same CPC using a HiperSockets link or interface. When the HiperSockets link or interface cannot be activated, TCP/IP creates a normal XCF link or interface. However, if the HiperSockets link or interface is successfully activated, but is then later stopped, TCP/IP does not create an XCF link or interface.

The HiperSockets for DYNAMICXCF device and link or interface are dynamically built and the device or interface is started during TCP/IP DYNAMICXCF stack initialization. The HiperSockets for DYNAMICXCF device and link and interface cannot be configured. The generated device name is IUTIQDIO. The generated IPv4 link name is IQDIOLNKnnnnnnnn, where *nnnnnnnn* is the character representation of the hexadecimal version of the DYNAMICXCF IP address. The generated IPv6 interface name is IQDIOINTF6. In general, where an XCF link or interface would normally have been used (for intra-CPC), a HiperSockets link or interface will be used.

Similar to IUTSAMEH, VTAM will dynamically build the TRLE for IUTIQDIO when the IUTIQDIO device is started. The TRLE statement is not configured (defined) by the user.

Although HiperSockets for DYNAMICXCF is not configured with TCP/IP DEVICE and LINK or INTERFACE statements, and the TRLE is not defined by the user, the following steps must be taken to define the HiperSockets subchannel devices and IQD CHPID:

1. Using HCD or IOCP, the system administrator must define (create the IOCDS) the HiperSockets IQD CHPID (channel path ID) and subchannel devices to the applicable LPARs. To dynamically build the HiperSockets TRLE, VTAM requires a minimum of 3 subchannel devices configured with each IQD CHPID within HCD. The maximum number of subchannel devices that VTAM will use (associate with each TRLE or MPC group) is 10. For additional details regarding configuring the HiperSockets subchannel devices and IQD CHPID, see [z/OS HCD Planning and Appendix D, "Using HCD," on page 1369](#).
2. When more than one IQD CHPID is configured to a specific LPAR, VTAM start option IQDCHPID must be used to specify which specific IQD CHPID this LPAR should use. The VTAM start option controls which IQD CHPID (and related subchannel devices) VTAM selects to include in the HiperSockets MPC group (IUTIQDIO) when it is dynamically built for HiperSockets for DYNAMICXCF connectivity. Start option IQDCHPID controls the VTAM IQD CHPID selection for the HiperSockets for DYNAMICXCF device IUTIQDIO (MPC group) only. It does not control IQD CHPID selection for a user defined HiperSockets device (MPCIPA). However, a user defined HiperSockets device (IQD CHPID) cannot use (conflict with) the same IQD CHPID that the HiperSockets for DYNAMICXCF device is currently using.

For example, if IQD CHPID 'FE'x is in use by DYNAMICXCF because of one of the following conditions, then an attempt to configure and start a user defined HiperSockets device IUTIQDFE is not allowed (IQD CHPIDs conflict):

- a. VTAM start option IQDCHPID=FE is specified

- b. VTAM start option IQDCHPID=ANY is specified, but the HiperSockets for DYNAMICXCF device IUTIQDIO is using the 'FE' CHPID

This option can also be modified with a VTAM modify command. In most cases, the default setting will be sufficient. For additional details regarding this start option, see [z/OS Communications Server: SNA Resource Definition Reference](#).

For additional details regarding HiperSockets, see [“HiperSockets concepts and connectivity”](#) on page 95.

## Network interfaces monitoring

Sysplex distributor and other dynamic VIPA (DVIPA) functions depend on an available network path to the TCP/IP stack that owns and advertises a dynamic VIPA. If connectivity is disrupted, clients might not be able to access the applications represented by the DVIPA, impacting their operations. Dynamic XCF interfaces can be configured to provide for a backup network path for DVIPAs. If the dynamic XCF interfaces fail for a given system, the sysplex autonomics function might automatically initiate a recovery action, resulting in the local TCP/IP stack leaving the sysplex and enabling other TCP/IP stacks to assume ownership of the DVIPAs.

However, there are some configurations in which it is not optimal to configure dynamic XCF interfaces as eligible backup network paths for TCP/IP stacks that own and advertise DVIPAs. In these configurations, incoming network traffic for the DVIPAs is expected to arrive over one or more external network interfaces. If these external interfaces fail, or the networks they are attached to experience a failure, the DVIPAs owned by the local TCP/IP stack can become isolated. Client traffic destined for these DVIPAs cannot reach the local TCP/IP stack; the DVIPA is unreachable.

The network interfaces monitoring function enhances the sysplex autonomics function by enabling you to specify key network interfaces that should be monitored by TCP/IP stacks. If a failure occurs on all specified interfaces, sysplex autonomics recovery can be triggered so other TCP/IP stacks in the sysplex can take over responsibilities for the DVIPAs owned by the local stack.

This level of monitoring is useful not only for TCP/IP stacks that currently own and advertise distributed and non-distributed DVIPAs, but also for TCP/IP stacks that are eligible backup stacks for these DVIPAs. This can help ensure that any backup TCP/IP stacks that are experiencing network connectivity problems do not attempt to perform DVIPA takeover activities if the primary DVIPA owner is stopped or fails. By being proactive and detecting these network connectivity problems, the backup stack can remove itself from the sysplex, enabling other healthy backup stacks to perform the takeover activities. While this monitoring function can also be enabled on TCP/IP stacks that act only as targets for distributed DVIPAs, the benefits for this configuration are minimal, as sysplex distributor already automatically monitors the ability of target TCP/IP stacks to communicate with distributed DVIPA clients.

The following functions are provided by the network interfaces monitoring function:

- You can identify which links and interfaces are critical for inbound network connectivity for a distributed DVIPA or DVIPA-owning TCP/IP stack. Specify which links and interfaces are to be monitored by sysplex autonomics using the MONSYSPLEX parameter on the LINK and INTERFACE statements.
- You have the option of enabling the TCP/IP stack to monitor the status of these interfaces through the MONINTERFACE keyword on the GLOBALCONFIG SYSPLEXMONITOR statement. If the MONINTERFACE keyword is specified, by default the TCP/IP stack also monitors the presence of dynamic routes over these interfaces. To override monitoring of dynamic routes, specify the MONINTERFACE NODYNROUTE keyword on the GLOBALCONFIG SYSPLEXMONITOR statement. The monitoring of dynamic routes enables TCP/IP to extend its monitoring beyond the status of the actual network interface, to also include the status of any routers that are connected to the local area network to which these interfaces are attached. Because a dynamic routing protocol is usually required for DVIPAs, by checking for the presence of dynamic routes, TCP/IP can determine whether the local OMPROUTE daemon is successfully communicating with these routers using dynamic routing protocols. If these network interfaces and dynamic routes become unavailable or experience network connectivity failures, the sysplex autonomics function can automatically initiate a recovery action.

If network interfaces monitoring is enabled, you must be aware of the following scenarios where the monitoring function can create problems:

- Monitored interfaces are deleted

To delete interfaces, the devices or interfaces must first be stopped. When the devices or interfaces are stopped, the interface becomes inactive. If the TCP/IP stack detects that all monitored interfaces are inactive as a result of stopping devices or interfaces, the TCP/IP stack can issue messages regarding the problem and possibly trigger a recovery action. You can disable monitoring of these interfaces before stopping the devices or interfaces, using the VARY TCPIP,,OBEYFILE command and specifying the NOMONSYSPLEX keyword for the LINK or INTERFACE statement. For more information about DEVICE and LINK statements and INTERFACE statements, see [z/OS Communications Server: IP Configuration Reference](#).

- The first hop routers are brought down for maintenance

If the MONINTERFACE keyword or MONINTERFACE DYNROUTE option is configured on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, and the first hop routers are brought down for maintenance, an inadvertent recovery action might be triggered. You can temporarily disable the monitoring of dynamic routes using the VARY TCPIP,,OBEYFILE command and specifying MONINTERFACE NODYNROUTE on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement.

- Preferred routing interface is not monitored

If you use multiple interfaces and at least one interface is preferred from a routing perspective over the other interfaces, ensure that the preferred interfaces are monitored (the MONSYSPLEX keyword is specified for the LINK or INTERFACE statement). If the preferred interfaces are not monitored, an inadvertent recovery action might be initiated.

For more information about sysplex autonomies, see [“Sysplex problem detection and recovery”](#) on page 480.

## Sysplex problem detection and recovery

Each sysplex member monitors itself and can automatically leave the sysplex group if it determines that it is no longer able to function correctly as a router, target, backup, or owner of a DVIPA. Through a variety of methods, it monitors:

- Internal resources and conditions, such as timely execution of sysplex functions, available private storage, and common storage
- External resources, such as availability of VTAM, or OMPROUTE if it is being used, or IPsec infrastructure (such as IKED) if IPsec is being used.

As long as the TCP/IP stack is a member of a TCP/IP sysplex group, the sysplex monitor gets control periodically. The time period is determined from the TIMERSECS value specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement in PROFILE.TCPIP. The default TIMERSECS value is 60 seconds.

After a problem is detected, further actions depend on whether RECOVERY or NORECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. NORECOVERY is the default value.

Joining the TCP/IP sysplex group can be delayed until certain network routing and connectivity availability conditions are met. Those conditions can include any combination of the following conditions:

- OMPROUTE is active
- Monitored interfaces are active
- Dynamic routes over those monitored interfaces are present
- IPsec components are active and operational

The first condition is activated using the DELAYJOIN option on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. The next two conditions are activated using the MONINTERFACE or MONINTERFACE DYNROUTE option on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. The last condition is activated by the DELAYJOINIPSEC option on the SYSPLEXMONITOR parameter on the GLOBALCONFIG statement. No sysplex-related definitions within the TCP/IP profile (that is, VIPADYNAMIC and DYNAMICXCF statements) are processed until the sysplex group is joined.

**Tips:**

- To determine whether the stack has joined a sysplex group, issue the `DISPLAY TCPIP,,SYSPLEX,GROUP` command.
- If you have procedures specified on the `AUTOLOG` profile statement that bind to a dynamic VIPA, specify the optional `DELAYSTART` parameter with the optional `DVIPA` subparameter for these procedures on the `AUTOLOG` statement. With the `DELAYSTART DVIPA` subparameter, the procedures will not start until the TCP/IP stack has joined the sysplex group and has processed the dynamic VIPA configuration.

During a planned or unplanned outage, the DVIPAs and distributed DVIPAs for a TCP/IP stack are taken over by backup TCP/IP stacks. When the primary TCP/IP stack is restarted, the DVIPAs and distributed DVIPAs are taken back from the backup TCP/IP stacks.

- If dynamic routing is used to advertise routes to these DVIPAs, and specified network routing and connectivity availability conditions are not met on the primary TCP/IP stack, existing connections to these DVIPAs might be reset and new connect requests to these DVIPAs might fail. By using the `GLOBALCONFIG SYSPLEXMONITOR DELAYJOIN` and `MONINTERFACE DYNROUTE` configuration statements in the TCP/IP profile on the primary TCP/IP stack, it is possible to delay taking back the DVIPAs and distributed DVIPAs until specified network routing and connectivity availability conditions are met. New and existing connections continue to be serviced by the backup TCP/IP stacks until `OMPROUTE` is active and monitored interfaces and dynamic routes over those monitored interfaces are present on the primary TCP/IP stack.
- When IPsec infrastructure is needed to establish IPsec protection for traffic using these DVIPAs, and all the necessary IPsec components are not yet operational on the primary TCP/IP stack, existing connections to these DVIPAs might be reset and new connect requests to these DVIPAs might fail. By using the `GLOBALCONFIG SYSPLEXMONITOR DELAYJOINIPSEC` configuration statement in the TCP/IP profile on the primary TCP/IP stack, it is possible to delay taking back the DVIPAs and distributed DVIPAs until the IPsec infrastructure is operational. New and existing connections continue to be serviced by the backup TCP/IP stacks until the IPsec infrastructure is operational on the primary TCP/IP stack.

For more information about the `GLOBALCONFIG` statement and its parameters, see [z/OS Communications Server: IP Configuration Reference](#).

**Problem detection**

If this stack is not the only member of the TCP/IP sysplex group and it is advertising DVIPAs (owns a DVIPA or is the primary routing node for a Distributed DVIPA), the following resource checks are made by the monitor:

- VTAM address space availability

If the VTAM address space is not currently active and the elapsed time since VTAM was last detected as active has exceeded the `TIMERSECS` value, message `EZZ9671E` is issued.

- Route availability

If there are no routes available to all partners, given the configured method chosen for forwarding data (`VIPAROUTE` statement or dynamic XCF interfaces), there are at least two other MVS systems in the sysplex, and the elapsed time since an active route was detected has exceeded the `TIMERSECS` value, message `EZZ9673E` or `EZD1172E` is issued.

If `OMPROUTE` was successfully initialized, it periodically sends a heartbeat to the stack, so the monitor can always make the following resource checks:

- If the elapsed time since a heartbeat was received has exceeded half of the `TIMERSECS` value, message `EZZ9672E` is issued as a warning and no other actions occur.
- If the stack is not the only member of a TCP/IP sysplex group, is advertising DVIPAs, and the elapsed time since a heartbeat was received has exceeded the `TIMERSECS` value, message `EZZ9678E` is issued.

Ensure that the WLM policy for the OMPROUTE address space receives sufficient priority in relationship to other work managed by WLM on the system, so that OMPROUTE receives the CPU cycles necessary for this task. For more information on this topic, see [Sysplex autonomies](#).

If the network monitoring function is enabled, at least one monitored interface is configured, the TCP/IP stack is not the only member of this sysplex group, and the TCP/IP stack participates in sysplex distribution (as a distributor or target) or acts as an owner or a backup for DVIPAs, the following network connectivity checks are made by the monitor:

- Critical interfaces are active

If the MONINTERFACE option is specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, all monitored interfaces become inactive, and the elapsed time since at least one active monitored interface was detected has exceeded the TIMERSECS value, message EZZ1209E is issued.

- Presence of dynamic routes available over critical interfaces

If the MONINTERFACE or MONINTERFACE DYNROUTE option is specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, there are no available dynamic routes found over any of the monitored interfaces, and the elapsed time since at least one dynamic route over the monitored interfaces was detected has exceeded the TIMERSECS value, message EZZ1210E is issued.

If the IPsec monitoring function is enabled (SYSPLEXMONITOR DELAYJOINIPSEC MONIPSEC on the GLOBALCONFIG statement) and sysplex-wide security associations (SWSA) are enabled with the DVIPSEC parameter on the IPSEC statement, the IPsec infrastructure is monitored. The IKE daemon periodically sends a heartbeat to the stack. The monitor checks if the elapsed time since a heartbeat was received has exceeded the TIMERSECS value. If so, message EZZ1977E is issued.

If this stack is advertising DVIPAs or is a sysplex distributor target, the following checks are made:

- The monitor checks for the availability of CSM storage. If CSM storage is continuously critical for greater than the TIMERSECS value, message EZZ9679E is issued. If CSM storage is continuously constrained for greater than three times the TIMERSECS value, message EZZ1974E is issued.
- If TCP/IP ECSA storage limits are defined on the ECSALIMIT parameter of the GLOBALCONFIG statement, monitoring of this storage is similar to CSM monitoring. If TCP/IP ECSA storage is continuously critical for a time greater than the TIMERSECS value, message EZZ1187E is issued. If there are no TCP/IP ECSA storage limits defined on the GLOBALCONFIG statement and a storage request cannot be satisfied, message EZZ1170E is issued. These messages indicate that there is a TCP/IP problem with ECSA storage.
- If TCP/IP private storage limits are defined on the POOLLIMIT parameter of the GLOBALCONFIG statement, monitoring of this storage is similar to CSM monitoring. If TCP/IP private storage is continuously critical for a time greater than the TIMERSECS value, message EZZ1187E is issued. If there are no TCP/IP private storage limits defined on the GLOBALCONFIG statement and a storage request cannot be satisfied, message EZZ1170E is issued. These messages indicate that there is a TCP/IP problem with private storage.

Note, however, that if all DVIPAs on this stack have a status of MOVING and the stack is not a DVIPA target, these checks are not made.

In addition to the sysplex monitor, when the stack joins the TCP/IP sysplex group it requests that XCF monitor the TCP/IP sysplex component on the local stack. The XCF component performs this function by monitoring a status field updated by the TCP/IP sysplex component. If XCF detects that the sysplex functions have not been responsive for the TIMERSECS value, it schedules a TCP/IP routine that issues message EZZ9674E.

If TCP/IP encounters a nonrecoverable sysplex error, it issues the eventual action message EZZ9670E.

If five TCP/IP abends occur in less than 1 minute, eventual action message EZZ1973E is issued.

All of these messages are eventual action messages. If the detected problem condition is corrected (for example, VTAM is started), the eventual action message is cleared. For more information about these eventual action messages, see [z/OS Communications Server: IP Messages Volume 2 \(EZB, EZZ\)](#) and [z/OS Communications Server: IP Messages Volume 4 \(EZZ, SNM\)](#).

## Recovery

Recovery actions occur if RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. If the default setting, SYSPLEXMONITOR NORECOVERY, is active, other than issuing the message, no further actions occur if the problem is not corrected.

The VARY TCPIP,,SYSPLEX,LEAVEGROUP command can be used to manually force the sysplex member to leave the TCP/IP sysplex group. As a stack leaves the TCP/IP sysplex group, message EZZ9670E is cleared, as well as message EZZ1170E. All other outstanding eventual action messages are cleared when the condition is cleared (for example, starting VTAM). For information on the [VARY TCPIP,,SYSPLEX](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement in the TCP/IP profile, and this stack is not the only member of the TCP/IP sysplex group, the stack leaves the TCP/IP sysplex group when one of the messages is issued. The one exception to this is EZZ9672E, which is issued only as an OMPROUTE warning message. No actions occur unless the corresponding EZZ9678E OMPROUTE message is subsequently issued.

To determine whether the stack is currently joined to a TCP/IP sysplex group, issue the DISPLAY TCPIP,,SYSPLEX,GROUP command. If the stack is not currently joined to a TCP/IP sysplex group, this command displays the following message:

```
EZZ8269I tcpstackname musname NOT A MEMBER OF A SYSPLEX GROUP
```

If the stack is currently joined, the name of the TCP/IP XCF group is displayed.

From any member of the sysplex, use the D XCF,GROUP,*groupname* command to see the systems currently in the sysplex group, where *groupname* is EZBTCPCS, or if subplexing is being used, EZBTvvtt, where vv is the VTAM XCF group ID suffix and tt is the TCP group ID suffix..

If the RECOVERY option is specified and a TCP/IP stack initiates an automated recovery action by leaving the TCP/IP sysplex group, all local DVIPAs are deactivated and all the VIPADYNAMIC block definitions are saved. Any applications bound to dynamically created DVIPAs (VIPARANGE or MODDVIPA) will receive an asynchronous error, EUNATCH (3448) - the protocol required to support the address family is unavailable.

If internal problems prevent the removal of these resources, eventual action message EZZ9675E is issued, and restarting the stack is necessary to be able to become part of the TCP/IP sysplex group. If all DVIPAs are successfully removed, eventual action message EZZ9676E is issued, indicating that sysplex problem detection cleanup has succeeded. There are two ways for the stack to rejoin the sysplex group and clear this message after a successful cleanup has occurred:

- If AUTOREJOIN was configured on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, the stack automatically rejoins the group and reprocesses its saved VIPADYNAMIC configuration when all detected problems have been relieved. The AUTOREJOIN option is the recommended setting when the RECOVERY option is configured.
- Issue the VARY TCPIP,,SYSPLEX,JOINGROUP command to cause the stack to rejoin the group, and reprocess its VIPADYNAMIC configuration.

Recovery is the preferred method of operation, because this allows other members of the TCP/IP sysplex to automatically take over the functions of a member with no actions needed by an operator. IBM Health Checker for z/OS can be used to check whether the RECOVERY parameter has been specified when the IPCONFIG DYNAMICXCF or the IPCONFIG6 DYNAMICXCF statement has been specified. For more details about [IBM Health Checker for z/OS](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

There are, however, some environments and scenarios where this automated recovery action might not be desirable and perhaps should not be enabled:

- DVIPAs or Distributed DVIPAs are defined, but no backup TCP/IP stacks are identified or no provisions are made to move the DVIPAs in cases of failure.

The basic premise of the automated recovery actions is that one or more other TCP/IP stacks in the system can pick up ownership responsibilities for any DVIPAs owned by the failing TCP/IP stack. If

this is not the case, it is suggested that you carefully evaluate the benefits of designating backup TCP/IP stacks and implement a configuration that includes backup capabilities. If this is not possible or desirable, RECOVERY should not be specified. If RECOVERY is not specified, automated recovery actions are disabled by default.

For example, one such configuration is if you are using only DVIPAs that are always bound to a specific TCP/IP stack (that is, in lieu of static VIPAs). In this scenario, because there is no possibility of having ownership of these DVIPAs transferred automatically, there is no value in triggering the automated recovery action and you should consider not enabling the automated recovery function or using static VIPAs (because static VIPAs are not affected by the automated recovery actions).

- Test environments where individual system images have very limited resources (CPU, storage, and so on).

This can include environments where you are running z/OS as a second level guest under z/VM, or in LPARs with shared processors and very limited resources. Not enabling the automated recovery actions in these environments can help prevent unwanted recovery actions that are triggered by false positive conditions, such as scenarios where artificial severe resource shortages are detected.

- Environments where VTAM, OMPROUTE, IKED or NSSD are stopped for intervals longer than the TIMERSECS value specified on the SYSPLEXMONITOR parameter.

If your current operations procedures have provisions for stopping VTAM, OMPROUTE, IKED or NSSD for extended periods of time, you should consider disabling and re-enabling the automated recovery processing around the periods of time where you stop and restart these components. This can be accomplished using the VARY TCPIP,,OBEYFILE command.

An alternative solution could be to increase the TIMERSECS value to accommodate the longest period of time you would expect VTAM, OMPROUTE, IKED or NSSD to be inactive during normal operating procedures. One potential drawback of this approach is that the monitoring of other conditions and triggering of automatic recovery functions is less responsive.

## Setting TIMERSECS

As described, the responsiveness of the self-monitoring and automated recovery actions is governed by the TIMERSECS value that is specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement. The default value is 60 seconds. Evaluate whether this default value is appropriate in your environment and, if not, specify a value that is better suited to your environment. The following considerations are some of the considerations to evaluate in selecting an appropriate value:

- Specifying a smaller TIMERSECS value increases the responsiveness of the self-monitoring functions.

The monitor periodically performs its checks for problem conditions, every 60 seconds or every quarter of the TIMERSECS interval ( $\text{TIMERSECS}/4$ ), whichever is less. Therefore, when a smaller TIMERSECS value is specified, operator message alerts are issued sooner if a problem condition is detected. Automated recovery actions are also triggered sooner if the RECOVERY option is in effect.

While this might be desirable, care should be taken to not specify a timer interval value that is small enough to trigger recovery actions for conditions that are transient in nature. For example, the value specified should probably be larger than the spin loop timeout interval for the system (SPINTIME parameter in the EXSPATxx parmlib member). Otherwise, a spin loop timeout condition that might be recoverable could trigger an unnecessary TCP/IP sysplex recovery action, as a result of the TCP/IP sysplex monitor not being able to be dispatched temporarily before any spin loop timeout recovery actions can take place. A good rule of thumb is to specify a TIMERSECS value that is at least two times larger than the spin loop timeout interval in effect for the system.

- Specifying a longer TIMERSECS value has the opposite effect, and the self-monitoring and automated recovery actions are less responsive.

In addition, a longer TIMERSECS value can cause disruptions to existing TCP connections when problem conditions are detected, even if automated recovery actions are initiated. For example, if the problem condition persists for a long enough interval and it impacts the delivery of data on existing TCP connections, the remote TCP/IP hosts might terminate these connections before a recovery action is initiated.

- Review your current settings for the sysplex failure detection interval (INTERVAL keyword in COUPLExx) and the ISOLATETIME value specified in your SFM policy, if defined. These values indicate how responsive the XCF component should be in removing systems from the sysplex when a status update missing condition occurs. As a result, these settings can provide a reasonable reference point for the setting of the TIMERSECS value. For more information on these intervals, see [z/OS MVS Setting Up a Sysplex](#).

## Summary of problems monitored and actions taken

When the sysplex monitor detects a problem, an operator message is issued. If RECOVERY was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement in the TCP/IP profile, the stack leaves the sysplex group, deletes all its dynamic VIPAs, and deactivates all its VIPADYNAMIC definitions. When the detected problem is relieved, the operator message is deleted. If AUTOREJOIN was specified on the SYSPLEXMONITOR parameter of the GLOBALCONFIG statement, the stack might or might not rejoin the sysplex group, depending on the severity of the problem.

Table 26 on page 485 summarizes the various problems that are monitored and the specific actions that are taken for each detected problem.

| Table 26. Sysplex problem monitoring |                                                                                            |                                                                                                                                                                                                                                                                                                                                                                                                                                                              |                                                                                     |

Delete the operator message when IPsec policy filters in effect.</li> </ol> | Stack rejoins the sysplex group and reprocesses the saved VIPADYNAMIC configuration |

## Sysplex autonomics for IPsec

Sysplex autonomics for IPsec provides:

- a mechanism for a TCP/IP stack to delay joining or rejoining the sysplex group until the IPsec infrastructure is active
- a mechanism for the TCP/IP stack to detect a problem in the IPsec infrastructure and optionally leave the sysplex group until the problem is resolved

You enable sysplex autonomics for IPsec by specifying the DELAYJOINIPSEC and MONIPSEC subparameters on the GLOBALCONFIG SYSPLEXMONITOR parameter.

## When should IPsec sysplex monitoring be enabled?

Consider enabling IPsec sysplex monitoring for a TCP/IP stack that has IPsec-protected TCP workloads that are distributed or backed up within the sysplex. A TCP/IP stack that serves only as a target for distributed workloads does not benefit from the monitoring function.

IPsec sysplex monitoring should only be enabled for a stack that has:

- IP security enabled with the IPSECURITY parameter on the IPCONFIG statement in the TCP/IP profile
- Sysplex-wide security associations (SWSA) enabled with the DVIPSEC parameter on the IPSEC statement in the TCP/IP profile
- IKED started on the system

IPsec sysplex monitoring should NOT be used in the following cases:

- IPsec is only used to protect Enterprise Extender (EE) traffic for this stack.

The actions that the Sysplex Monitor offers rely on DVIPA addresses which are not typically used with EE.

- IKED to NSSD connection uses DVIPA addresses.

If NSSD is being used for IPsec certificate services and the IKED to NSSD connection uses a DVIPA as the source or destination IP address, then IPsec sysplex monitoring should not be used. IPsec sysplex monitoring requires that IKED successfully connect to NSSD before the stack joins the sysplex group, but DVIPA addresses are not available until the stack has joined the sysplex group. This could lead to a case where the stack is not able to join the sysplex.

IKED uses the stack's default address as the source address for the TCP connection to NSSD. The destination address is configured on the NssSecurityServer or NssSecurityServerBackup statement in the IKE configuration file.

- Policy Client to Policy Server connection uses DVIPA addresses.

If a centralized policy server is being used and the policy client and policy server connection uses a DVIPA as the source or destination address, then IPsec sysplex monitoring should not be used. IPsec sysplex monitoring requires that the policy client successfully connect to the policy server and load the policy, but DVIPA addresses are not available until the stack has joined the sysplex group. This could lead to a case where the stack is not able to join the sysplex.

The policy client uses the stack's default address as the source address for the TCP connection to the policy server. The destination address is configured on the ServerHost or ServerHostBackup parameter on the ServerConnection statement in the policy agent configuration file.

- A limited amount of sysplex traffic is IPsec protected.

It might be useful to enable DELAYJOINIPSEC so that the stack does not join the sysplex until the IPsec infrastructure is active. However, you might choose NOMONIPSEC to prevent the stack from leaving the sysplex for an IPsec infrastructure failure that only impacts a limited number of connections.

When DELAYJOINIPSEC is configured for a stack, AUTOLOG DELAYSTART DVIPA should not be configured for your Policy Agent, IKED, or NSSD procedures. Note that Policy Agent, IKED, and NSSD are generic servers (those without affinity to a specific stack) and AUTOLOG would not typically be used to start them.

## What is monitored in the IPsec infrastructure?

The IPsec infrastructure monitored by sysplex problem detection and recovery (SPDR) includes the Policy Agent, the Internet Key Exchange (IKE) daemon, and the Network Security Server (NSS) daemon (if configured). The following checking determines if the IPsec infrastructure is considered active:

1. IP security is enabled with the IPSECURITY parameter on the IPCONFIG statement in the TCP/IP profile.
2. Sysplex-wide security associations (SWSA) is enabled with the DVIPSEC parameter on the IPSEC statement in the TCP/IP profile.
3. IPsec policy is installed and active for the TCP/IP stack.

4. IKED is active and was able to establish UDP sockets for ports 500 and 4500 for use in negotiating tunnels with peers.
5. IPsec policy is installed in the IKE daemon. The policy must include key exchange policy and dynamic VPN actions which are used for tunnel negotiation. While monitoring cannot determine if your IPsec policy is accurate for individual tunnel negotiations, it ensures that the installed policy contains the appropriate types of policy used for tunnel negotiations.
6. If the IKE daemon is providing certificate services, the IKE key ring can be accessed. Again, monitoring cannot determine if the certificates on your key ring are correct for the tunnels you plan to negotiate. But it ensures that the key ring itself can be accessed and that there is at least one end entity certificate available on the key ring.
7. If the Network Security Server (NSS) is providing certificate services:
  - IKED is connected to NSS and is protected by a TLS session.
  - IKED successfully authenticated using the userid and password/passticket configured in the IKE configuration file.
  - Certificate services are enabled in the IKED configuration file, and permission is defined for the userid to read the EZB.NSS.sysname.clientname.IPSEC.CERT SERVAUTH profile.
  - The NSS key ring can be accessed. Again, monitoring cannot determine if the certificates on your key ring are correct for the tunnels you plan to negotiate. But it ensures that the key ring itself can be accessed and that NSS has provided at least one certificate authority certificate for use in negotiations.

**Tip:** If you are only using pre-shared keys to authenticate all IKE peers then your IPsec infrastructure does not need a keyring or certificates. You can add the NoKeyRing parameter to your IKE configuration file to indicate that no keyring/certificate checking is needed. Checks 6 and 7 are skipped.

**Restriction:** If both a primary and backup NSSD are configured in the IKED configuration file (NetworkSecurityServer and NetworkSecurityServerBackup), IPsec sysplex monitoring treats NSSD as a centralized resource. The following is done:

- For DELAYJOINIPSEC processing, check 7 above is still applicable.
- For MONIPSEC processing, check 7 is not done. It is likely that a problem with the IKED to NSSD connection for a centralized NSSD affects multiple stacks in the sysplex. Taking a recovery action, such as leaving the sysplex, is not likely to allow a backup stack to re-establish the IPsec tunnels.

## What messages are generated when monitoring for IPsec infrastructure issues?

When DELAYJOINIPSEC is configured but sysplex-wide security associations (SWSA) is not enabled for the TCP/IP stack, message EZZ0839I THE DELAYJOINIPSEC PARAMETER ON THE GLOBALCONFIG SYSPLEXMONITOR STATEMENT IS IGNORED BECAUSE SWSA IS NOT ENABLED is generated.

**Note:** SWSA is enabled with the DVIPSEC parameter on the IPSEC statement block in the TCP/IP profile.

When DELAYJOINIPSEC is configured and the TCP/IP stack is waiting for the IPsec infrastructure to become active, you see eventual action message EZZ1976E *stackname* DELAYING SYSPLEX PROFILE PROCESSING – IPSEC INFRASTRUCTURE IS NOT ACTIVE.

When MONIPSEC is configured and an IPsec infrastructure problem is detected after the TCP/IP stack has joined the sysplex, you see eventual action message EZZ1977E *stackname* HAS DETERMINED THAT THE IPSEC INFRASTRUCTURE WAS NOT RESPONSIVE FOR AT LEAST *timersecs* SECONDS.

When MONIPSEC is configured, if the IPsec default filter rules are activated, you see eventual action message EZZ1979E *stackname* HAS DETERMINED THAT THE DEFAULT IPSEC FILTERS HAVE BEEN IN EFFECT FOR AT LEAST *timersecs* SECONDS.

## How do I know why I am seeing message EZD1976E or EZD1977E?

When EZD1976E or EZD1977E is present, syslogd should be reviewed for IKED message EZD2050I IPsec infrastructure problem detected for stack *stackname* : *reason*. The *reason* value provides a more detailed explanation of the detected problem.

The TCP/IP stack relies on IKED to provide a heartbeat indicating that the IKED and NSSD infrastructure is active (checks 4-7 above). IKED withholds the heartbeat if a problem is detected and generates an EZD2050I message. As the TCP/IP stack, Policy Agent, IKED, and NSSD are starting, IKED might generate an EZD2050I message for a condition that is cleared once all resources are active. IKED generates an EZD2049I message when a problem condition is cleared. For more information on messages [EZD2049I](#) and [EZD2050I](#), see [z/OS Communications Server: IP Messages Volume 2 \(EZB, EZD\)](#).

Depending on the *reason* reported in EZD2050I, syslogd should be reviewed to determine what errors are being reported. Errors could be specific to IKED or NSSD. Errors could be related to establishing the AT-TLS connection required between IKED and NSSD, or errors could be related to resource permissions.

## Target server connection setup responsiveness monitoring

Sysplex distributor measures the responsiveness of target servers in accepting new TCP connection requests at intervals of approximately 1 minute. Target server responsiveness (TSR) values calculated from these measurements are used to modify the weight when using WLM system weight distribution, WLM server-specific weight distribution, or weighted active distribution, to favor those servers that are more successfully accepting new TCP connection setup requests.

### TSR

TSR values are displayed as a percentage. Thus, a value of 100 indicates full responsiveness and a value of 0 indicates no responsiveness in setting up new TCP connections. A value of 0 for the TSR causes this target server to be bypassed when new TCP connection setup requests are distributed to target servers for a DVIPA and port, even if the distribution method is round-robin. Periodically, the distributor sends a new connection request to a target with a TSR of 0, to check whether the responsiveness of that target has improved.

The calculated TSR values are applied to the WLM weights only if there are no stacks participating in the distribution of connections for this DVIPA that are at a release level earlier than z/OS V1R7. The TSRs are calculated by combining two factors, the target connectivity success rate (TCSR) and the Servers' accept Efficiency Fraction (SEF). These factors are defined as follows:

#### TCSR

The target connectivity success rate is the measure of how many new TCP connection setup requests (SYNs) sent by the distributing stack to a target stack are received by the target stack. A low value could indicate a problem with the connectivity between the distributing stack and the target stack.

#### SEF

The Servers' accept Efficiency Fraction measures how well a target server is accepting new TCP connection setup requests and managing its backlog queue.

### CER

The connection establishment rate (CER) measures how many TCP connection setup requests received by the target stack become established (that is, how many enter the ESTAB state). The CER value is displayed as a percentage; 100 indicates that all of the connection setup requests that were received entered the established state. A lower value could indicate a routing problem in the network. The CER value is shown only as a diagnostic aid, and its value has no affect on the WLM weight.

## Workload balancing

---

Load balancing is the ability for a cluster to distribute workload evenly (or based on some policy) to target servers comprising the cluster. Usually, this load balancing is calculated based on the perceived load on

each of the target servers. Various techniques are available to perform IP load balancing for a System z sysplex. These techniques typically fall into the following categories:

- Internal load balancing solutions

These solutions typically rely on a component executing within the z/OS sysplex to perform the load balancing with very few dependencies on the external network. Because they are executing within the sysplex environment, these solutions typically have access to information that can be used to optimize load balancing, such as system capacity and current load information. An example of this technique is the sysplex distributor.

- Sysplex-aware external load balancing solutions

These solutions are typically comprised of an external load balancer that relies on components inside the z/OS sysplex for advice on how workload should be distributed. As a result, these solutions usually provide for load balancing that is optimized for a z/OS sysplex environment. Examples of these solutions include the IBM Network Dispatcher and any external load balancing solution that supports the Server/ Application State Protocol (SASP) provided by the z/OS Load Balancing Advisor (for example, the CISCO Content Switching Module).

- External load balancing solutions

These solutions are usually comprised of load balancing components that execute outside of the z/OS sysplex, typically on one or more hosts or routers in the network, with little or no specific awareness of the z/OS sysplex environment. Several vendors provide such load balancing solutions.

This information describes and compares these three load balancing techniques and selected associated solutions. Each solution identifies the target System z servers that can receive client connections based on some specification.

By providing load balancing, clustering techniques must also provide for other system requirements in addition to the dispatching of connections. These include the ability to advertise some single systemwide image or identity so that clients can uniquely and easily identify the service. Additionally, clustering techniques should also provide for horizontal growth of the system and ease of management.

## Single systemwide image

Clients connecting to a cluster should not be aware of the internal makeup of a cluster. More specifically, clients should not even be aware that the service they are requesting is actually being serviced by a collection or cluster of servers. Instead, clients must be provided with some single image identifier to be used when connecting to the service. For example, most of the load balancing solutions (internal or external) discussed in this information use a single IP address to represent a cluster of servers to clients. The clients use this IP address to establish connections and are not aware that the load balancing solution directs requests to a specific instance of the server.

## Horizontal growth

As the clients' demands on the service increase, clusters must provide a way to expand the cluster of servers to accommodate for such growing demand. Put in another way, the cluster must provide a mechanism by which to add servers without disrupting the operation of the cluster. To this end, the service is made available to clients at all times and can grow horizontally to accommodate for increased demand placed on the cluster by the clients.

## Ease of management

The administrative burden associated with the cluster (sysplex) should not increase as you add servers to the cluster. You should use the same configurations for many systems in the cluster. Within a sysplex, servers are homogenous, because a sysplex is comprised solely of System z servers. As such, many of the configurations can be shared among the different System z servers, which reduces the administrative burden associated with the sysplex. Additionally, as the size of the cluster increases, the administrative overhead in adding systems to the cluster should be as low as possible.

Administrative activities required to maintain a load balancing solution are highly dependent on the type of load balancing solution deployed. For example, administrative tasks associated with the maintenance of internal load balancing solutions typically consist of administrative tasks within the z/OS sysplex, such as changing z/OS configuration files. External load balancing solutions typically require administrative tasks performed on the external load balancing components, while sysplex-aware external load balancing solutions might require administrative tasks on both internal and external load balancing components. Depending on your environment and organizational structure, the administrative scope required by the various load balancing solutions can play a key role in your selection process. For example, do you need to deploy a solution that requires only administrative tasks on z/OS, or can you make required updates to network components as necessary?

## Internal load balancing solutions

Internal load balancing solutions typically rely on components that are within the z/OS sysplex to perform the load balancing. While other components might be required in the network, after the solution is configured, minimal changes should be needed from network components outside of the sysplex. An example of an internal load balancing solution is the sysplex distributor. For information about the sysplex distributor, see [“Sysplex distributor” on page 503](#).

## Sysplex-aware external load balancing solutions

Sysplex-aware external load balancing solutions are typically comprised of an external load balancing solution that communicates with components within the z/OS sysplex, to optimize load balancing based on the current conditions and workloads in the sysplex environment. Examples of these solutions include:

- External load balancers that use the Server/Application State Protocol (SASP) to obtain recommendations and topology information related to applications and systems within a sysplex environment.
- The IBM Network Dispatcher can obtain WLM recommendations from z/OS, and uses these recommendations to determine how workload requests are routed.

External load balancers can obtain detailed information regarding the state of target z/OS applications and systems by communicating with the z/OS Load Balancing Advisor using the SASP protocol. Using SASP, external load balancers can also obtain detailed recommendations on how workload should be distributed within the sysplex environment.

A key component of these recommendations is derived from the z/OS Workload Manager (WLM). The WLM information reflects the current available system capacity for target systems, and can also reflect how well individual server applications are performing compared to the WLM policy goals specified for that application. These recommendations are also influenced by how well the applications are performing from a TCP/IP perspective. For example, are the applications processing new requests quickly enough? Or are new requests filling up the backlog queues that TCP/IP maintains for each application?

Using SASP, external load balancers can perform load balancing that is optimized for your sysplex environment, based on the current configuration and workload conditions. SASP supports TLS/SSL for secure authentication, access control, and encryption of data. For more information on SASP and the z/OS Load Balancing Advisor, see [Chapter 21, “z/OS Load Balancing Advisor,” on page 1177](#).

## External IP workload balancing solutions

IBM's Network Dispatcher (part of WebSphere Edge Server) and Cisco's Content Switching Module (CSM) are examples of external IP workload balancing solutions. Such solutions exist outside the sysplex, but can direct work into the sysplex. External IP workload balancing solutions typically define a single IP address representing all instances of the server, and then balance new work requests (for example, new TCP connection requests) among available servers.

External load balancers typically use a cluster IP address to represent the set of applications being load balanced. Client applications use this cluster IP address as the destination IP address for all their requests. External load balancers might be capable of using different methods for forwarding packets to their destinations. Various load balancing solutions might use different terms when describing these

methods. In this discussion, dispatch mode and directed mode are discussed as two examples of these methods.

When a load balancer uses dispatch mode, the destination IP addresses for incoming IP packets is not changed. Instead, the load balancer forwards the packet to a target z/OS system by using the MAC address of a network adapter on that system. This technique works well when the target systems and the load balancer are attached to the same network (that is, there are no intervening routers). The receiving z/OS system inspects the destination IP address of the packet, and if it matches one of the IP addresses in its HOME list, it accepts the packet. As a result, with dispatch mode, all target z/OS systems must have the load balancer's cluster IP address defined in their HOME list. It is important, however, that these addresses are not advertised externally through dynamic routing protocols. One way to accomplish this is by defining these IP addresses as loopback addresses on z/OS.

Dispatch mode also has special considerations when the load balancer is more than one hop away from the target systems (that is, a packet must be routed to the target), or when multiple z/OS target systems share the same OSA adapter. In these scenarios, you can use the following techniques to route packets to the correct target system:

- VMAC addresses

Causes the OSA to route packets using a MAC address that is exclusively owned by the target system.

- GRE tunnels

Causes the OSA to route packets using an IP address that is exclusively owned by the target system.

On the other hand, when a load balancer uses directed mode, the load balancer converts the destination IP address (that is, the cluster IP address) to an IP address owned by the target z/OS system, using technologies such as network address translation (NAT). When IP packets for these connections are sent back to clients, the load balancer converts the source IP address (that is, the target z/OS system's IP address) back to the cluster IP address that the application had used on its request.

Some load balancer configurations might also perform NAT on the client's IP address. The client's IP address can be replaced with an IP address owned by the load balancing device. This might be necessary to ensure that all outgoing packets from a target system traverse the load balancing device, so that NAT can be performed to change the server's IP address back to the cluster IP address that the client had originally used. Therefore, it is important to note that with directed mode solutions, the IP addresses of load balanced connections reaching the sysplex might not reflect the real IP addresses of the clients making the requests. This can be an important consideration if any definitions or configuration within the sysplex rely on the client's IP address being visible on incoming connections.

External load balancing solutions might provide several configuration options that influence how workload is distributed, such as round-robin, weighted round-robin, and so on. Some of the solutions might also obtain recommendations from components inside the z/OS sysplex that might affect their workload balancing decisions. For more information, see [“Sysplex-aware external load balancing solutions”](#) on page 498.

## Choosing a load balancing solution

Several load balancing solutions are available for a z/OS environment. The solution that is best for your environment depends on several factors that are related to your environment and the workload being load balanced, including:

- What type of workload needs to be load balanced, and does a particular load balancing solution support this type of workload? For example, does the workload have affinities to specific servers? Can these affinities be determined only by inspecting data content? If so, an external load balancing solution that supports content inspection and affinities might be the most appropriate solution.
- Is it important that the solution is primarily configured and maintained within the z/OS sysplex, with minimal interactions with network components? In these scenarios, an internal load balancing solution might be the preferred answer.

- Do you already have an external load balancing solution in the network? If so, can it be used to load balance z/OS workloads? Does it support SASP, so that it can perform more optimal load balancing decisions?
- Does the load balancing solution have the needed level of availability? For example, if the primary load balancer fails, can a secondary load balancer take over transparently? Can it do so without disrupting existing connections? What if target applications or systems fail? Does the load balancer recognize these conditions?

While a single load balancing solution might be desirable for all workloads in some environments, you can select multiple solutions based on your specific requirements. For example, you might select an external load balancing solution for a particular workload, while an internal load balancing solution might be enabled for another workload. [Table 27 on page 500](#) lists some of the key attributes of the various load balancing techniques and specific solutions that were discussed in this information. It can be used as a quick reference for comparing these solutions.

| <i>Table 27. Load balancing solution quick reference</i> |                                                                                                                                                                                                                                                                  |                                                                                                                                                                 |                                                                                                                                                                                                                                                                |
|----------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Features or considerations</b>                        | <b>Sysplex distributor</b>                                                                                                                                                                                                                                       | <b>External load balancers with SASP</b>                                                                                                                        | <b>External load balancers</b>                                                                                                                                                                                                                                 |
| How is the solution configured and administered?         | Initial setup might require some interaction with the network (dynamic routing protocols, DNS updates for dynamic VIPAs, and so on). Ongoing administration (adding and removing target server applications and systems) typically confined within z/OS systems. | Initial setup and configuration on load balancer and on z/OS. Ongoing administration might need to be performed on both the load balancer and the z/OS systems. | Initial setup and configuration on load balancer, some configuration on z/OS might be required. Ongoing administration should be mostly confined to the load balancer, although z/OS configuration might be necessary, such as when adding new target systems. |
| When is the server instance decision made?               | Connection setup (in line Syn segment)                                                                                                                                                                                                                           | Connection setup (in line Syn segment)                                                                                                                          | Connection setup (in line Syn segment)                                                                                                                                                                                                                         |
| Support for TCP and UDP applications?                    | TCP only                                                                                                                                                                                                                                                         | Depends on the load balancer implementation; SASP supports both TCP and UDP                                                                                     | Depends on the load balancer implementation                                                                                                                                                                                                                    |
| Extra network flows?                                     | No, for outbound traffic. Yes, for inbound traffic. Inbound traffic must traverse the sysplex distributor node. If sysplex distributor is configured as service manager for CISCO routers, the inbound traffic can flow directly to the target application.      | Depends on the load balancer implementation; can be avoided if the load balancer is implemented as part of a router or switch.                                  | Depends on the load balancer implementation; can be avoided if the load balancer is implemented as part of a router or switch.                                                                                                                                 |

Table 27. Load balancing solution quick reference (continued)

| <b>Features or considerations</b>                                             | <b>Sysplex distributor</b>                                  | <b>External load balancers with SASP</b>                                                                                                    | <b>External load balancers</b>                                                                                                              |
|-------------------------------------------------------------------------------|-------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|
| Support for affinities between TCP connection requests based on data content? | No, but support does exist for timer-based affinities       | Depends on implementation; some support affinities for HTTP and HTTPS requests by inspecting data content (correlating cookies, jsessionid) | Depends on implementation; some support affinities for HTTP and HTTPS requests by inspecting data content (correlating cookies, jsessionid) |
| Network address translation?                                                  | Not needed; client and server IP addresses are not modified | Might be required by some implementations; client and server IP addresses might be translated                                               | Might be required by some implementations; client and server IP addresses might be translated                                               |
| Support for IPv6?                                                             | Yes                                                         | Depends on the load balancer implementation; SASP supports both IPv4 and IPv6                                                               | Depends on the load balancer implementation                                                                                                 |
| z/OS WLM recommendations?                                                     | Yes, system level and server level                          | Yes, system level and server level                                                                                                          | Depends on the load balancer implementation                                                                                                 |
| z/OS network QoS recommendations?                                             | Yes, based on z/OS QoS policy                               | No                                                                                                                                          | No                                                                                                                                          |
| z/OS TCP/IP server health information?                                        | Yes                                                         | Yes                                                                                                                                         | No                                                                                                                                          |

## Sysplex distributor

Sysplex distributor extends the notion of dynamic VIPA and automatic VIPA takeover to allow for load distribution among target servers within the sysplex. It extends the capabilities of dynamic VIPAs to enable distribution of incoming TCP connections to ensure high availability of a particular service within the sysplex.

The functionality of sysplex distributor is that one IP entity advertises ownership of an IP address by which a particular service is known. In this fashion, the single system image of sysplex distributor is that of a special IP address. This IP address is called a distributed DVIPA. Further, in sysplex distributor, the IP entity advertising the distributed DVIPA and dispatching connections destined for it is itself a system image within the sysplex, referred to as the distributing stack.

Sysplex distributor makes use of Workload Manager (WLM) and its ability to gauge server load and provide a WLM recommendation. In this paradigm, WLM provides the distributing stack with a WLM recommendation for each target system (a WLM system weight), or the target stacks provide the distributing stack with a WLM recommendation for each target server (a WLM server-specific weight). The distributing stack uses this information to optimally distribute incoming connection requests between a set of available servers. Additionally, sysplex distributor has the ability to specify certain policies within the Policy Agent so that it can use QoS information from target stacks to further modify the WLM recommendation. Further, these policies can specify which target stacks are candidates for clients in particular subnetworks.

Sysplex distributor also measures the responsiveness of target servers in accepting new TCP connection setup requests, favoring those servers that are more successfully accepting new requests. For more information, see [“Target server connection setup responsiveness monitoring”](#) on page 496.

The Workload Manager weight is a relative value. The WLM system weight is an indication of the target system's capacity for additional work, and the WLM server-specific weight is a more granular indication of the specific target server's capacity for additional work. Higher numbers indicate a target with comparatively greater capacity. The Netstat VDPT/-O display shows these values. WLM system weights are indicated by a B beside the weight, and WLM server-specific weights are indicated by an S beside the weight.

Distribution using WLM system weights is the default distribution method. This can be specified by using the BASEWLM parameter on the VIPADISTRIBUTE statement. Distribution using WLM server-specific weights can be specified by using the SERVERWLM parameter on the VIPADISTRIBUTE statement. If the SERVERWLM parameter is used and all stacks are able to provide WLM server-specific weights for that VIPA/port, WLM server-specific weights are used. Otherwise, WLM system weights are used.

## BASEWLM - Distribution using WLM system weights

When determining a WLM system weight recommendation, WLM assigns a relative weight to each system in the sysplex, with the highest weight going to the system with the most available capacity. The available capacity is based on the system's available general CPU capacity, and optionally (if there are no systems in the sysplex that are prior to V1R9), available System z Application Assist Processor (zAAP) capacity and available System z Integrated Information Processor (zIIP) capacity. When PROCTYPE for BASEWLM is configured on the VIPADISTRIBUTE statement, a composite WLM weight is determined by the sysplex distributor based on the WLM weight for each processor type and expected usage of each processor type by an application.

If all systems in the sysplex are running at or near 100%, WLM assigns the highest weights to the systems with the largest amount of lower importance work. In this way, new connection requests are distributed to the systems with the highest *displaceable* capacity. However, this assumes that the new work is of a high enough importance level to displace this work. A system can be so loaded that only higher importance work is running on that system, in which case the new work request is not able to meet the goals specified in the WLM policy for that server. For more information on how displaceable capacity is calculated and using the Sysplex Routing Services, see [z/OS MVS Programming: Workload Management Services](#).

Use the Netstat VDPT/-O report option with the DETAIL modifier to determine the WLM system weight recommendations for each processor type, along with the modified weight for each processor based on the expected usage proportion configured on the VIPADISTRIBUTE statement.

## SERVERWLM - Distribution using WLM server-specific weights

When WLM determines a WLM server-specific recommendation, it determines the service class of the server address space and then assigns a weight that is based on the following criteria:

- How well that server is actually meeting the goals of its service class.
- The amount of displaceable workload available, given the importance of the service class.
- If the distributor and target systems are not prior to V1R9, the WLM recommendation is a composite weight based on the available and displaceable capacity of each processor type (general, zAAP, and zIIP) and the current usage of each processor type by this application.

If the distributor and target systems are not running a release prior to V1R11, you can use the PROCXCOST and ILWEIGHTING parameters on the VIPADISTRIBUTE statement to influence the WLM server-specific recommendation.

- PROCXCOST

For applications that are designed to have a portion of their workload run on a zAAP or zIIP specialty processor, use the PROCXCOST parameter on the VIPADISTRIBUTE statement to influence how aggressively WLM favors servers on systems with available zAAP or zIIP capacity over servers on systems where work targeted for the specialty processors has instead run on the conventional processor. The PROCXCOST parameter specifies a crossover cost in the range 1–100 that is applied to the amount of zAAP-targeted or zIIP-targeted workload that actually ran on the conventional processor. The resulting cost is used to reduce conventional processor use by the application, which in turn reduces the WLM recommendation for that server. A crossover cost of 1 means that zAAP-targeted or zIIP-targeted workload that runs on the conventional processor should not be penalized; the WLM recommendation is not reduced.

Before specifying a high crossover cost, give careful consideration to the effect this might have on workload distribution, because servers with less zAAP or zIIP processor capacity might receive a significantly lower percentage of the overall workload. The RMF Workload Activity Report shows the zAAP and zIIP processor use, as well as how much crossover took place. Run this report before and after using the PROCXCOST parameter to better understand how it affects your overall workload performance.

- ILWEIGHTING

Use the ILWEIGHTING parameter on the VIPADISTRIBUTE statement to influence how aggressively WLM favors servers on systems with displaceable capacity at lower importance levels over servers on systems with displaceable capacity at higher importance levels. Work is categorized into one of seven importance levels (importance levels 0 through 6). The most important work runs at importance level 0 and the least important work runs at importance level 6.

The ILWEIGHTING parameter value specifies how WLM should consider displaceable capacity when determining a server-specific recommendation. The higher the value specified for ILWEIGHTING, the more a stack with displaceable capacity at lower importance levels is favored. The possible ILWEIGHTING parameter values and examples of their effect are as follows:

- ILWEIGHTING 0

Specifies that WLM should ignore importance levels when comparing displaceable capacity. This is the default value. For example, if system A and system B are running at 100 percent capacity and new work will be running at importance level 2, all work at importance level 3 and greater is considered to be available displaceable capacity.

- If system A has 500 service units of work at importance level 3 that can be displaced as the new work runs on this system, it initially has a raw WLM weight of 500.
- If system B has 500 service units of work at importance level 6 that can be displaced, it also has an initial raw WLM weight of 500.

The WLM weights are initially the same for both systems, but might be different after the health and performance of the application are considered. The actual WLM weights returned to the invoker are normalized by WLM so that they are in the range 0–64.

In this example, as 100 connections are received, 50 connections are distributed to system A and 50 connections are distributed to system B, assuming that the health and performance of each application are optimal.

#### – ILWEIGHTING 1

Specifies that WLM should weigh displaceable capacity at each successively lower importance level slightly higher than the capacity at the preceding higher importance level. The weighting grows proportionally to the square root of the importance level difference plus 1. This provides a moderate bias when comparing displaceable capacity at different importance levels. Using the previous example but with ILWEIGHTING 1 specified, system B is preferred over system A even though 500 service units of work are to be displaced on either system.

- The raw WLM weight of system A is 707:

$$\begin{aligned} & 500 \times \text{SQUAREROOT} ((\text{Importance level of displaced work} - \text{Importance level of new work}) + 1) \\ &= 500 \times \text{SQUAREROOT} ((3 - 2) + 1) \end{aligned}$$

- The raw WLM weight of system B is 1118:

$$\begin{aligned} & 500 \times \text{SQUAREROOT} ((\text{Importance level of displaced work} - \text{Importance level of new work}) + 1) \\ &= 500 \times \text{SQUAREROOT} ((6 - 2) + 1) \end{aligned}$$

In this example, as 100 connections are received, roughly 39 are distributed to system A and 61 are distributed to system B, assuming that the health and performance of each application are optimal.

**Guideline:** If you are using an ILWEIGHTING value for the first time other than the default value 0, use the value 1 initially.

#### – ILWEIGHTING 2

Specifies that WLM should weigh displaceable capacity at each successively lower importance level significantly higher than the capacity at the preceding higher importance level. The weighting grows proportionally to the importance level difference plus 1. This provides an aggressive bias when comparing displaceable capacity at different importance levels. Using the original example but with ILWEIGHTING 2 specified:

- The raw WLM weight of system A is 1000:

$$\begin{aligned} & 500 \times ((\text{Importance level of displaced work} - \text{Importance level of new work}) + 1) \\ &= 500 \times ((3 - 2) + 1) \end{aligned}$$

- The raw WLM weight of system B is 2500:

$$\begin{aligned} & 500 \times ((\text{Importance level of displaced work} - \text{Importance level of new work}) + 1) \\ &= 500 \times ((6 - 2) + 1) \end{aligned}$$

In this example, as 100 connections are received, roughly 28 are distributed to system A and 72 are distributed to system B, assuming that the health and performance of each application are optimal; more than twice as many are routed to system B than system A.

#### – ILWEIGHTING 3

Specifies that WLM should weigh displaceable capacity at each successively lower importance level significantly higher than the capacity at the preceding higher importance level. The weighting grows proportionally to the square of the importance level difference plus 1. This provides an exceptionally aggressive bias when comparing displaceable capacity at different importance levels. Using our original example but with ILWEIGHTING 3 specified:

- The raw WLM weight of system A is 2000:

$$\begin{aligned} & 500 \times \text{SQUARE} ((\text{Importance level of displaced work} - \text{Importance level of new work}) + 1) \\ & = 500 \times \text{SQUARE} ((3 - 2) + 1) \end{aligned}$$

- The raw WLM weight of system B is 12500:

$$\begin{aligned} & 500 \times \text{SQUARE} ((\text{Importance level of displaced work} - \text{Importance level of new work}) + 1) \\ & = 500 \times \text{SQUARE} ((6 - 2) + 1) \end{aligned}$$

In this example, as 100 connections are received, roughly 14 are distributed to system A and 86 are distributed to system B, assuming that the health and performance of each application are optimal; more than six times as many are routed to system B than system A.

Use the Netstat VDPT/-O report option with the DETAIL modifier to determine the WLM server-specific weight recommendations for each processor type, along with the modified weight for each processor based on the current usage of each processor type.

Evaluate whether WLM server-specific weight distribution can be used as an alternative to WLM system weight distribution for an application. In addition to the reasons mentioned previously, WLM server-specific weight distribution has the added advantage that processor proportions are automatically determined and dynamically updated by WLM based on the actual CPU usage by the application. If you need to determine the processor proportions necessary for WLM system weight distribution, study the workload usage of assist processors by analyzing SMF records, use performance monitor reports such as RMF, and so on.

While WLM server-specific recommendations can be very effective in helping load balancers optimize their routing decisions, there are some scenarios in which applications that are load balancing targets might experience issues that WLM is not aware of through its normal monitoring functions. For example, consider a scenario in which a specific server application instance is executing on a system with excess CPU capacity, yet it cannot successfully process any transactions routed to it because the back-end database it requires on that system is not currently available. From a WLM perspective, this server application instance appears to be a very good candidate to receive requests, given the current available capacity of the system, and the fact that transactions routed to this server appear to be completing very quickly and consuming very little CPU capacity. WLM would therefore assign a higher server-specific weight to this server instance, causing more work to be routed to the ailing server. This type of problem is sometimes referred to as a storm drain problem.

To help alleviate this problem, WLM also considers the health of the server application in its server-specific recommendations. The health of the server is directly determined by information that the server application provides to WLM through programming interfaces. In this way, the WLM perceived health of the application depends directly on the amount of information that an application provides to WLM, if any. WLM uses this information to potentially reduce the weight recommendations for specific server applications that are experiencing problems. This enables sysplex distributor to direct fewer new TCP connections to these servers, selecting instead servers that are not experiencing these problems. WLM considers the following components when determining a server application's health:

- Rate of abnormal transaction completions reported by the server application

This is applicable to applications, such as the CICS Transaction Server for z/OS, that act as Subsystem Work Managers, reporting transaction status using Workload Management Services, such as IWMRPT. For example, if an application reports to WLM that 90% of all transactions it processed completed abnormally, this server is probably not a good candidate for receiving many new TCP connection requests, as these requests will likely also complete abnormally. As a result, WLM significantly reduces the weight recommendation that is returned to sysplex distributor for this server.

- General health of the application as reported by the server application

This health indicator is available only for applications that provide this information to WLM using the IWM4HLTH or IWMSRSRG services. The health indicator provides a general health indication for an application or subsystem. Under normal circumstances, the value of this field is 100, meaning the server is 100% healthy. Any value less than 100 indicates that the server is experiencing problem conditions that are not allowing it to process new work requests successfully. A value of less than 100 also causes the WLM to reduce the recommendation provided to sysplex distributor for this server instance.

## Choosing between the BASEWLM and SERVERWLM distribution methods

For most applications, the WLM server-specific recommendations provide a more accurate way to distribute workload to the servers. However, when a server acts as an access point to applications that run in other address spaces (and therefore in a different service class), WLM system weights might be the preferred distribution method. For example:

- The TN3270E Telnet server (Telnet) is a communication gateway function that enables clients to access SNA applications over an IP network. As a result, most of the actual work associated with a Telnet workload takes place in the SNA application, which is typically classified to a different WLM service class than Telnet and probably at a lower importance level. Therefore, although the WLM server-specific recommendation can provide an accurate assessment of how well an individual TN3270E Telnet server is performing, it does not necessarily provide an accurate assessment of the available capacity required by the back-end SNA applications that the client is accessing. As a result, WLM system weight is probably a more appropriate distribution method for this server.
- The INET daemon also provides access to other applications that are probably associated with service classes of a lower importance level (for example, z/OS UNIX Telnet, REXECD, and RSHD). As a result, similar considerations apply, and WLM system weights are the more appropriate distribution method for this server.
- The FTP daemon address space typically performs very little processing on behalf of new FTP sessions. After accepting a new connection, it performs a fork() for an FTP server process that will service the new FTP session. The FTP server process is classified again by WLM, possibly resulting in a different service class than that of the FTP daemon.
  - If the FTP servers run in a different service class than the FTP daemon, then WLM system weights should be used.
  - If WLM policies are set up so that the FTP servers are classified in the same service class as the FTP daemon, WLM server-specific weights should be the distribution method. Although the WLM recommendation will not take into account how well the actual FTP server is meeting its goal, the recommendation will more accurately reflect the amount of displaceable capacity because it is based on the importance of the service class.

## BASEWLM and SERVERWLM display example

In the following Netstat VDPT/-O example, the weights represent normalized weights. That is, the original raw weights received from WLM are proportionally reduced for use by the distribution algorithm. Connections are distributed to these servers in a weighted, round-robin fashion using the normalized weights. In this example, the target server responsiveness (TSR) values are all 100, indicating that all servers are fully responsive to new connection requests. A value of 100 is also displayed for stacks that are at a level prior to z/OS V1R7. In that case, no target server responsiveness calculations are applied to the WLM values.

The SERVERWLM parameter was not coded for DVIPA 201.2.10.11, port 245, so it is using WLM system weights.

```

MVS TCP/IP NETSTAT CS VxRx TCPIP NAME: TCPCS 12:19:18
Dynamic VIPA Distribution Port Table:
Dest IPAddr DPort DestXCF Addr Rdy TotalConn WLM TSR Flg

201.2.10.11 00245 201.1.10.10 001 0000000000 12 100 DB
201.2.10.11 00245 201.1.10.15 001 0000000000 04 100 B
201.2.10.12 04011 201.1.10.10 001 0000000000 04 100 S
201.2.10.12 04011 201.1.10.15 001 0000000000 08 100 S
201.2.10.12 04011 201.1.10.40 001 0000000000 16 100 S

```

If the BASEWLM parameter or the SERVERWLM parameter is specified and WLM weights are not available, incoming connections are distributed among all available servers using round-robin distribution.

Now consider the same example, as shown in the following Netstat VDPT/-O display, but with TSR values indicating that some of the servers are not accepting new connection setup requests productively. The displayed WLM weights have been modified by the TSR values:

```

MVS TCP/IP NETSTAT CS VxRx TCPIP NAME: TCPCS 12:19:18
Dynamic VIPA Distribution Port Table:
Dest IPAddr DPort DestXCF Addr Rdy TotalConn WLM TSR Flg

201.2.10.11 00245 201.1.10.10 001 0000000000 09 075 DB
201.2.10.11 00245 201.1.10.15 001 0000000000 04 100 B
201.2.10.12 04011 201.1.10.10 001 0000000000 03 090 S
201.2.10.12 04011 201.1.10.15 001 0000000000 06 075 S
201.2.10.12 04011 201.1.10.40 001 0000000000 03 020 S

```

The SERVERWLM parameter was coded for DVIPA 201.2.10.12, port 4011. For the server on destination 201.1.10.10, a TSR value of 90 indicates that the server is 90% responsive in accepting new connection requests. For the server on 201.1.10.15, a TSR value of 75 indicates that this server is 75% responsive in handling new connection requests. Likewise, for the server on 201.1.10.40, a TSR value of 20 indicates that it is only 20% effective in accepting new connection requests. These factors are used to modify the WLM server-specific weights, and the modified weights are normalized. As a result, the server on destination XCF 201.1.10.10 has a normalized WLM value of 3, the server on XCF 201.1.10.40 has a WLM value of 3, and the server on destination XCF 201.1.10.15 has a WLM value of 6. So, the server on destination XCF 201.1.10.15 is now favored over the other servers, and the server at 201.1.10.40 is now equal to the server at 201.1.10.10. Connections are distributed to these servers in a weighted, round-robin fashion using these normalized weights.

The SERVERWLM parameter was not coded for DVIPA 201.2.10.11 port 245, so it is using WLM system weights. The server at 201.1.10.10 has a TSR of 75, so the normalized weight is 9, three-quarters of what it was in the previous example. The server at 201.1.10.15 has a TSR of 100, so the normalized weight is the same as it was in the previous example.

## WEIGHTEDACTIVE - Distribution based on active connection load

In some instances, rather than using WLM recommendations, weighted active connections (WEIGHTEDActive) can provide a more appropriate solution to control workload distribution:

- Application scaling concerns

Target systems vary significantly in terms of capacity (small systems and larger systems). WLM recommendations might favor the larger systems significantly. However, a target application might not scale well to larger systems; because of its design, it might not be able to take full advantage of the additional CPU capacity on the larger systems. This can result in these types of servers getting inflated WLM recommendations when running on larger systems and getting overloaded with work.

- Unequal number of SHAREPORT servers

SHAREPORT is being used, but not all systems have the same number of SHAREPORT server instances (for example, one system has two instances and the other has three). The current round-robin or WLM recommendations do not change distribution based on the number of server instances on each target. Round-robin distribution distributes one connection per target stack regardless of the number

of SHAREPORT server instances on that stack. WLM server-specific weights from a target stack with multiple server instances reflect the average weight.

- You need to control the amount of capacity that specific workloads can consume on each system.

For example, you might need to reserve some capacity on certain systems for batch workloads that are added into selected systems during specific time periods and have specific time window completion requirements. If those systems are also a target for long-running distributed DVIPA connections, WLM recommendations allow that available capacity to be consumed. This can potentially impact the completion times of the batch jobs when they begin to run, if they are not able to displace the existing non-batch workloads. Similarly, the existing connections on that system can experience performance problems if the batch jobs displace those workloads.

Weighted active connections provide granular control over workload distribution based on predetermined active connection count proportions for each target (fixed weights). Distribution of incoming TCP connection requests is balanced across the targets so that the number of active connections on each target is proportionally equivalent to a configured active connection weight for each target (specified on the DESTIP parameter for each target). Control is gained at the expense of losing the dynamic benefits of WLM recommendations; however, server-specific abnormal completion information, the general health indicator, and the TSR value are used to reduce the active connection weight when these indicators are not optimal. If weighted active connections are used, study and determine the comparative workload that you want on each system so that you can configure appropriate connection weights.

To enable the distributing stack to use server-specific abnormal completion and health information to affect the active connection weight, specify SYSPLEXROUTING on the IPCONFIG statement for all participating stacks.

You can select this type of distribution for DVIPA and port targets by specifying the WEIGHTEDActive option on the DISTM parameter of the VIPADISTRIBUTE statement, and specifying the proportion of active connections that you want on each target using the WEIGHT option on the DESTIP *dynxcfp* parameter of the VIPADISTRIBUTE statement.

## Choosing between RoundRobin and WeightedActive distribution

If weighted active connections are configured with default proportions for each target, connections are evenly distributed across all target servers; the goal is to have an equal number of active connections on each server. This is similar to the round-robin distribution method; the difference is that round-robin distribution distributes connections evenly to all target servers without consideration for the active number of connections on each server.

In certain scenarios, a round-robin distribution might be appropriate for specific server applications. Select this type of distribution for particular targets by specifying the DISTM ROUNDROBIN parameter on the VIPADISTRIBUTE statement.

Although both round-robin and weighted active connection distribution do not consider WLM recommendations in their target selection, weighted active connection distribution does use the server-specific abnormal completion information, the general health indicator, and the TSR value to reduce the weight when these values are less than optimal. For round-robin distribution, connections are not distributed to a target if its TSR value is 0. Periodically, the distributor sends a new connection request to a target with a TSR of 0 to check whether the responsiveness of that target has improved.

## Hot standby distribution

You can use the hot standby distribution method to configure sysplex distributor to have one preferred target server and one or more backup (hot standby) target servers. In this configuration, sysplex distributor does not perform load balancing of new connection requests across multiple targets; rather, a preferred target server with an active listener receives all new incoming connection requests. The hot standby target servers, which typically also have a ready listener application, do not receive any new connections requests; they act as backup target servers in case the designated preferred target server become unavailable. A target is considered unavailable if any of the following conditions are true:

- The target is not ready.

- The distributor does not have an active route to the target.
- The target is not healthy.

The hot standby distribution method is useful in situations where there is a trade-off between availability and performance, such as a scenario where data sharing between multiple server applications and LPARs is required for availability, but it is more efficient if the work runs on one LPAR instead of interlocking access to the same data across multiple LPARs. For example, if you prefer that an application instance on one LPAR, if available, always handle the workload, and an application instance on another LPAR that is otherwise performing lower priority work be available for backup, use the hot standby distribution method.

## Steps for configuring hot standby distribution

You can use hot standby distribution to have one preferred target server and one or more backup (hot standby) target servers. The preferred target server receives all new incoming connection requests and the hot standby servers act as backups in case the preferred target server becomes unavailable.

### Before you begin

You need to determine which server should initially receive the workload (the preferred server), and which server or servers should be a backup server.

### Procedure

Perform the following steps to configure hot standby distribution on the VIPADISTRIBUTE statement:

1. Configure HOTSTANDBY on the DISTMETHOD parameter.
2. Configure the AUTOSWITCHBACK parameter or the NOAUTOSWITCHBACK parameter.
  - Configure AUTOSWITCHBACK if you want the distributor to automatically switch distribution back to the preferred target when it is available. For example, if the preferred target becomes a standby target because its server is no longer ready, when the server is again in the listening state, the distributor automatically switches back to the preferred target as the active target. This is the default value.
  - Configure NOAUTOSWITCHBACK if you want the distributor to continue to use a backup target when the preferred target is available.

**Rule:** If NOAUTOSWITCHBACK is configured, then the active server is initially determined by order of activation; the first ready listener becomes the active server regardless of the configured server type (PREFERRED or BACKUP), and remains the active server unless it becomes unavailable.
3. Configure the HEALTHSWITCH parameter or the NOHEALTHSWITCH parameter.
  - Configure HEALTHSWITCH if you want the distributor to automatically switch from the active target when it is not healthy. This is the default. A target is not healthy when there is a severe problem detected by one of the following health metrics:
    - Target server responsiveness (TSR) value is 0%
    - Rate of abnormal transaction completions is 1000
    - General health of the application is 0%

For more information, see [“Target server connection setup responsiveness monitoring” on page 496](#), and the WLM health metric information in [“SERVERWLM - Distribution using WLM server-specific weights” on page 504](#).

**Rule:** When a switch occurs because a target is no longer healthy, the target is not used as a backup target even if its health recovers, unless all available backup targets have previously had health problems. Health metric indicators typically recover when a server is no longer receiving any work, and although a server can appear healthy, the distributor cannot determine if the server is actually healthy. When the distributor detects that the server is transitioning back to the ready state, it again uses the target as a backup.

**Tip:** You can use the VARY TCPIP,,SYSPLEX,QUIESCE command and the VARY TCPIP,,SYSPLEX,RESUME command to manually bring a server back to the ready state. You can also use these commands before and after planned maintenance, or to temporarily divert new workload requests from a particular target. For more information, see [“Manually quiescing DVIPA sysplex distributor server applications”](#) on page 413.

- Configure NOHEALTHSWITCH if you want the distributor to ignore health metrics. The distributor switches from the active target only when it is not ready or when the distributor does not have an active route to the target.
4. Configure the PREFERRED option or the BACKUP option after each XCF address on the DESTIP parameter to designate the preferred server and the backup servers, and configure a rank value for each backup server.
- Configure PREFERRED to designate the preferred server. This must be configured for one, and only one, XCF address.
  - Configure BACKUP to designate a backup (hot standby ) server. This must be configured for at least one XCF address. Also configure a rank value on the BACKUP option for each backup server. The distributor switches to the highest ranked backup if the preferred server becomes unavailable.

## Hot standby configuration example

The following example shows configuration for the hot standby distribution method:

```
VIPADISTRIBUTE DISTMETHOD HOTSTANDBY AUTOSWITCHBACK HEALTHSWITCH
9.67.240.02 PORT 10000
DESTIP
 203.3.10.16 PREFERRED
 203.3.10.17 BACKUP 50
 203.3.10.18 BACKUP 100
```

Because server 203.3.10.16 is the preferred server and AUTOSWITCHBACK is configured, that server becomes the active target when it enters the listening state. Servers 203.3.10.17 and 203.3.10.18 are the backup servers. The highest ranked backup server (203.3.10.18) becomes the active server if server 203.3.10.16 becomes unavailable.

Use the Netstat VIPADCFG/-F command to display the configuration:

```
Dynamic VIPA Information:
:
VIPA Distribute:
Dest: 9.67.240.02..10000
DestXCF: 203.3.10.16
DistMethod: HotStandby SrvType: Preferred
AutoSwitchBack: Yes HealthSwitch: Yes
SysPt: No TimAff: No Flg:
OptLoc: No
Dest: 9.67.240.02..10000
DestXCF: 203.3.10.17
DistMethod: HotStandby SrvType: Backup Rank: 050
AutoSwitchBack: Yes HealthSwitch: Yes
SysPt: No TimAff: No Flg:
OptLoc: No
Dest: 9.67.240.02..10000
DestXCF: 203.3.10.18
DistMethod: HotStandby SrvType: Backup Rank: 100
AutoSwitchBack: Yes HealthSwitch: Yes
SysPt: No TimAff: No Flg:
OptLoc: No
```

Use the Netstat VDPT/-O command to display the status of the servers:

```
Dest: 201.2.10.15..5000
DestXCF: 203.3.10.16
TotalConn: 0000000000 Rdy: 001 WLM: 10 TSR: 100
DistMethod: HotStandby SrvType: Preferred
Flg: Active
Dest: 201.2.10.15..5000
DestXCF: 203.3.10.17
TotalConn: 0000000000 Rdy: 001 WLM: 10 TSR: 100
```

```

DistMethod: HotStandby SrvType: Backup
Flg: Backup
Dest: 201.2.10.15..5000
DestXCF: 203.3.10.18
TotalConn: 0000000000 Rdy: 001 WLM: 10 TSR: 100
DistMethod: HotStandby SrvType: Backup
Flg: Backup

```

The Active and Backup flags show the current status of each server. For example, the preferred server (203.3.10.16) is displayed with the Active flag, indicating that it is the active server. Each server uses a default WLM weight of 10 for displays and health calculations.

If the active server becomes unavailable for some reason, the Netstat VDPT/-O command displays something similar to the following status:

```

Dest: 201.2.10.15..5000
DestXCF: 203.3.10.16
TotalConn: 0000000000 Rdy: 001 WLM: 00 TSR: 000
DistMethod: HotStandby SrvType: Preferred
Flg: Backup
Dest: 201.2.10.15..5000
DestXCF: 203.3.10.17
TotalConn: 0000000000 Rdy: 001 WLM: 10 TSR: 100
DistMethod: HotStandby SrvType: Backup
Flg: Backup
Dest: 201.2.10.15..5000
DestXCF: 203.3.10.18
TotalConn: 0000000000 Rdy: 001 WLM: 10 TSR: 100
DistMethod: HotStandby SrvType: Backup
Flg: Active

```

The target server responsiveness (TSR) value for server 203.3.10.16 dropped to zero (TSR: 000), and the distributor switched to use the highest ranked backup, 203.3.10.18 (configured with a Backup rank of 100). The backup target becomes the active target (Flg: Active), and the preferred target becomes a backup target (Flg: Backup). However, because the switch from the preferred target occurred because the TSR value is 0, even when the TSR begins to recover, automatic switchback to this target does not occur. If server 203.3.10.16 is quiesced and resumed, the distributor can switch distribution back to this preferred server.

## Timed affinity

The distribution method does not have any effect on incoming connection requests that have an active affinity established to a specific server instance (through the TIMEDAFFINITY parameter). When an affinity exists, it has priority over the distribution method setting.

## SHAREPORT

Specifying the SHAREPORT parameter on the PORT statement in the TCP/IP profile enables a group of servers to listen on the same port, and thereby share the incoming workload. As new connections are received, the number of active connections is evenly balanced across the available servers using a weighted, round-robin distribution based on the Servers' accept Efficiency Fractions (SEFs). Specifying the SHAREPORTWLM parameter on the PORT statement enables connections to be distributed in a weighted, round-robin fashion based on the WLM server-specific recommendations modified by the SEFs. For more information on SEFs, see [“Target server connection setup responsiveness monitoring” on page 496](#).

Use the same considerations concerning application type to determine the type of port sharing distribution to use. If the shared port is a sysplex distributed port and WLM server-specific weight is the distribution method that is being used by the distributor, code the SHAREPORTWLM parameter on each target's PORT statement to take advantage of the WLM server-specific recommendations when connections are received at the target. Otherwise, use the SHAREPORT parameter on the PORT statement.

## QDIO Accelerator

You can use QDIO Accelerator to provide accelerated forwarding at the DLC layer for some sysplex distributor packets. QDIO Accelerator is supported over both OSA-Express (QDIO) and Network Express (EQDIO) interfaces. For more information, see [“QDIO Accelerator” on page 122](#).

## Inbound workload queuing

You can use QDIO inbound workload queuing to improve throughput for inbound sysplex distributor packets. Inbound Workload Queuing is supported by both OSA-Express (QDIO) and Network Express (EQDIO) devices. For more information, see [“Inbound workload queuing” on page 75](#).

## Optimizing local connections

You can configure sysplex distributor to optimize connections when both connection endpoints potentially are on the same TCP/IP stack within the sysplex. This feature can be useful if your environment includes multi-tier server applications within a single sysplex. In this environment, if communication between the tiers is based on the TCP protocol, sysplex distributor can provide higher server availability. For example, without sysplex distributor or some other form of IP load balancing, when an application in tier 1 tries to connect to a tier 2 application on the local system, if the tier 2 server application is not available, these connections fail and the workload is disrupted. Sysplex distributor dynamically reroutes these connections to another tier 2 application that is running elsewhere in the sysplex, which provides a high availability solution. You can use the OPTLOCAL keyword to further optimize load balancing for this type of configuration; for more information about the OPTLOCAL keyword, see [“Sysplex distribution optimizations for multi-tier z/OS workloads” on page 515](#).

**Tip:** In networks that have CISCO routers, it might be possible to remove the requirement that all inbound traffic needs to traverse the distributing stack.

Sysplex distributor also enhances the dynamic VIPA and automatic VIPA takeover functions. The enhancements allow a DVIPA to move nondisruptively to another stack. That is, in the past, a DVIPA was allowed to be active only on one single stack in the sysplex. This led to potential disruptions in service when connections existed on one stack, yet the intent was to move the DVIPA to another stack. With sysplex distributor, the movement of DVIPAs can now occur without disrupting existing connections on the original DVIPA owning stack.

See [“Configuring distributed DVIPAs - sysplex distributor” on page 410](#) for more information.

## Policy interactions

The Policy Agent interacts with the sysplex distributor to assist with workload balancing. There will be one Policy Agent running on an LPAR regardless of how many stacks are configured. First, the Policy Agent can be configured to collect network performance statistics for applications being distributed on target stacks. These network performance statistics are then used to modify the overall WLM weight assigned to a target server. In this way, processor performance, server performance, and application network performance are taken into account when distributing work. Second, policies established on the distributing stack can be configured to restrict the set of target stacks to be considered for any given inbound connection request. In this way, the total set of target stacks can be partitioned among different groups of users or applications requesting connections to distributed applications.

Previously, the QoS performance data was collected by the Policy Agent on the target for each DVIPA and port or application. After collecting the QoS information, the Policy Agent on the target stack pushed this information down to the stack sysplex function which then forwarded it to the stack sysplex function on the distributing stack. There are two significant additions to Policy Agent and sysplex interaction:

- The Policy Agent at each target will collect information with an additional level of granularity; the QoS performance data will be collected for each service level that a target's DVIPA port or application supports.
- The Policy Agent on the distributing stack drives the collection of this information by pulling it from the Policy Agents on the target stacks:

- The Policy Agent on the distributor opens up one or two TCP connections to each of the Policy Agents on the target stacks. The distributor can be configured to distribute connections to IPv4 DVIPAs, IPv6 DVIPAs, or both. The Policy Agent opens an IPv4 connection to a target stack's IPv4 XCF address if it is configured to distribute to an IPv4 DVIPA on that target, and likewise opens an IPv6 connection to a target stack's IPv6 XCF address if it is configured to distribute to an IPv6 DVIPA on that target. As a result, if the routing stack is distributing connections to both IPv4 and IPv6 DVIPAs on a given target, then two connections to that target are opened.

For more information on how the sysplex distributor determines its targets, see [“Configuring distributed DVIPAs - sysplex distributor”](#) on page 410.

- The Policy Agent on the distributing stack will send across a list of QoS service level names to the Policy Agent on each target.
- The Policy Agent on each target will send back a QoS Policy Action weight fraction for each requested service level that each target DVIPA port/application supports. A specific Policy Action weight fraction will not be sent unless the distributing stack's Policy Agent requests it. Only weight fractions for IPv4 DVIPA ports and applications flow on the IPv4 Policy Agent connection, and similarly, only IPv6 weight fractions flow on the IPv6 Policy Agent connection.
- Upon receiving the QoS Policy Action weight fraction, the Policy Agent on the distributing stack will pass this information down to the sysplex distribution function on the stack. If two connections to a given target Policy Agent are active, weight fractions for IPv4 DVIPA ports or applications and IPv6 DVIPA ports or applications are passed to the sysplex distribution function separately. The stack sysplex distribution function uses this additional information when it is selecting targets for incoming connections. If it does not have a QoS Policy Action weight fraction, then it uses the existing weight fraction to make the load distribution decision instead.

## Steps for enabling Policy Agent load distribution functions

The Policy Agent interacts with the sysplex distributor to assist with workload balancing.

### Procedure

Perform the following steps to enable Policy Agent load distribution functions:

1. Define the PolicyPerfMonitorForSDR statement in the PAGENT configuration file to enable the policy performance monitor function.  
This function must be active on the target and distributing stacks.
2. z/OS Communications Server load distribution needs to be specifically enabled for each service level; a Policy Action with the same service level name needs to be defined on each of the appropriate target stacks and also on the distributing stack for these targets.

Note that it is reasonable to have a subset of key service level names defined to the distributing stack. Traffic mapping to those service level names that are defined to the distributing stack will receive z/OS Communications Serverload distribution by service level. All other traffic will receive Communications Server V2R10 load distribution.

3. A backup distributing stack must have the same Policy Action configuration definitions as the active distributing stack for the corresponding DVIPA targets that it is backing up, if you want the Policy Action behavior to stay the same when the backup distributing stack takes ownership of the DVIPA. It also must have the Policy Agent performance monitor function active.
4. Common PAGENT port numbers will be used by the listener (pagentQosListener) and the collector (pagentQosCollector)

They are part of the /etc/services install file. If PAGENT is running on an LPAR containing a target stack, it will open a listening connection using the pagentQosListener port number. PAGENT running on an LPAR containing a distributing stack will establish a TCP connection with each PAGENT listener using the pagentQosCollector as the source port and the pagentQosListener as the destination port. The listener will fail a connect request if the source/destination port does not match the defined collector/listener port. The /etc/services file on all LPARs in the sysplex must be updated to contain these port numbers.

5. Define these two port numbers as reserved ports for PAGENT using the PORT statement in the PROFILE.TCPIP data set.
6. Define the DYNAMICXCF parameter on the IPCONFIG or IPCONFIG6 statements in PROFILE.TCPIP. The PAGENT TCP connections use the XCF IP addresses.

## Results

For more information on setting up policies, see [“Sysplex distributor policy performance monitoring configuration”](#) on page 860, [“Sysplex distributor policy example”](#) on page 866, or [“Sysplex distributor routing policy example”](#) on page 1425.

## Sysplex distribution optimizations for multi-tier z/OS workloads

---

You can configure sysplex distributor to optimize connections when both connection endpoints potentially are on the same TCP/IP stack within the sysplex. This feature can be very useful in environments in which multi-tier server applications are located within the same z/OS system images in a single sysplex. In this environment, if communication between the tiers is based on the TCP protocol, you can use sysplex distributor to provide higher availability.

For example, without sysplex distributor or some other form of IP load balancing, if an application in tier 1 tries to connect to a tier 2 application on the local system, but the tier 2 server application is not available, then these connections fail and the workload is disrupted. With sysplex distributor, these connections are dynamically rerouted to another tier 2 application that is running elsewhere in the sysplex, which provides a high availability solution.

Examples of tier 1 server applications on z/OS that can be used with tier 2 server applications on the same z/OS logical partition (LPAR) are the IBM HTTP Server, the CICS Transaction Gateway, and the WebSphere Application Server. Examples of applications that can be used as tier 2 servers in the same z/OS system and sysplex as tier 1 servers are the CICS Transaction Server, IMS Connect, and Db2.

## Sysplex distributor optimization with the OPTLOCAL keyword

[Figure 59 on page 516](#) shows a sample configuration that uses the OPTLOCAL keyword.

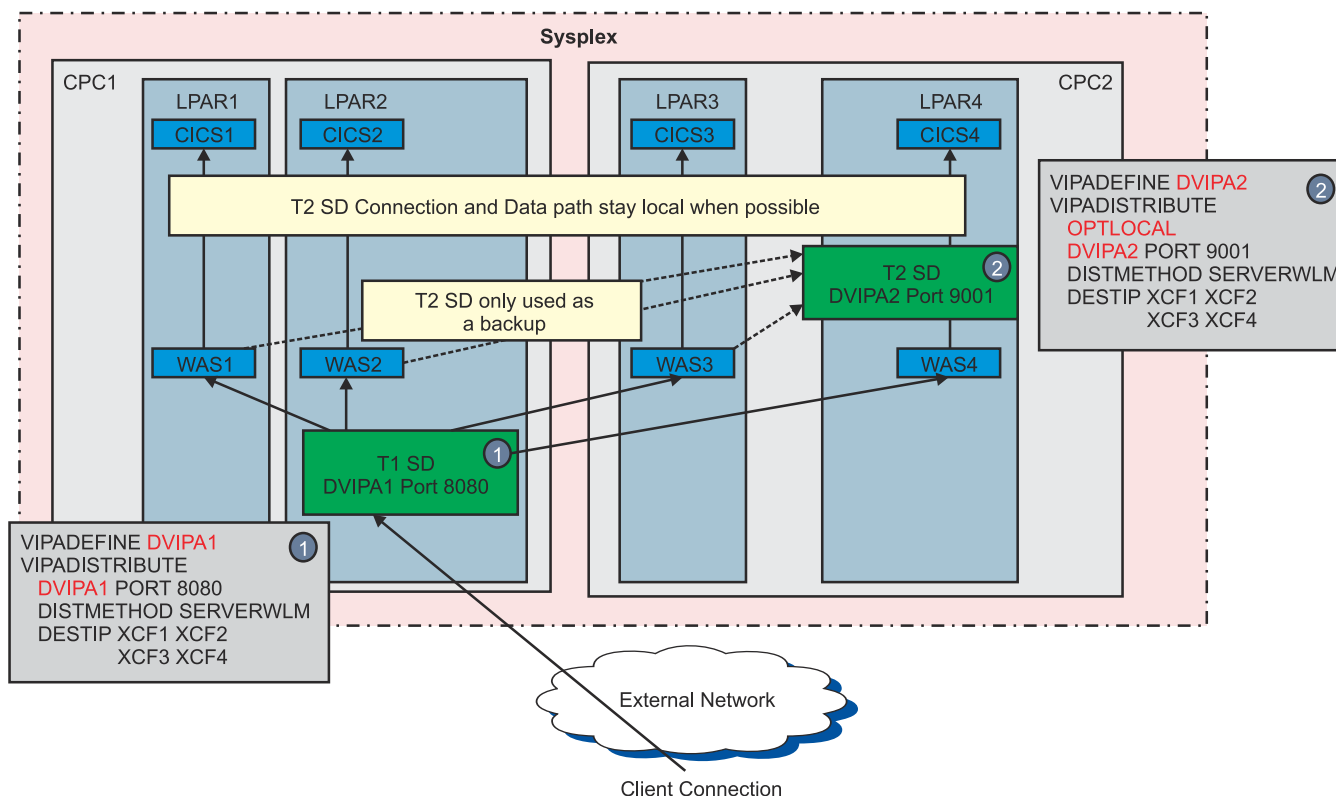

Figure 59. z/OS multi-tier application load balancing using sysplex distributor and the OPTLOCAL keyword

In Figure 59 on page 516, two tiers of servers are configured across four LPARs that are on two central processor complexes (CPCs) in a sysplex environment. The tier 1 servers consist of z/OS WebSphere Application Server (WAS) instances that are listening on port 8080 and that are represented by distributed DVIPA1. Sysplex distributor is configured on LPAR2 to receive and distribute any incoming connections for DVIPA1 to any of the active WAS instances in the four LPARs, based on server-specific WLM recommendations for each WAS instance (designated by the dynamic XCF address of each target LPAR). After a request is directed to a tier 1 WAS instance, the request is processed by that server. One or more secondary TCP connections can be established to a back-end tier 2 server, which is a cluster of CICS regions (one CICS region per LPAR).

You can use other sysplex distributor functions to distribute the tier 2 connections in this scenario, but that configuration does add some additional pathlength and processing, because all connection requests and traffic for those connections are forwarded through the sysplex distributor routing stack on LPAR4 so that they can get forwarded to the selected tier 2 server instance. This additional pathlength and processing occurs even in the case where the selected tier 2 server for a given connection is on the same LPAR as the tier 1 server that originated the connection.

To reduce excess pathlength but still retain high availability, you can specify the OPTLOCAL keyword for DVIPA2 to optimize processing in several ways:

- As long as local target resources are available and are not constrained, extra network flows and overhead through the distributor are avoided, because the local system makes the decision to route the connection to the local instance.
- When the decision is made to make the connection local, TCP/IP enables this connection for fast local sockets processing. This provides a more efficient path through the TCP/IP stack for these communications. All traffic for this connection remains on the local system and is not routed to the distributing stack.
- Optionally, multi-tier applications can also provide their own optimizations by using the Sysplex Sockets API (SO\_CLUSTERCONNTYPE) or the trusted TCP connections API (SIOCGPARTNERINFO ioctl). These APIs enable the multi-tier applications to dynamically determine that they both are on the same system, and as a result, to optimize their processing based on their locality (for example, avoiding

encryption of data, sharing memory, and so on). For more information about [trusted TCP connections](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

- If local target resources are unavailable or constrained, normal sysplex distributor processing is performed on the connections as a fallback, enabling the sysplex distributor to select another application that is available.

The OPTLOCAL feature provides for optimal performance in the most common scenario in which the local applications and systems are available and healthy, yet the feature also provides a high availability solution when the local applications or systems are not available or are overly constrained.

You can implement the OPTLOCAL feature using the OPTLOCAL keyword on the VIPADISTRIBUTE statement in the VIPADYNAMIC block, which enables a target stack to keep outbound connections for local resources on the local stack without having to send the connection request to the distributing stack. The level of preference that is shown to the local stack can be adjusted using the integer value specified on the OPTLOCAL keyword.

#### **Value**

##### **Meaning**

#### **0**

Specifying 0 means that the connections should remain local as long as the server is healthy. The relative capacity of the other systems is not considered in this case.

#### **1**

Specifying 1 is the same as specifying 0, except that if the WLM weight for the server on the local stack is 0, the connection request is forwarded to the sysplex distributor to find the best available server.

#### **2 - 16**

The values 2 through 16 are used as multipliers against the WLM weight for the server on the local stack, causing its weight to increase and therefore be favored over servers on other stacks. The larger the value specified, the more the local stack is favored.

If the OPTLOCAL keyword is specified with the value 0 or 1, the distribution method is not used for connections that originate from the specified target stack, if that target application is on the same stack and is able to handle its current workload. Regardless of the value that is specified on the OPTLOCAL keyword, connections are sent to the distributing stack if any of the following conditions are true:

- No local server is available.
- The server's accept efficiency fraction (SEF) has fallen below 75.
- The abnormal transaction completions value is greater than 250.
- The health indicator is less than 75.

For more information about the OPTLOCAL keyword on the VIPADISTRIBUTE statement in the VIPADYNAMIC statement summary block, see [z/OS Communications Server: IP Configuration Reference](#).

## **Sysplex distributor enhanced workload distribution for z/OS multi-tier, OPTLOCAL configurations**

In environments in which OPTLOCAL is used to optimize the load balancing between tier 1 and tier 2 server applications, more optimization is possible if sysplex distributor is also used as the load balancer for the tier 1 server applications. This optimization makes both tiers of z/OS server applications on a given system visible to sysplex distributor when making a load balancing decision on an incoming tier 1 connection request. When you are using WLM-based recommendations such as SERVERWLM, this optimization enables sysplex distributor to compute a composite WLM weight for each system, which includes the capacity, performance, and health characteristics of both the tier 1 server applications and the tier 2 server applications. [Figure 60 on page 518](#) shows an example configuration that enables this enhancement.

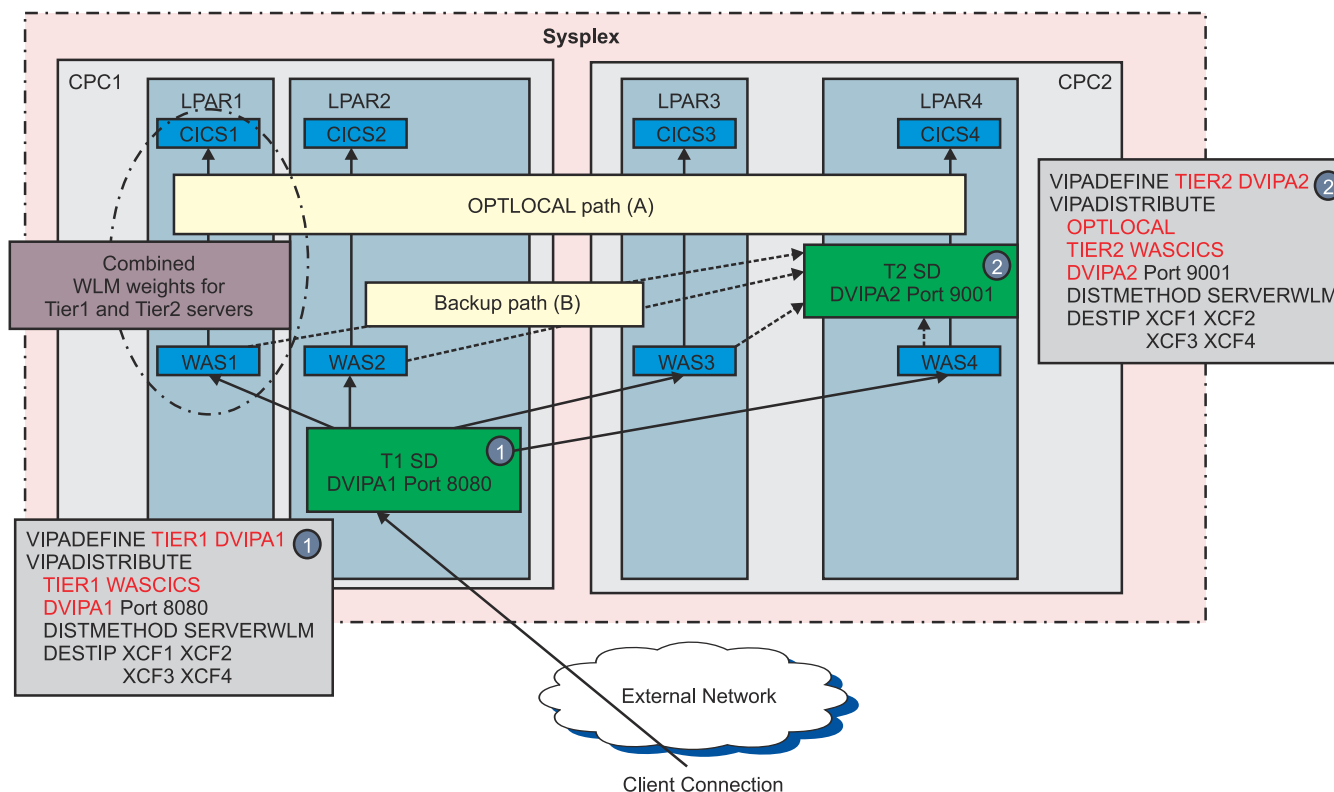

Figure 60. Enhanced z/OS multi-tier application load balancing using sysplex distributor

As shown in Figure 60 on page 518, two VIPADISTRIBUTE statements are required in this configuration. The first statement for DVIPA1 represents the distribution to the tier 1 server applications, a cluster of WebSphere Application Server instances running on each LPAR. The second statement for DVIPA2 represents the tier 2 server applications, a cluster of CICS regions on the same LPARs as the tier 1 servers.

The VIPADISTRIBUTE statement for each DVIPA includes a tier specification that indicates the role of each DVIPA (TIER1 or TIER2). The two DVIPAs are linked by a common group name specification, WASCICS. This association enables sysplex distributor to compute a single weight for each DVIPA1 target system that reflects the combination weight of the tier 1 and tier 2 server applications that are running on that system. Sysplex distributor performs its workload balancing of incoming connection requests to DVIPA1 based on these combined weights, enabling distribution of requests to the target z/OS systems to be based on the aggregate capacity of each system to perform the processing of both server application tiers.

In addition, because the VIPADISTRIBUTE statement for DVIPA2 also includes the OPTLOCAL specification, incoming tier 1 connection requests are typically directed to a system that also enables the subsequent tier 2 connection requests to stay local. This provides an improvement over the base OPTLOCAL configuration, because new workload is directed toward systems that have more capacity to process the work while retaining the local optimizations provided by OPTLOCAL.

**Rule:** To use this feature, the distribution method for the tier 1 and tier 2 servers must be BASEWLM or SERVERWLM.

**Guideline:** To take full advantage of this feature, set the distribution method for both tier 1 and tier 2 servers to SERVERWLM. This enables sysplex distributor to obtain server-specific WLM recommendations for each application server tier; the combined weight reflects the composite performance of the servers instead of the capacity of the system.

For more information about the TIER1 and TIER2 keywords on the VIPADISTRIBUTE statement in the VIPADYNAMIC statement summary block, see [z/OS Communications Server: IP Configuration Reference](#).

## Sysplex distributor enhanced workload distribution for z/OS multi-tier, OPTLOCAL configurations with CPC affinity

In addition to multi-tier application awareness and optimizing distribution when these applications are local, you can use the CPCSCOPE keyword to further optimize sysplex distributor load balancing decisions. This configuration option helps to avoid workload distribution to tier 1 servers that cannot perform the tier 2 processing on the same CPC, which requires distribution of those tier 2 connections to systems that are on a different CPC. Figure 61 on page 519 shows an example configuration in which this option might be useful.

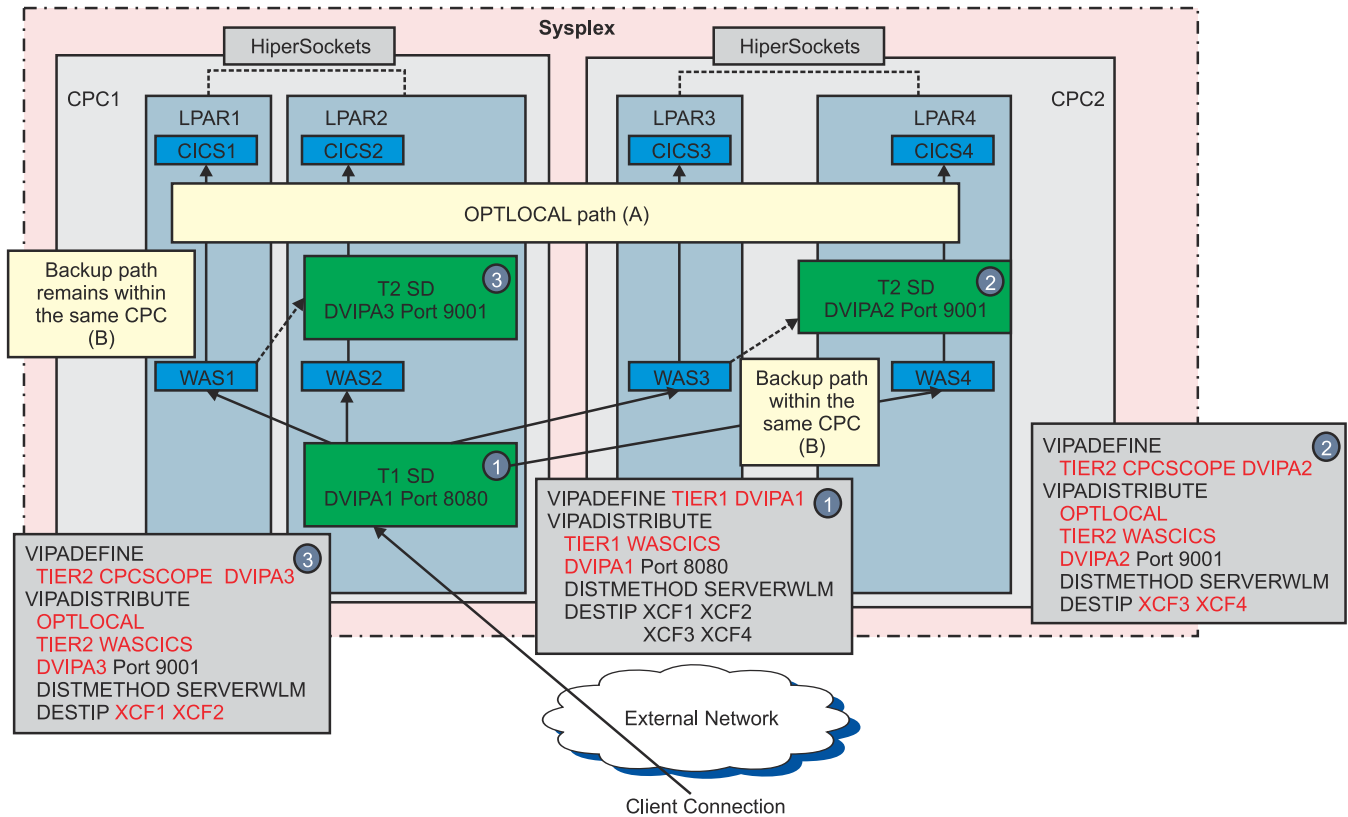

Figure 61. z/OS multi-tier application configuration using CPCSCOPE DVIPAs

In Figure 61 on page 519, connection requests for tier 1 server applications are distributed to systems based on the aggregate WLM recommendations of the tier 1 and tier 2 server applications running on each system. When connections are directed to a tier 1 server instance, any subsequent tier 2 connections that are originated by that server instance are likely to be directed to the local tier 2 server as a result of the OPTLOCAL keyword, assuming that the tier 2 server application is active on the local system.

If the tier 1 server cannot access a tier 2 server on the same system, the connection requests and their associated data flows are sent to the sysplex distributor for the tier 2 DVIPA; this distributor might be on another system in the sysplex. That system might be on the same CPC as the tier 1 server, or it might be on another CPC at the same site or potentially at a remote site. The sysplex distributor then selects a target tier 2 server instance that is on the same CPC or in another CPC. In either case, inbound traffic from the tier 1 server to the tier 2 server might need to traverse one or more CPCs or external network links before it reaches the tier 2 server.

You can optimize these flows by using the CPCSCOPE keyword and confining the activation and movement of a DVIPA to a specific CPC, which in turn enables any connection using the backup path to a tier 2 server to also remain within an LPAR on the same CPC. This optimization enables these backup data flows to leverage secure, high speed, virtual network links inside the CPC, such as HiperSockets. This configuration also helps to ensure that these data flows are optimized by avoiding the need to traverse external links, which might result in additional network latency and encryption requirements.

Three DVIPAs are defined in [Figure 61 on page 519](#):

- DVIPA1 represents the tier 1 servers that are on LPAR1 - LPAR4. DVIPA1 is defined as a tier 1 DVIPA, and is associated with the group name WASCICS.
- DVIPA2 represents the tier 2 servers that are on LPAR3 and LPAR4 on CPC2. DVIPA2 is defined as a tier 2 DVIPA, and is associated with the group name WASCICS. DVIPA2 also specifies the CPCSCOPE keyword, which ensures that DVIPA2 remains within LPARs on CPC2, even in recovery scenarios where DVIPA takeover is required.
- DVIPA3 represents the tier 2 servers that are on LPAR1 and LPAR2 on CPC1. DVIPA3 is similar to DVIPA2; it is also a tier 2 DVIPA, is associated with the same group name (WASCICS), and also specifies the CPCSCOPE keyword. If a takeover is required for this DVIPA, it remains within any backup LPARs on CPC1.

**Requirement:** Configure the tier 1 application servers on each CPC to use a unique, CPC-specific DVIPA for their tier 2 connections. The tier 1 application server configurations need to be unique based on the CPC where they are.

**Guideline:** Before activating this feature, consider the benefits that the feature provides versus the additional configuration requirements that this type of configuration requires. You must carefully define the tier 2 DVIPAs to ensure that the correct VIPADEFINE and VIPBACKUP definitions are maintained on each of the LPARs based on the CPC on which the LPARs are defined. These definitions can have implications on your recovery plans and procedures that might allow z/OS systems or tier 1 server applications to be restarted on LPARs in different CPCs, rather than in the CPC in which they were originally activated.

For more information about the CPCSCOPE keyword on the VIPADISTRIBUTE statement in the VIPADYNAMIC statement summary block, see [z/OS Communications Server: IP Configuration Reference](#).

---

## Chapter 9. TCP/IP in an ensemble

OSA-Express Ethernet features in QDIO mode can access the external data network when configured with the OSD channel path ID (CHPID) type. The OSD CHPID type is the default CHPID type on the IPAQENET and IPAQENET6 INTERFACE statements in the TCP/IP profile.

IBM zEnterprise System (zEnterprise) provides communications access to two internal networks through OSA-Express3 or later adapters that are configured with the OSA-Express for Unified Resource Manager (OSM) or OSA-Express for zBX (OSX) CHPID types. Communications Server supports OSA-Express3 or later adapters that are configured with these CHPID types, thus allowing TCP/IP connectivity to the following internal networks.

- Intraensemble data network (CHPID type OSX)

The intraensemble data network (IEDN) provides access to other images connected to the IEDN, and to applications and appliances that are running in an IBM zEnterprise BladeCenter Extension (zBX). The IEDN can be accessed through 10 gigabit OSA-Express3 or later adapters that are configured with CHPID type OSX. OSX interfaces can be IPv4 or IPv6, and must be on a VLAN. To configure OSX interfaces, see [“Steps for configuring an interface for the intraensemble data network \(CHPID type OSX\)”](#) on page 522.

OSX connectivity also enables HiperSockets connectivity to the IEDN; you configure an Internal Queued Direct I/O (IQD) CHPID for HiperSockets to enable the Internal Queued Direct I/O extensions (IQDX) function, referred to as the z/OS Communications Server IEDN-enabled HiperSockets function. For more information about the z/OS Communications Server IEDN-enabled HiperSockets function and its benefits, see [“HiperSockets connectivity to the intraensemble data network”](#) on page 522.

- Intranode management network (CHPID type OSM)

The intranode management network (INMN) is an IPv6 network that provides connectivity between network management applications within a zEnterprise node, and can be accessed through 1000BASE-T Ethernet OSA-Express3 or later adapters that are configured with CHPID type OSM. OSM interfaces are not configured in the TCP/IP profile, but are generated by the stack and have only link-local IP addresses. The stack does not report OSM interfaces to OMPROUTE, and OMPROUTE is unaware of these interfaces; there are no OMPROUTE configuration considerations for OSM interfaces. To use the INMN, see [“Steps for using the intranode management network \(CHPID type OSM\)”](#) on page 527.

**Requirement:** To access the IEDN or the INMN, the IBM zEnterprise 196 (z196) central processor complex (CPC) and the logical partition (LPAR) must be configured as members of an ensemble. For information about using the ENSEMBLE start option to specify that an LPAR is a member of an ensemble, see [z/OS Communications Server: SNA Resource Definition Reference](#).

For more information about zEnterprise and ensembles, see the following information in IBM Documentation at <https://www.ibm.com/docs/en>:

- *zEnterprise BladeCenter Extension Installation Manual*
- *zEnterprise System Introduction to Ensembles*
- *IBM z Systems Ensemble Workload Resource Group Management Guide*
- *IBM z Systems Ensemble Planning Guide*

## Steps for configuring an interface for the intraensemble data network (CHPID type OSX)

---

The intraensemble data network (IEDN) can be accessed through OSA-Express for zBX (OSX) interfaces. The IEDN provides access to other images connected to the IEDN, and to applications and appliances running in an IBM zEnterprise BladeCenter Extension (zBX).

### Before you begin

- To access the IEDN, the IBM zEnterprise 196 (z196) central processor complex (CPC) and the logical partition (LPAR) must be configured as members of an ensemble.

For information about using the [ENSEMBLE start option](#) to specify that an LPAR is a member of an ensemble (ENSEMBLE=YES), see [z/OS Communications Server: SNA Resource Definition Reference](#).

- Before the OSX device can become active, the Hardware Management Console (HMC) must be configured in the following way:
  - The VLAN ID specified at the HMC must match the ID specified on the VLANID parameter of the IPAQENET or IPAQENET6 statement.
  - The HMC must have added the LPAR and CHPID combination to the definition for that VLAN.

See the information about creating and managing virtual server networks in *IBM z Systems Ensemble Planning Guide*.

- To use a zBX with OSX, you must configure the zBX from the HMC to use addresses on the same network specified on the IPAQENET or IPAQENET6 statements.

See the information about obtaining the pairing code for accelerator authentication in the *IBM Smart Analytics Optimizer for Db2 for z/OS: Installation Guide*.

### Procedure

Perform the following steps to configure an interface for the IEDN:

1. Specify CHPIDTYPE OSX on the INTERFACE statement for the IPAQENET or IPAQENET6 interface.
2. Include the CHPID parameter to have VTAM dynamically create the associated transport resource list element (TRLE) definition, and include the VLANID parameter.

Unlike OSD interfaces, OSX interfaces must be associated with a specific VLAN, and can communicate only with other applications and images that have access to the same VLAN on the IEDN.

The following example is a sample INTERFACE definition; adjust values as needed:

```
INTERFACE QDIO0SX1 DEFINE IPAQENET
CHPIDTYPE OSX CHPID F1 VLANID 10
MTU 8992 IPADDR 172.16.1.1/24
```

3. For IPv6, if you connect an external router on this network, then you can use stateless address autoconfiguration. Otherwise, you must configure IPv6 addresses and prefixes manually.

### Results

For more information about configuring CHPID type OSX for [INTERFACE-IPAQENET OSA-Express QDIO interfaces](#) and [INTERFACE -- IPAQENET6 OSA-Express QDIO interfaces](#) statement interfaces, see [z/OS Communications Server: IP Configuration Reference](#). Some INTERFACE statement defaults are different for OSX interfaces than for OSD interfaces, and some INTERFACE statement parameters that apply to OSD interfaces do not apply to OSX interfaces.

## HiperSockets connectivity to the intraensemble data network

---

IBM zEnterprise System (zEnterprise) provides the capability to integrate HiperSockets connectivity to the intraensemble data network (IEDN); HiperSockets connectivity to the IEDN is referred to as the z/OS

Communications Server IEDN-enabled HiperSockets function. Within each central processor complex (CPC) that is a member of an ensemble, you can define a single Internal Queued Direct I/O (IQD) channel path ID (CHPID) for HiperSockets to provide connectivity to the IEDN; you configure the designated IQD CHPID using a channel parameter in the hardware configuration definition (HCD), which enables the Internal Queued Direct I/O extensions (IQDX) function of HiperSockets. The IQDX function is a channel function and is not a new CHPID type. When the IQDX function is configured, the single IQD CHPID is integrated with the IEDN; for communications within the CPC, the IQDX function enables secure network access using the designated IQD CHPID.

The z/OS Communications Server IEDN-enabled HiperSockets function provides the following benefits:

- Combines the existing high-performance attributes of HiperSockets for intra-CPC communications with the secure access control, virtualization, and management functions of the IEDN that are provided by zEnterprise Unified Resource Manager (zManager)
- Converges OSA connectivity and HiperSockets connectivity into a single logical network interface

The single interface simplifies network management by reducing the number of resources that are required to represent individual unique networks, including the following resources:

- IQD CHPIDs
- IP interfaces
- IP subnetworks (VLANs)
- IP addresses
- IP routes

- Eliminates the HiperSockets configuration tasks within z/OS Communications Server and zManager

The HiperSockets network configuration is inherited from the OSA-Express for zBX (OSX) configuration.

- Simplifies z/OS movement by eliminating or minimizing reconfiguration tasks

The z/OS network configuration that is related to the IP topology (IP address, IP subnet, and VLAN) for the IEDN, which is configured with the OSX interface, does not change when a z/OS image is moved to a different CPC. Given that IQDX configuration attributes are inherited from the OSX configuration, no reconfiguration tasks are required for IQDX interfaces.

- Enables sysplex network traffic to transparently use HiperSockets connectivity for VIPAROUTE processing over OSX interfaces

Figure 62 on page 524 shows the key concepts of the z/OS Communications Server IEDN-enabled HiperSockets function; HiperSockets connectivity is transparently converged with OSA-Express connectivity.

Figure 62. z/OS Communications Server IEDN-enabled HiperSockets overview

Communications Server provides transparent access to the IQD CHPID that is configured for the IQDX function. For each configured OSX CHPID and for each IP version, Communications Server dynamically creates and associates an IQDX interface and transport resource list element (TRLE) to the IQD CHPID. The dynamically created IQDX interfaces inherit the VLAN IDs and IP addresses of their associated OSX interfaces, thus eliminating the need for IP topology, routing, or security changes in the network. Communications Server dynamically determines whether traffic routed to the IEDN over a given OSX CHPID can also use the IQDX interface; if the traffic can use the IQDX interface, Communications Server routes the traffic over the high-performance HiperSockets IQD CHPID.

IQDX interfaces and TRLEs are created when the AUTOIQDX parameter is specified (or is specified by default) on the GLOBALCONFIG statement in the TCP/IP profile and an IQD CHPID is configured for the IQDX function.

- The naming convention for the dynamically created IQDX interfaces is EZAIQXxx (IPv4) and EZ6IQXxx (IPv6), where xx is the OSX CHPID number to which a particular IQDX interface is associated.

The IQDX interfaces are identified by interface type IPAQIQDX for IPv4 and interface type IPAQIQDX6 for IPv6. Traffic for unique VLANs over the same OSX CHPID (multiple VLANs) share the same IQDX interface.

- The naming convention for the dynamically created IQDX TRLEs is IUTIQXxx (IPv4) and IUTIQ6xx (IPv6), where xx is the OSX CHPID number to which a particular IQDX interface is associated.

To enable Communications Server to access the IEDN using HiperSockets interfaces, see [“Steps for enabling HiperSockets access to the intraensemble data network”](#) on page 526.

## Operating and managing IEDN-enabled HiperSockets interfaces

Internal Queued Direct I/O extensions (IQDX) interfaces are dynamically operated. They are started and stopped when the associated OSA-Express for zBX (OSX) interfaces are started and stopped. Optionally, IQDX interfaces can be separately operated if at least one of the associated OSX interfaces is active. If an IQDX interface fails, the TCP/IP stack dynamically attempts recovery, as it does with other configured HiperSockets devices and interfaces.

z/OS Communications Server dynamically allocates two control channels and up to eight data devices for each dynamically created IQDX transport resource list element (TRLE). TCP/IP stacks that share OSX CHPIDs also share dynamically created IQDX TRLEs; each stack uses one of the data devices for the IQDX

TRLE. You should configure sufficient subchannels for the Internal Queued Direct I/O (IQD) CHPID that is configured for the IQDX function. For more information about defining IQD CHPIDs and device types, see [z/OS HCD Planning](#).

Routing, IP security, and packet tracing of the dynamic IQDX interfaces is controlled through their associated OSX interfaces; the IQDX interfaces are generally not visible to these functions.

- Routing daemons such as OMPROUTE are aware of only the associated OSX interfaces; the stack does not report IQDX interfaces to OMPROUTE, and static routes cannot reference the dynamic IQDX interfaces. z/OS Communications Server makes the decision to direct traffic over an IQDX interface after the associated OSX interface is chosen as the route for the traffic.
- IQDX interfaces are not directly visible to IP security. If IP security is enabled, then traffic over an IQDX interface inherits the security class (SECCLASS) from the associated OSX interface. For packets that are sent and received over the IQDX interfaces, IPsec filtering applies to the security class of the associated OSX interface.
- Packet tracing of an OSX interface includes traffic that is redirected or received over its associated IQDX interface. If you perform a packet trace for data over an IQDX interface, the trace includes only inbound packets that are discarded before the stack can determine the associated OSX interface.

You can use Netstat reports to display information about dynamically created IQDX interfaces.

- The Netstat DEvlinks/-d report displays information for each IQDX interface, as it does for any defined interface. The Netstat DEvlinks/-d report for a given OSX interface displays how much traffic was rerouted to the associated IQDX interface. For more information about the [Netstat DEvlinks/-d report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).
- You can monitor which IP addresses are reachable over the OSX interfaces and over the associated IQDX interfaces using the Netstat ARp/-R and Netstat ND/-n reports. For more information about the [Netstat ARp/-R report](#) and the [Netstat ND/-n report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).
- You can display information about the dynamic IQDX TRLEs and their associated datapath devices by issuing the `D NET,ID=trle` command or the `D NET,TRL,TRLE=trle` command. For more information about the [DISPLAY ID command](#) and the [DISPLAY TRL command](#), see [z/OS Communications Server: SNA Operation](#).

## Performance considerations for the IEDN-enabled HiperSockets function

For network traffic within a central processor complex (CPC), HiperSockets processing can provide a fast response time (low latency). This fast response time is most likely for interactive (request and response) workloads where low latency is critical. However, when large amounts of data are transmitted (typically, streaming or bulk data workloads) as a significant portion of the intra-CPC workload, you might prefer OSA-Express processing due to differences in the OSA-Express processing for large data transmissions. The savings offered by OSA-Express processing for large data transfers vary; HiperSockets transmissions generally use more processor cycles than OSA transmissions, and this difference in processing cycles is magnified as transmission size grows.

If you prefer to use OSA-Express processing for large transmissions, the Communications Server IEDN-enabled HiperSockets function uses the strengths of both the HiperSockets and OSA-Express technologies, providing a configuration option that transparently controls traffic selection. Specifying `NOLARGEDATA` on the `AUTOIQDX` parameter of the `GLOBALCONFIG` statement transparently directs large data transmissions over OSA-Express for zBX (OSX) interfaces while directing small data transmissions over Internal Queued Direct I/O extensions (IQDX) interfaces; you can enable this setting to get the fast HiperSockets response time for small data transmissions, while avoiding the processor cost penalty sometimes incurred with HiperSockets for large data transmissions. If you do not anticipate a significant amount of large data transmissions or you always need high throughput levels (regardless of processor cycle consumption), you should not specify `NOLARGEDATA` on the `AUTOIQDX` parameter; if you do not specify `NOLARGEDATA` on the `AUTOIQDX` parameter, IQDX interfaces are favored for all transmission sizes.

### Guidelines:

- When NOLARGEDATA is specified for the AUTOIQDX parameter, Communications Server forces large TCP transmissions to the OSX path. Communications Server defines a large transmission as a TCP socket send of 32 K or larger. All other traffic is transmitted over IQDX interfaces.
- When an OSA adapter is shared among two or more logical partitions (LPARs), the processor savings offered by the OSA adapter is less than the savings offered by configurations that use multiple OSA adapters that are not shared. Some OSA assist functions, such as segmentation offload, are not available for the shared OSA configuration.
- Regardless of whether NOLARGEDATA is specified for the AUTOIQDX parameter, if large data workloads are part of the overall IEDN workload, then you should use the HiperSockets multiple write assist with IBM Z Integrated Information Processor (zIIP) function, which minimizes the increase in general-purpose processor usage that is incurred with HiperSockets. You should also use the 64 K Internal Queued Direct I/O (IQD) frame size.
- To be sure to take advantage of IQDX for streaming workloads, use an IQDX frame size larger than 16K if you are using an MTU size larger than 8192 bytes for OSX. Otherwise, certain streaming workloads are not able to use IQDX.

## Steps for enabling HiperSockets access to the intraensemble data network

---

OSA-Express for zBX (OSX) connectivity enables HiperSockets connectivity to the intraensemble data network (IEDN). You configure an Internal Queued Direct I/O (IQD) channel path ID (CHPID) for HiperSockets with a channel parameter to enable the Internal Queued Direct I/O extensions (IQDX) function, referred to as the z/OS Communications Server IEDN-enabled HiperSockets function.

### Before you begin

- To access the IEDN, the IBM zEnterprise 196 (z196) central processor complex (CPC) and the logical partition (LPAR) must be configured as members of an ensemble.

For information about using the [ENSEMBLE start option](#) to specify that an LPAR is a member of an ensemble (ENSEMBLE=YES), see [z/OS Communications Server: SNA Resource Definition Reference](#).

- Configure all OSX interfaces to the IEDN.

OSX connectivity to the IEDN is required to enable HiperSockets connectivity to the IEDN. For OSX configuration information, see [“Steps for configuring an interface for the intraensemble data network \(CHPID type OSX\)”](#) on page 522.

- Define a HiperSockets CHPID for the IQDX function using a channel parameter in the hardware configuration definition (HCD), and sufficient subchannel addresses to enable creation of one dynamic IQDX transport resource list element (TRLE) per OSX CHPID per IP version.

You must define 10 IQDX subchannel addresses for each OSX CHPID that is in use for IPv4, and 10 subchannel addresses for each OSX CHPID that is in use for IPv6. Multiple VLAN does not affect the required number of subchannel addresses. For more information, see the information about defining IQD CHPIDs and device types in [z/OS HCD Planning](#).

### Procedure

Perform the following steps to enable HiperSockets access to the IEDN.

1. Determine whether you want large outbound TCP protocol data to be transported to the IEDN over OSX interfaces or IQDX HiperSockets interfaces.

For more information, see [“Performance considerations for the IEDN-enabled HiperSockets function”](#) on page 525.

2. If necessary, configure the appropriate value for the AUTOIQDX parameter on the GLOBALCONFIG statement in the TCP/IP profile.

- If you want all eligible traffic to be transported over IQDX HiperSockets interfaces, no other action is necessary. The AUTOIQDX parameter with the value ALLTRAFFIC is the default setting on the GLOBALCONFIG statement in the TCP/IP profile.
- If you want large outbound TCP protocol data transmissions to be transported to the IEDN over OSX interfaces, specify the value NOLARGEDATA on the AUTOIQDX parameter of the GLOBALCONFIG statement in the TCP/IP profile.

## Steps for enabling IPv6 on a stack for access to the intranode management network

---

The intranode management network (INMN) is an IPv6 network that provides connectivity between network management applications within a zEnterprise node

### Procedure

Perform the following steps to enable IPv6 on a stack so that the stack can access the INMN:

1. Use the NETSTAT CONFIG command to view the current TCP/IP configuration.

If an IPv6 Configuration Table section is reported, no further actions are required.

2. Test and migrate any scripts that you use to format Netstat output in long format.

After you enable a z/OS TCP/IP stack for IPv6, Netstat output for the stack is available in the long format only. While you are still using IPv4 for your data networks, you can test the Netstat reports in the long format using one of the following methods:

- Use the FORMAT/-M LONG option on the Netstat command.
- Specify the FORMAT LONG parameter on the IPCONFIG statement in your TCP/IP profile.

For more information about the [Netstat](#) command, see [z/OS Communications Server: IP System Administrator's Commands](#). For more information about the [IPCONFIG](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

3. Update the BPXPRMxx parmlib member to include an additional NETWORK statement for IPv6.

Find the existing NETWORK DOMAINNAME(AF\_INET) statement, note the MAXSOCKETS and TYPE values that are specified, and add the following statement after the existing statement using those same values:

```
NETWORK DOMAINNAME(AF_INET6)
DOMAINNUMBER(19)
MAXSOCKETS(number)
TYPE(file_system_type)
```

For more information about updating BPXPRMxx, see [“Defining TCP/IP as a UNIX System Services physical file system” on page 40](#).

## Steps for using the intranode management network (CHPID type OSM)

---

The intranode management network (INMN) is an IPv6 network that provides connectivity between network management applications within a zEnterprise node. The INMN can be accessed through 1000BASE-T Ethernet OSA-Express3 or later adapters that are configured with channel path ID (CHPID) type OSM.

### Before you begin

The stack must be enabled for IPv6. For information about enabling a stack for IPv6, see [“Steps for enabling IPv6 on a stack for access to the intranode management network” on page 527](#).

To access the INMN, the IBM zEnterprise 196 (z196) central processor complex (CPC) and the logical partition (LPAR) must be configured as members of an ensemble. For information about using the

ENSEMBLE start option to specify that an LPAR is a member of an ensemble, see [z/OS Communications Server: SNA Resource Definition Reference](#).

If the stack is enabled for IPv6 and the LPAR is configured as a member of an ensemble, Communications Server automatically configures, locates, and activates up to two interfaces (named EZ6OSM01 and EZ6OSM02) onto the INMN. Each of these interfaces is an IPv6 interface that has only a link-local IP address. You cannot configure static or dynamic routes over OSA-Express for Unified Resource Manager (OSM) interfaces.

The INMN is intended for only authorized applications, such as those performing platform Performance Management functions. For more information about these applications, see *IBM z Systems Ensemble Planning Guide*.

## Procedure

Perform the following steps to use the INMN:

1. Authorize the application to the EZB.OSM.sysname.tcpname resource.  
To use IOCTL calls to retrieve information about an OSM interface or to send or receive data over an OSM interface, an application must have READ authorization to the EZB.OSM.sysname.tcpname resource. If used on this image, authorize the application to this resource.
2. Reserve the UDP port that the platform management application is to use to listen for multicast traffic over the INMN.
3. Authorize any user IDs to this resource that might issue diagnostic commands, such as Ping and Traceroute, over OSM interfaces to verify connectivity.
4. If you enable IP security for IPv6, you can configure a security class for IP filtering that applies to all OSM interfaces.  
Use the OSMSECCLASS parameter on the IPCONFIG6 statement. This enables you to configure filter rules for traffic over the EZ6OSM01 and EZ6OSM02 interfaces.
5. If the multicast address that is used by the platform management application is configured into a network access zone, then give the user ID for this application read permission to the resource profile for that zone.

## Routing considerations for the intraensemble data network

The TCP/IP stack does not allow IP forwarding within the intraensemble data network (IEDN) between two OSA-Express for zBX (OSX) interfaces. However, the stack does allow IP forwarding within the IEDN by the sysplex distributor when VIPAROUTE is used. The stack also allows IP forwarding between an OSX interface and a non-OSX interface.

If an external router is attached to the IEDN, dynamic and static routing considerations for OSX interfaces are the same as those considerations for OSD interfaces connected to an external router. However, if no external router is present on that network, see the following guidelines.

### Guidelines:

- Implement the IEDN as a flat network, meaning that all addresses that are reachable through the IEDN are in the same subnet (or IPv6 prefix) as the IEDN. In this configuration, a single route (static or dynamic) to this subnet enables all addresses on the IEDN to be reached.
- Static routing might be appropriate in the following cases:
  - The IEDN is implemented as a flat network, in which case a single static route over the OSX interface to the subnet of the IEDN can reach all destinations in the IEDN.
  - A z/OS host will not be routing traffic between external networks and the IEDN, so you do not want to advertise the intraensemble subnet addresses to the external network.

**Tip:** If you are using static routing over the IEDN and there are destination IP addresses on the IBM zEnterprise BladeCenter Extension (zBX) that are not part of the intraensemble subnet, you must

define static routes to those destination IP addresses on the intraensemble network by using OSX interfaces.

- Dynamic routing might be appropriate in the following cases:
  - You want destinations on the intraensemble subnet to be reachable from outside the ensemble, and therefore want to advertise the IEDN addresses to the external network.
  - There are destination IP addresses on the zBX that are not part of the intraensemble subnet, and you do not want to code individual static routes to reach them (for example, if other hosts on the IEDN have VIPA addresses that are not in the intraensemble subnet).

## OMPROUTE considerations for the intraensemble data network

---

In an ensemble environment with dynamic routing where a z/OS stack is the router for the ensemble, you can control whether the subnet of the intraensemble data network (IEDN) is advertised.

- If you want to prevent external traffic from being routed to this VLAN, then do one of the following items so that OMPROUTE does not advertise the intraensemble subnet:
  - Define the OSA-Express for zBX (OSX) interface to OMPROUTE using an INTERFACE statement or IPV6\_INTERFACE statement, and do not enable the IMPORT\_DIRECT\_ROUTES function of AS boundary routing. This function is disabled by default, so ensure that the IMPORT\_DIRECT\_ROUTES parameter of the AS\_BOUNDARY\_ROUTING statement or the IPV6\_AS\_BOUNDARY\_ROUTING statement is not set to YES.
  - Do not define the OSX interface to OMPROUTE, and ensure that GLOBAL\_OPTIONS IGNORE\_UNDEFINED\_INTERFACES is configured to OMPROUTE.

You might also want to install IPsec filter rules to restrict which traffic can flow on this network.

- If you want to allow external traffic to be routed to this VLAN, then define the OSX interface to OMPROUTE as an OSPF\_INTERFACE or IPV6\_OSPF\_INTERFACE, and code a nonzero value for the ROUTER\_PRIORITY parameter on the interface. As long as no other hosts on that OSX VLAN have coded their interfaces as OSPF interfaces, then OMPROUTE advertises the subnet (or IPv6 prefixes) of the IEDN into the OSPF network. This advertisement makes all addresses that fall into the intraensemble subnet (or IPv6 prefixes) reachable using OSPF. In addition, if you have a subset of hosts on the IEDN with VIPAs that are not in the intraensemble subnet, which you want to be able to reach over the IEDN, you can define the OSX interfaces on those hosts as OSPF interfaces; OMPROUTE communicates with them (and only them) and can route to their VIPAs, while still preserving the ability to route to the other hosts by subnet only.

**Tip:** These definitions apply per interface, so you could implement advertising on one VLAN while not advertising on a different VLAN attached to the same z/OS router.

## Sysplex distributor considerations for the intraensemble data network

---

In a sysplex distributor configuration, if the client, sysplex distributor, and at least one sysplex distributor target are all connected over the intraensemble data network (IEDN), then the client, sysplex distributor, and all potential sysplex distributor targets must be connected to the same VLAN on the IEDN.

## Multilevel security and network access control considerations

---

In a multilevel secure environment, you should treat the intraensemble data network (IEDN) and the OSA-Express for zBX (OSX) interfaces as any other data network with OSA-Express access. Because access to the IEDN through dynamic Internal Queued Direct I/O extensions (IQDX) interfaces is dependent on OSX access, traffic that is permitted or restricted over OSX interfaces is similarly permitted or restricted over IQDX interfaces. However, the intranode management network (INMN) and the OSA-Express for Unified Resource Manager (OSM) interfaces require special considerations. For information about these additional considerations, see [Chapter 4, “Preparing for IP networking in a multilevel secure environment,”](#) on page 213.

If you are using network access control, the IEDN and the OSX interfaces are subject to the same network access control as any other data network with OSA-Express access. Because access to the IEDN through dynamic IQDX interfaces is dependent on OSX access, traffic that is permitted or restricted over OSX interfaces is similarly permitted or restricted over IQDX interfaces. However, all traffic to and from the INMN over OSM interfaces is exempt from network access control, and is instead subject to OSM access control. Only multicast addresses to which a platform management application binds are subject to network access control.

---

## Chapter 10. Shared Memory Communications

Shared Memory Communications (SMC) enables two SMC capable peers to communicate by using memory buffers that each peer allocates for the partner's use. There are two types of Shared Memory Communications:

- Shared Memory Communications over Remote Direct Memory Access (SMC-R)
- Shared Memory Communications - Direct Memory Access (SMC-D)

SMC improves throughput, lowers latency and cost, and maintains existing functions. You do not need to change resources, such as host names and IP addresses, because you can use existing IP topology and addressing to identify virtual servers. You do not need to modify applications to use SMC to gain the performance benefits of communication by using SMC. Existing functions are preserved when SMC is used, such as the following functions:

- Load balancing, for example, sysplex distribution
- IP security zones
- Connection level security

### Reference:

- The Network Express feature introduces a new generation of OSA along with simplifications and improvements in RoCE connectivity. This technology also introduces new terminology. For more information, refer to the Network Express and SMC-R topics in the Conventions and terminology section under Abstract for IP Configuration Guide.
- See [Shared Memory Communications reference information](#) for a comprehensive list of materials for solutions that are related to Shared Memory Communications: SMC-R, SMC-D, and SMC Applicability Tool (SMC-AT).

---

### Shared Memory Communications over Remote Direct Memory Access

Shared Memory Communications over Remote Direct Memory Access (RDMA), or Shared Memory Communications over RDMA (SMC-R), is a protocol solution that is based on sockets over RDMA. SMC-R enables TCP sockets applications to transparently use RDMA, which enables direct, high-speed, low-latency, memory-to-memory (peer-to-peer) communications. Communicating peers such as TCP/IP stacks dynamically learn about the shared memory capability by using traditional TCP/IP connection establishment flows, enabling the TCP/IP stacks to switch from TCP network flows to more optimized direct memory access flows that use RDMA.

RDMA is available on standard Ethernet-based networks by using the industry (InfiniBand Trade Association) standard referred to as RDMA over Converged Ethernet (RoCE). RoCE enables the use of both standard TCP/IP and RDMA solutions such as SMC-R over the same physical LAN fabric. SMC-R requires *RoCE* feature, which is sometimes referred to as an RDMA network interface card (RNIC). SMC-R provides an enterprise class of services for RDMA that are designed for IBM enterprise class data center networks.

As shown in [Figure 63 on page 532](#), SMC-R enables two virtual servers that support RoCE to logically share memory through *RoCE* feature and over the RoCE network. When a virtual server that supports RoCE detects that a remote TCP connection partner supports shared memory communications, the connection is transparently and dynamically switched to use SMC-R protocols. The applications are unaware of the use of shared memory for communications.

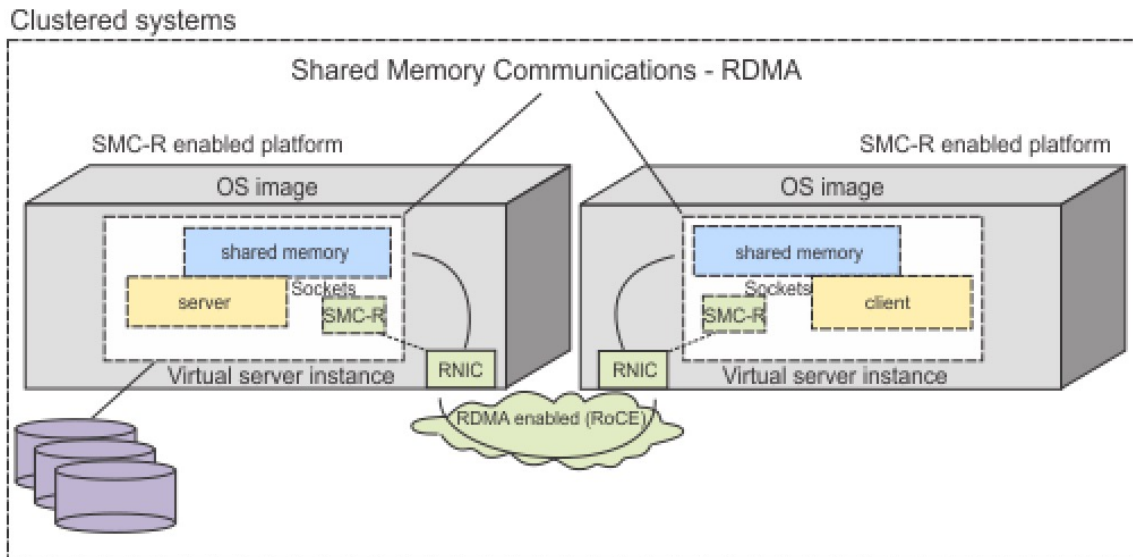

Figure 63. Shared Memory Communications over RDMA (SMC-R)

When redundant RoCE PFIDs are shared, SMC-R also transparently provides the capability for failover processing when a failure is detected with SMC-R communications.

## Remote Direct Memory Access over Converged Ethernet

Remote Direct Memory Access (RDMA) enables a host to make a subset of its memory directly available to a remote host. After RDMA connectivity is established between two TCP/IP stacks, either host can write to the memory of the remote host with no involvement from the remote host processors or operating system. RDMA enables efficient communications between the hosts because all the low-level functions are managed by RDMA network interface cards (RNICs) that are connected to each host, rather than by the software stack as is normally done for TCP/IP communications.

RDMA was traditionally confined to high-performance computing (HPC) environments where the cost of maintaining RDMA-capable network fabrics such as InfiniBand was justified given the emphasis of performance over cost. Now that RDMA is available on Ethernet fabrics through standards such as RDMA over Converged Ethernet (RoCE), the cost of adopting RDMA is lower because it can be enabled on the existing Ethernet fabrics that are used for IP network communications. Standard Ethernet management techniques are used to configure the RNIC adapters.

z/OS Communications Server provides support for sockets over RDMA by using SMC-R protocols. VTAM device drivers use Peripheral Component Interconnect Express (PCIe) operations to manage RoCE features that are defined to z/OS. Up to 16 RoCE PFID values can be defined to a z/OS TCP/IP stack.

## Sharing RoCE Features

RoCE features can be shared among TCP/IP stacks or LPARs using the System z virtualization for PCI devices. z/OS Communications Server uses PCIe Virtual Function (VF) services to manage the 10 GbE RoCE Express feature, and System z provides the Physical Function management.

A 10 GbE RoCE Express feature operating in a shared RoCE environment can be shared by up to 31 operating system instances or TCP/IP stacks across the same central processor complex (CPC). Each TCP/IP stack within an LPAR, or each operating system instance, uses a unique FID value to define its representation of the 10 GbE RoCE Express feature. These FID values are defined by using HCD tools. In the shared environment, both 10 GbE RoCE ports can be used at the same time.

**Guideline:** For a TCP/IP stack, the FID value is represented by a PFID value on the GLOBALCONFIG statement in the TCP/IP profile. In addition, the same or different TCP/IP stacks can share the two 10 GbE

RoCE Express ports of an individual 10 GbE RoCE Express feature if different PFID values are configured for the individual ports.

Figure 64 on page 533 is an example of a 10 GbE RoCE Express feature operating in a shared RoCE environment. Two z/OS images are using the 10 GbE RoCE Express features identified by PCHID values 100 and 200. Four unique PFID values are defined, two per z/OS image, to represent the usage of the features. The PFID values correspond to the FID values defined for the features in the HCD. In this example, the combination of PFID and port is unique for all four interfaces, but TCP/IP stacks are sharing the same feature and port.

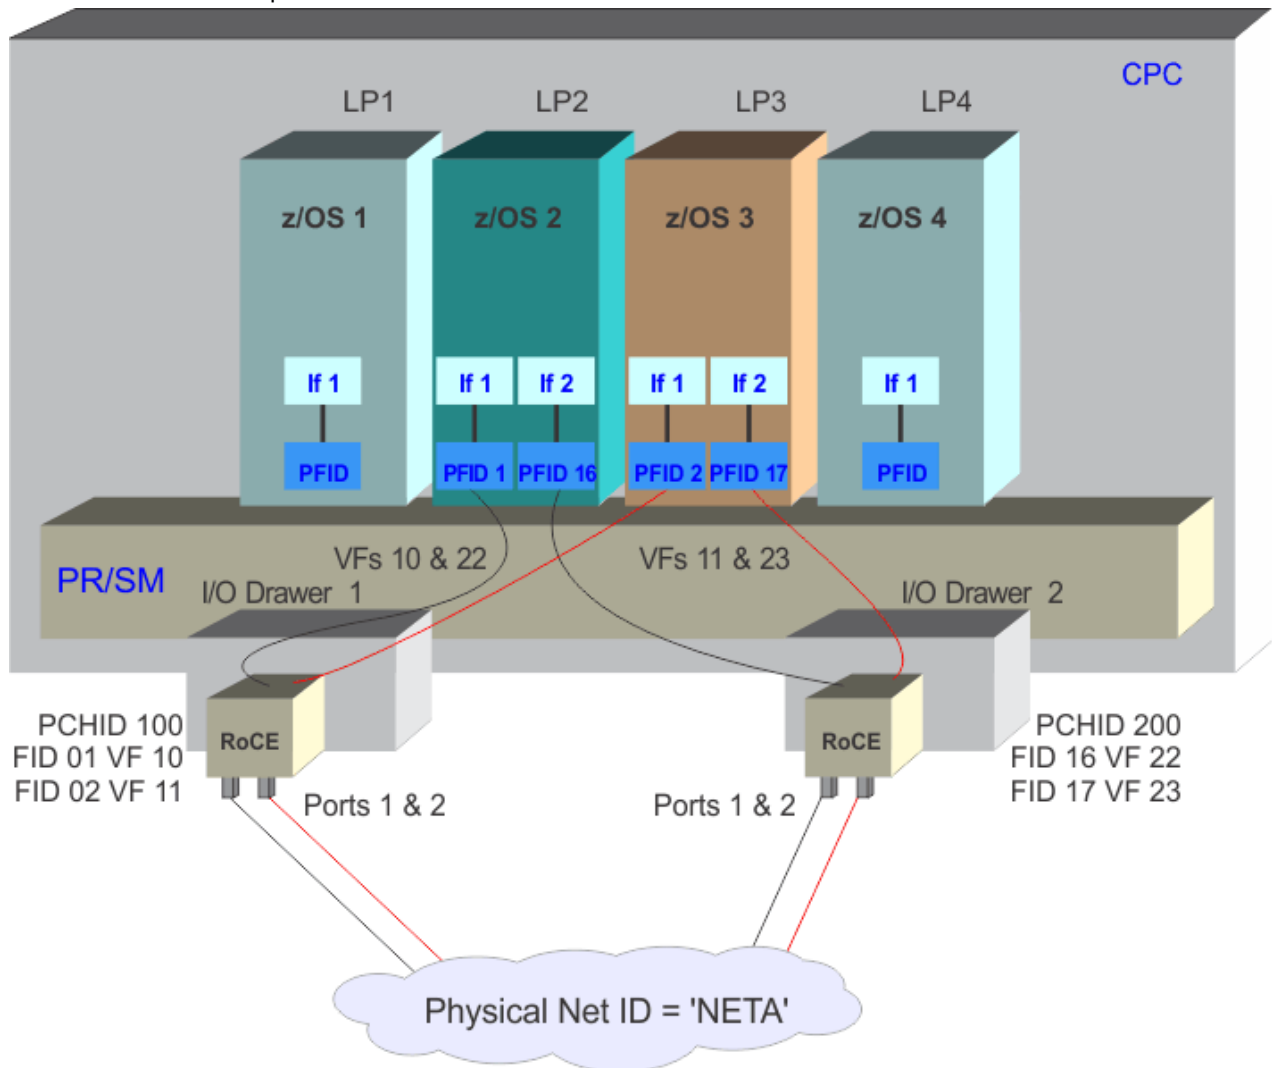

Figure 64. 10 GbE RoCE Express feature in a shared RoCE environment

**Guideline:** For full redundancy at a TCP/IP stack, configure PFID values that are associated with physically separate 10 GbE RoCE Express features. For example, in the figure above, for z/OS 2, the two features are in different System z I/O drawers. Therefore, the failure of one I/O drawer or one feature does not affect the other I/O drawer or feature.

A shared RoCE environment must be used on the IBM z13<sup>®</sup> (z13) or later systems.

## RoCE Express features virtualization environment

RoCE Express features operate in a shared RoCE environment. In general, the same rules and guidelines for defining, sharing and using RoCE Express features apply to all RoCE Express features. Each RoCE Express port can be shared by 31 or 63 operating system instances or TCP/IP stacks across the same CPC, depending on the system z model's capability. RoCE Express2 was introduced with z14 and RoCE

Express3 was introduced with z16. See “Sharing RoCE Features” on page 532 topic for a description of operating in a shared RoCE environment.

## Network Express feature virtualization environment

Starting with the IBM z17, the Network Express feature provides both OSA and RoCE connectivity with a single adapter (PCHID). Network Express features are logically divided and managed by the system into two PCHIDs. Each PCHID has a single port. Both the OSA and RoCE functions can be configured and shared among multiple stacks or LPARs. Network Express PFIDs are defined as a NETH PFID. For RoCE connectivity, each Network Express port can be shared by defining up to 16 NETH PFIDs for up to 16 z/OS instances (LPARs) or TCP/IP stacks across the same CPC. For a description of operating in a shared RoCE environment using Network Express, see the “Sharing Network Express features” on page 534 topic.

## Network Express feature virtualization environment

Starting with the IBM z17, the Network Express feature provides both OSA and RoCE connectivity with a single adapter (PCHID). Network Express features are logically divided and managed by the system into two PCHIDs. Each PCHID has a single port. Both the OSA and RoCE functions can be configured and shared among multiple stacks or LPARs. Network Express PFIDs are defined as a NETH PFID. For RoCE connectivity, each Network Express port can be shared by defining up to 16 NETH PFIDs for up to 16 z/OS instances (LPARs) or TCP/IP stacks across the same CPC. For a description of operating in a shared RoCE environment using Network Express, see the “Sharing Network Express features” on page 534 topic.

## Sharing Network Express features

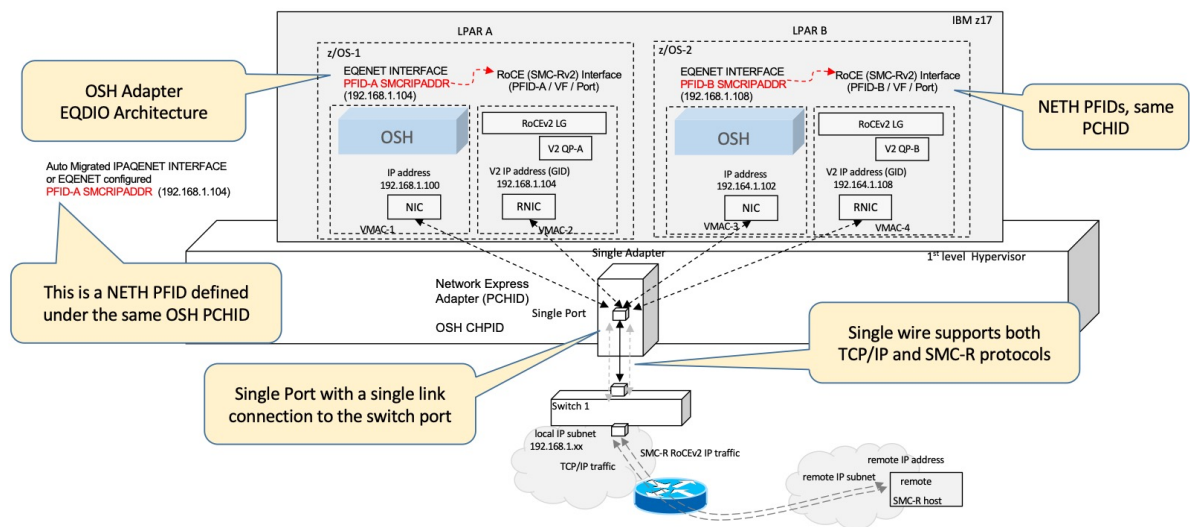

Figure 65. Sharing Network Express features

Some of the key considerations for sharing (virtualizing) OSA and NETH devices are:

- The PFID configured on the EQENET (EQENET6) INTERFACE statements for OSH must reference a PFID on the same physical adapter (PCHID).
- Network Express supports a single port per PCHID. Port number cannot be configured (in z/OS or HCD).
- The rules and guidelines for reusing PFIDs or SMCIPADDRs for Network Express and for configuring SMC-Rv1 and SMC-Rv2 are the same rules as defined for SMC-R for RoCE Express features. For additional details, see the EQENET INTERFACE statement in the [z/OS Communications Server: IP Configuration Reference](#).

- When IPAQENET (IPAQENET6) for OSD interfaces are defined with SMC-R on z17 or after, then the configured PFID must reference a NETH PFID on any valid PCHID accessible to z/OS. This configuration uses two physical ports, OSD and NETH.
- Network Express supports up to 16 PFIDs. Consideration should be given to the throughput requirements of each user (LPAR or stack) for each protocol, TCP/IP and SMC-R, along with the overall capacity of the adapter (total bandwidth) required for all users.
- Considerations must be given to redundancy for high availability when configuring two Network Express features.

## Shared Memory Communications - Direct Memory Access

Shared Memory Communications - Direct Memory Access (SMC-D) uses internal shared memory (ISM) for communication between two SMC capable peers that are located on the same central processor complex (CPC). The communicating peers, such as TCP/IP stacks, dynamically detect the shared memory capability by using traditional TCP/IP connection establishment flows. The shared memory enables the TCP/IP stacks to switch from TCP network flows to more optimized direct memory access flows that use ISM.

As shown in Figure 66 on page 535, SMC-D enables two virtual servers that support ISM to logically share memory. When a virtual server that supports ISM detects that a TCP connection partner also supports shared memory communications by using ISM, the connection is transparently and dynamically switched to use SMC-D protocols. The applications are unaware of the use of shared memory for communications.

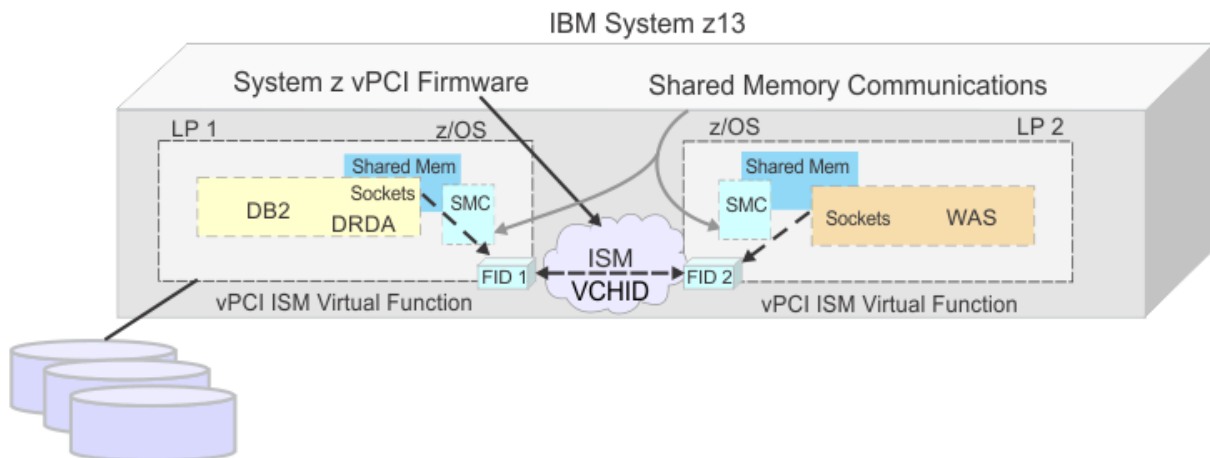

Figure 66. Shared Memory Communications - Direct Memory Access (SMC-D)

## Shared Memory Communications concepts

The following concepts apply to Shared Memory Communications (SMC).

### Rendezvous processing

Shared Memory Communications (SMC) is enabled by using the GLOBALCONFIG statement in the TCP/IP profile data set.

- Shared Memory Communications over RDMA (SMC-R) is enabled by specifying one or more Peripheral Component Interconnect Express (PCIe) function ID (PFID) values on the SMCR parameter of the GLOBALCONFIG statement in the TCP/IP profile data set. Each PFID value represents a "RoCE Express" feature that is configured by using the traditional hardware configuration definition (HCD) tools. TCP/IP activates "RoCE Express" interfaces when the first SMC-R capable interface is started. SMC-R capable interfaces include IPAQENET (IPAQENET6) or EQENET (EQENET6) interfaces. Any TCP connections that are routed over SMC-R capable interfaces are eligible for SMC-R communications.

- Shared Memory Communications - Direct Memory Access (SMC-D) is enabled by specifying the SMCD parameter of the GLOBALCONFIG statement in the TCP/IP profile data set. When SMC-D capable interfaces are activated, z/OS Communications Server selects an available ISM device that is associated with the same physical network as the SMC-D capable interface. Only one ISM device is activated for each physical network. The ISM device is represented by a Peripheral Component Interconnect Express (PCIe) function ID (PFID) value that is configured by using the traditional hardware configuration definition (HCD) tools. SMC-D capable interfaces include IPAQENET (IPAQENET6), EQENET (EQENET6), OSA interfaces, IPAQIDIO (IPAQIDIO6) HiperSockets interfaces, and EZAZCX (EZ6ZCX) ZCX interfaces. Any TCP connections that are routed over SMC-D capable interfaces are eligible for SMC-D communications.

**Restriction:** EZAZCX and EZ6ZCX interfaces are enabled for SMC-Dv2 (multiple IP subnet support) only.

The decision about whether an eligible connection uses SMC communications is reached during traditional TCP connection establishment. *Rendezvous processing* is the term that is used to describe the sequence of connection management flows (shown in Figure 67 on page 536) that are required to establish SMC-R communications between two peers.

Figure 67. Rendezvous processing

The exchange of information occurs in different stages:

- Extra information in TCP connection establishment flows

Applications still use the standard three-way handshake mechanisms to establish TCP connections. When SMC-R or SMC-D communications are enabled, the client and the server can indicate support for either SMC-R or SMC-D protocols:

- The client adds TCP option 254 in the SYN request to indicate that SMC is supported by the client.
- The server responds with TCP option 254 in the SYN-ACK to indicate that the server also supports SMC.

No additional exchange of information is required in this stage of the rendezvous processing.

**Tip:**

Some firewalls can be configured to drop TCP options. The SMC protocol requires TCP option 254 to flow on the TCP/IP 3-way handshake. If you are enabling SMCv2 (SMC multiple IP subnet support) it is recommended that you verify that your firewalls permit TCP option 254 to flow. For more information about the SMC protocol, see RFC 7609.

**Tip:**

If you are enabling SMC-Rv2 with RoCEv2, it is also recommended that you verify that UDP port 4791 (RoCEv2) is open in your firewalls.

- In-band SMC Connection Layer Control (CLC) messages

Conceptually, CLC messages are similar to the SSL handshake processing that occurs after the TCP connection is established.

SMC-D protocols are preferred over SMC-R protocols. If both the client and the server indicate support for SMC-D processing, after the TCP connection is established, the client and the server negotiate the use of SMC-D for this TCP connection by using SMC-D CLC messages that flow as in-band data over the TCP connection.

The SMC-D CLC messages exchange the following information:

- Peer identification information
- SMC-D buffer information that is necessary to exchange data between the peers

For detailed description about the information that SMC-D CLC messages exchange, see [“SMC-D links” on page 541](#).

If the attempt to establish SMC-D communications succeeds, the SMC-D link is established, and the peers can start exchanging data by using the SMC-D buffers.

If SMC-D communications is not available, and both the client and the server indicate support for SMC-R processing, the client and the server negotiate the use of SMC-R for this TCP connection by using SMC-R CLC messages that flow as in-band data over the TCP connection.

The SMC-R CLC messages exchange the following information:

- Network routing information
- RDMA over Converged Ethernet (RoCE) routing credentials
- SMC-R buffer information that is necessary to select or establish the RoCE path between the peers

For detailed description about the information that SMC-R CLC messages exchange, see [“SMC-R links” on page 538](#).

- SMC-R Link Layer Control (LLC) messages

After the SMC-R information is exchanged, SMC-R LLC messages are exchanged across the RoCE fabric to confirm that the RoCE information is correct and that the remote memory can be accessed. This stage is skipped if an existing RoCE connection is used for this TCP connection.

The TCP/IP stack does not allow the client and server applications to exchange application data during rendezvous processing. Because no application data is exchanged, the TCP connection can revert to IP protocols if there is a failure during the setup of the SMC communications. However, after the TCP connection is committed to using SMC protocols, the TCP connection cannot fall back to using IP protocols if SMC communications encounter an error.

- For SMC-R communications, the TCP connection is committed to use SMC logic after the RoCE connection is confirmed by using the SMC-R LLC messages.
- For SMC-D communications, the TCP connection is committed to use SMC logic after the successful exchange of SMC-D CLC messages.

Both the client and the server nodes maintain a series of rendezvous timers to ensure that the rendezvous processing completes in time. If one of the timed events does not complete as expected, the TCP connection reverts to using IP protocols. However, future TCP connections can still attempt to use SMC.

To reduce the overhead of persistent rendezvous failures (TCP connections reverting to using IP protocols) to the same destination IP address, you can use the default AUTOCACHE function. This function is controlled by the AUTOCACHE and NOAUTOCACHE subparameters of the SMCGLOBAL parameter on the GLOBALCONFIG profile statement and is set to AUTOCACHE by default. The AUTOCACHE function caches rendezvous failures per IP address destination. If the AUTOCACHE function detects too many rendezvous failures to a specific IP address, the function prevents additional rendezvous attempts to that IP address. The AUTOCACHE function is started only when you enable SMC. For more information about enabling SMC, see the description of the GLOBALCONFIG SMCR and SMCD parameters in [z/OS Communications Server: IP Configuration Reference](#).

Even though the data is sent out of band with SMC communications, the TCP connection remains active, primarily to facilitate connection termination processing. If you have TCP server applications that primarily use many short-lived TCP connections, you might want to avoid rendezvous processing. You can prevent these server applications from using SMC in one of the following ways:

### Use the AUTOSMC monitoring function

The AUTOSMC monitoring function dynamically monitors incoming TCP connections to local TCP server applications and determines whether the use of SMC is beneficial for the workload. This function is configured by the AUTOSMC and NOAUTOSMC subparameters of the SMCGLOBAL parameter on the GLOBALCONFIG profile statement and is set to AUTOSMC by default. However, the AUTOSMC monitoring function is started only when you enable SMC. For more information about enabling SMC, see the description of the GLOBALCONFIG SMCR and SMCD parameters in [z/OS Communications Server: IP Configuration Reference](#). If the function determines that most of the incoming connections are short-lived and exchange a small amount of data then SMC processing will be bypassed for all new connections to this server. This monitoring is dynamic in nature so that it can detect changes in workload patterns. You can monitor the results of this dynamic monitoring and SMC enablement/disablement using the Netstat ALL/-A command. For more information about the Netstat ALL/-A command, see [z/OS Communications Server: IP System Administrator's Commands](#).

### Disable SMC eligibility for the port

Explicitly specify the NOSMC parameter on the [PORT](#) statement or [PORTRANGE](#) statements that define the port or ports that the server application uses. For more information, see [z/OS Communications Server: IP Configuration Reference](#).

## Shared Memory Communications links and link groups

After two Shared Memory Communications (SMC) peers recognize during rendezvous processing that shared memory communications are possible, the peers create SMC links and, in the case of SMC-R, SMC link groups.

### SMC-R links

After two Shared Memory Communications over RDMA (SMC-R) peers recognize during rendezvous processing that shared memory communications are possible, a logical point-to-point SMC-R link is established between the stacks over the RDMA over Converged Ethernet (RoCE) fabric. An SMC-R link, as shown in [Figure 68 on page 539](#), is uniquely defined by a combination of the following information:

- Remote and local virtual MAC (VMAC) values

A VMAC is a 6-byte value that is a virtual representation of the physical MAC address for a "RoCE" interface (shown as RNIC in [Figure 68 on page 539](#)).

Each TCP/IP stack that activates a particular "RoCE" interface is assigned a different VMAC value.

- Remote and local global ID (GID) values

A GID is a 16-byte value. z/OS Communications Server generates the GID values by converting the VMAC address of the "RoCE" interface into an IPv6 link-local address.

- Remote and local queue pair (QP) values

A QP represents one end of the logical connection between two RDMA peers. A combination of two reliable connected queue pairs (RC QPs) forms a single logical point-to-point link. The link enables exactly one pair of communicating RDMA peers to send and receive messages and initiate RDMA activities between themselves. A "RoCE" interface associates units of work, such as confirmation of sent data or indication of received data, to a specific QP to enable the SMC-R protocols to identify which TCP/IP stack to notify for the unit of work. The stack then determines which TCP connection that uses that RC QP is to process the data.

- Virtual LAN (VLAN) ID

You can optionally use VLANs to isolate application traffic into different virtual networks on the same physical Ethernet.

- If you define VLANs, the VLAN ID specified on the IPAQENET, IPAQENET6, EQENET or the EQENET6 INTERFACE statement is used as an attribute to create unique SMC-R links between the peers for unique VLANs. In other words, the SMC-R links are VLAN qualified.
- If you do not use VLANs, no VLAN ID is used to define the SMC-R links between the peers. In other words, the SMC-R links are not VLAN qualified.

For more information about using VLANs, see [“SMC-R VLANID usage for RoCE features”](#) on page 546.

Application traffic between the two peers that uses the same remote and local VMACs, GIDs, and QPs, and that is associated with the same VLAN when VLANs are defined, can use the same SMC-R link.

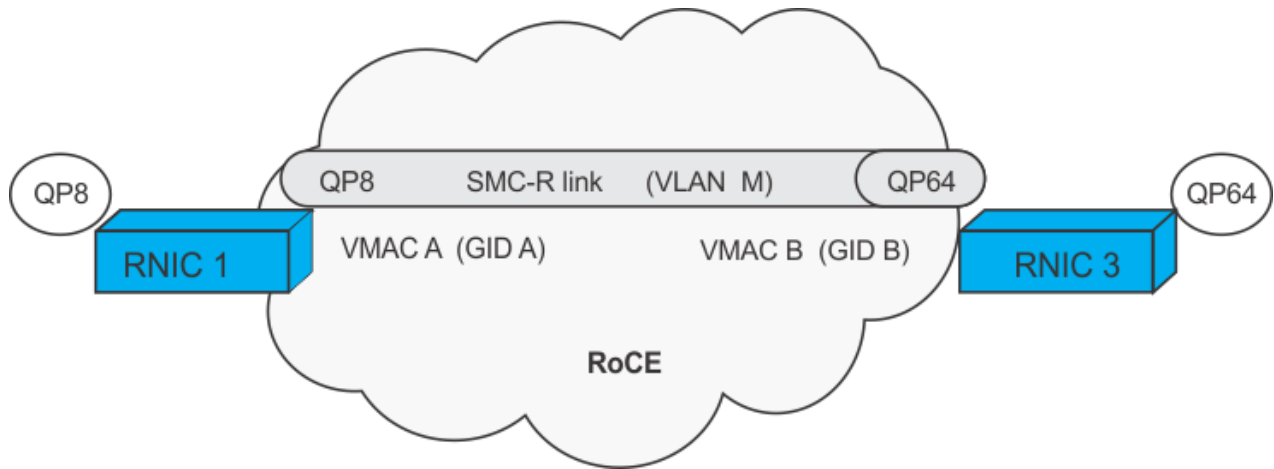

Figure 68. Identifying an SMC-R link

In addition to the 7-tuple (local VMAC, GID, QP# + remote VMAC, GID, QP# + VLAN ID) that uniquely defines an SMC-R link, each peer assigns a 4-byte SMC-R link ID value that uniquely identifies the SMC-R link within its own resource space. This SMC-R link ID is exchanged between peers and is intended to be used for network management and diagnostic purposes. For instance, you can use the SMC-R link ID to filter Netstat report information that is related to a specific SMC-R link. For more information, see [“Displaying SMC information”](#) on page 585.

An SMC-R link supports multiple TCP connections between the same two peers, as shown in [Figure 69](#) on page 539. The first TCP connection between the peers establishes the SMC-R link, and subsequent TCP connections between the peers can use the previously established link. Because subsequent TCP connections between the peers can use the previously established link, extra SMC-R link setup costs between the peers are avoided.

Figure 69. Multiple TCP connections over one SMC-R link

## SMC-R link groups

A Shared Memory Communications over RDMA (SMC-R) link group is a logical grouping of SMC-R links between two communicating peers, as shown in [Figure 70](#) on page 540. An SMC-R link group is formed when the initial SMC-R link is established between two peers.

All SMC-R links in an SMC-R link group must be *equal* links. SMC-R links are considered to be equal when all of the following conditions are true:

- The links provide access to the same RDMA memory buffers at the remote peer virtual servers.
- The links have the same VLAN ID, or they do not use a VLAN ID.
- The links have the same TCP server and TCP client roles or relationship.

A peer that is acting as the TCP connection server has different responsibilities for establishing and maintaining SMC-R communications than a peer that is acting as the TCP connection client. Unique SMC-R link groups are established between two peers when the peers act as both servers and clients for TCP connections.

When the initial SMC-R link is established and a second "RoCE Express" interface is available, Communications Server establishes an equal SMC-R link between the peers. The "RoCE Express" interfaces are shown as RNICs in [Figure 70 on page 540](#).

Adding a second SMC-R link to the SMC-R link group provides the following benefits:

- High availability

To maintain high availability, you need two SMC-R links between SMC-R peers. If a failure occurs with one SMC-R link, TCP connections that are using the failing SMC-R link are switched to the other active link in the link group and disruptions to application workloads are avoided. For more information, see ["SMC-R high availability considerations" on page 550](#).

- Workload balancing

TCP connections are distributed across the SMC-R links in a link group, increasing bandwidth and avoiding bottlenecks.

**Rule:** Workload balancing within an SMC-R link group occurs only when both the local and the remote peers have two "RoCE Express" interfaces, and thus two SMC-R links are established in the link group.

**Guideline:** When you are provisioning PFIDs for a specific PNetID for each TCP/IP stack, you should assign "RoCE Express" PFIDs with the same link speed (i.e. 10 GbE, 25 GbE). If this guideline is not followed, this will result in SMC-R link groups being created with SMC-R links with unequal throughput capacities. During error recovery scenarios, fail over processing might overload the lower capacity SMC-R link that could result in recovery failures.

Figure 70. SMC-R link group

Because SMC-R links within a link group are considered equal, TCP connections can be assigned to any SMC-R link within the group. Furthermore, the client and the server can choose to assign the TCP connection to different SMC-R links within the group, and can move the TCP connections from one SMC-R link to another within the group. For example, in [Figure 70 on page 540](#), client traffic might flow over one SMC-R link (between RNICs A and C) and server traffic might flow over the other SMC-R link (between RNICs B and D). The peers do not have to exchange knowledge of which physical "RoCE Express"

interface is being used for data transmission, and the recipient is only aware that data was placed into the RDMA memory buffer.

An SMC-R link group remains active for up to 10 minutes after the last TCP connection that is using the link group is stopped.

## SMC-D links

After two Shared Memory Communications - Direct Memory Access (SMC-D) peers recognize during rendezvous processing that shared memory communications are possible, a logical SMC-D link is established between the peers by using internal shared memory (ISM). An SMC-D link, as shown in [Figure 71 on page 541](#), is uniquely defined by a combination of the following information:

- Remote and local global ID (GID) values

An SMC-D GID is an 8-byte value that the ISM device assigns.

- Virtual LAN (VLAN) ID

You can optionally use VLANs to isolate application traffic into different virtual networks on the same physical Ethernet or HiperSockets CHPID.

- If you use VLANs, the VLAN ID that is specified on the IPAQENET, IPAQENET6, IPAQIDIO, or IPAQIDIO6 INTERFACE statement is used as an attribute to create unique SMC-D links between the peers for unique VLANs. In other words, the SMC-D links are VLAN qualified.
- If you do not use VLANs, no VLAN ID is used to define the SMC-D links between the peers. In other words, the SMC-D links are not VLAN qualified.

For more information about using VLANs, see [“VLANID considerations” on page 546](#).

If the application traffic that is between the two peers uses the same remote and local GIDs, and is associated with the same VLAN when VLANs are defined, the application traffic can use the same SMC-D link.

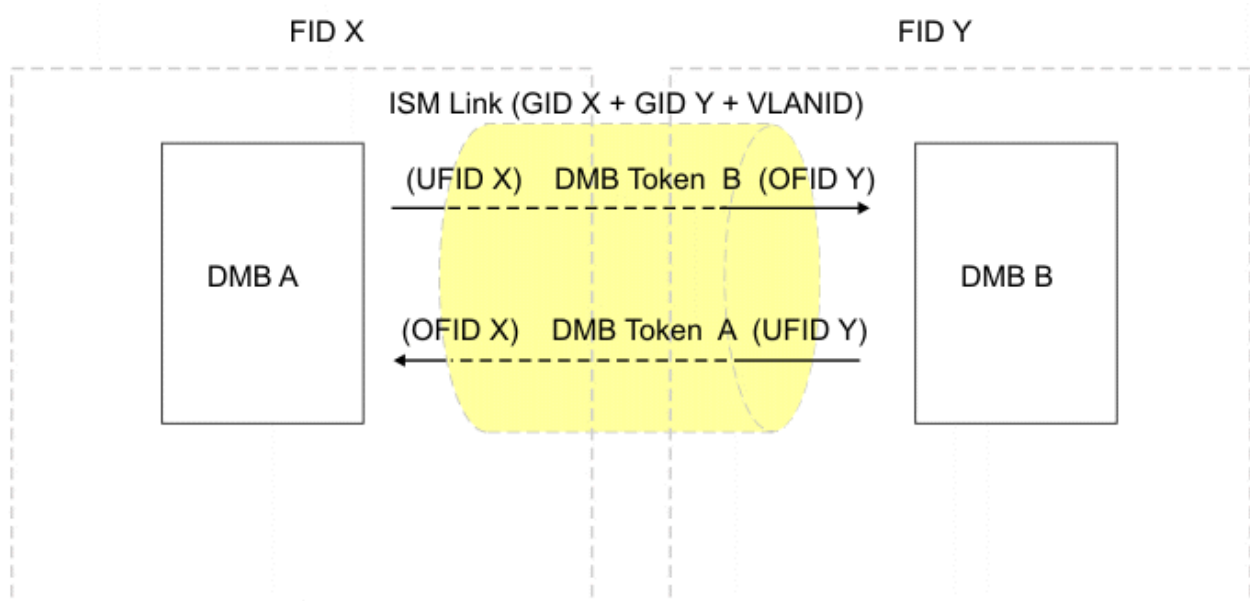

Figure 71. Identifying an SMC-D link

Besides the 3-tuple (local GID + remote GID + VLAN ID) that uniquely defines an SMC-D link, each peer assigns a 4-byte SMC-D link ID that uniquely identifies the SMC-D link within its own resource space. This SMC-D link ID is exchanged between peers and can be used for network management and diagnostic purposes. For instance, you can use the SMC-D link ID to filter Netstat report information that is related to a specific SMC-D link. For more information, see [“Displaying SMC information” on page 585](#).

An SMC-D link supports multiple TCP connections between the same two peers. The first TCP connection between the peers establishes the SMC-D link, and subsequent TCP connections between the peers can use the previously established link.

## SMC memory buffers

Each stack locally allocates memory for an SMC memory buffer to receive inbound data that uses SMC communications. An SMC memory buffer that is used for SMC-R communications is called a remote memory buffer (RMB), and an SMC memory buffer that is used for SMC-D communications is called a direct memory buffer (DMB). The sending operating system places TCP socket application data directly into the memory buffer that the receiving stack assigns to receive data for a TCP connection. The receiving stack then copies the data from the memory buffer into the receive buffer of the receiving socket application.

A memory buffer is partitioned into elements of equal size, and each element is associated with a single TCP connection. Direct memory buffers are partitioned into direct memory buffer elements (DMBEs), and remote memory buffers are partitioned into remote memory buffer elements (RMBEs). In the Connection Layer Control (CLC) messages during rendezvous processing, each peer communicates the location of its local DMBE, or its RMBE and a remote key, to allow remote access to the memory buffer. The remote host has write access and the local host reads the data for passing to the socket application.

## SMC-R usage of memory buffers

For z/OS Communications Server, an RMB is a contiguous, 1-MB block of fixed 64-bit private storage. In Figure 72 on page 542, an RMB is created on z/OS, into which the peer node can write, and an RMB is created on the peer node, into which z/OS can write. An RMB must be registered with the "RoCE" interface so that the storage is available to the remote peer.

Each RMB is associated with the reliable connected queue pairs (RC QPs) and therefore with the SMC-R link for the two communicating peers. The association of the RMB to the RC QPs ensures that only the two peers have RDMA access to this particular RMB. In addition, all RMBs that are associated with a particular SMC-R link must be accessible to the remote peer by using any SMC-R link in the link group. This accessibility enables the remote peer to use any link within the link group to place the TCP connection data into the correct RMB.

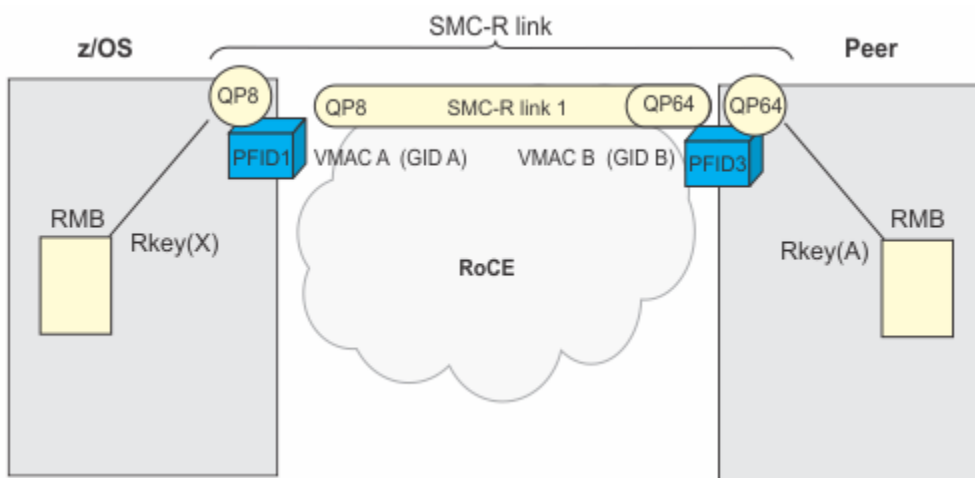

Figure 72. RMBs assigned to an SMC-R link

The SMC-R peers are not required to assign RMBEs of the same size for the client and the server of a specific TCP connection. The peers can use one or more RMBs for the TCP connections that are using the same SMC-R link.

When an SMC-R link group is first established, z/OS Communications Server allocates a basic set of three RMBs for the link group. The RMBE sizes for the RMBs are not defined initially, but instead are determined by the needs of the TCP connections that use the SMC-R link. z/OS Communications Server uses RMBE

sizes of 32 KB, 64 KB, 128 KB, 256 KB, and greater than 256 KB. The appropriate size for the TCP connection is selected based on the receive buffer size of the local application. When the application does not explicitly set the buffer size by using `SETSOCKOPT()`, the default value is determined by the value of the `TCPRCVBUFSIZE` parameter on the `TCPCONFIG` statement.

More RMBs are allocated as needed to accommodate more TCP connections or different receive buffer sizes.

## SMC-D usage of memory buffers

For z/OS Communications Server, a DMB is a contiguous, 1 MB block of pinned 64-bit private storage. A DMB is created on z/OS, into which the peer node can write, and a DMB is created on the peer node, into which z/OS can write. A DMB must be registered with the ISM interface so that the storage is available to the remote peer. Each DMB is associated with one and only one SMC-D link.

The SMC-D peers are not required to assign DMBEs of the same size for the client and the server of a specific TCP connection. The peers can use one or more DMBs for the TCP connections that are using the same SMC-D link.

When an SMC-D link is first established, z/OS Communications Server allocates a basic set of three DMBs for the link. The DMBE sizes for the DMBs are not defined initially, but instead are determined by the needs of the TCP connections that use the SMC-D link. z/OS Communications Server uses DMBE sizes of 64 KB, 128 KB, 256 KB, and greater than 256 KB. The appropriate size for the TCP connection is selected based on the receive buffer size of the local application. When the application does not explicitly set the buffer size by using `SETSOCKOPT()`, the default value is determined by the value of the `TCPRCVBUFSIZE` parameter on the `TCPCONFIG` statement.

More DMBs are allocated as needed to accommodate more TCP connections or different receive buffer sizes.

## SMC-R staging buffers

Each TCP/IP stack allocates 64-bit fixed private staging buffer memory for outbound Shared Memory Communications over RDMA (SMC-R) data. Staging buffers are not associated with specific SMC-R links or link groups, but are used by all TCP connections that traverse SMC-R links on this stack.

Like remote memory buffers (RMBs), staging buffers are 1 MB in length and must be registered with the "RoCE" interface before they are used for SMC-R communications. Unlike RMBs, the address of the staging buffer is not shared with the remote SMC-R peer because only local applications access the staging buffer storage.

z/OS Communications Server allocates 4 MB of staging buffer storage when the first "RoCE" interface is activated, and allocates more buffers as necessary to accommodate application workloads.

## SMC filters

Shared Memory Communications filters are provided to allow the administrator to have a more granular level of control of which TCP connections are eligible to use SMC. SMC filters control all forms of SMC. For more details, see [“SMC filters” on page 567](#).

## Shared Memory Communications terms

---

The following terms apply to Shared Memory Communications (SMC). You can use this list as needed for brief descriptions when you are using other SMC information.

### Associated ISM interface

An internal shared memory (ISM) interface that is associated with an Shared Memory Communications - Direct Memory Access (SMC-D) capable interface that has the same physical network ID.

**Associated RNIC interface**

An IBM 10 GbE RoCE Express interface that is associated with an Shared Memory Communications over Remote Direct Memory (SMC-R) capable interface that has the same physical network ID.

**Direct memory buffer (DMB)**

Local memory that is used to receive inbound data over an SMC-D link. The remote peer places TCP socket application data directly into the DMB that the local peer assigns to receive data for the TCP connection. The local peer then copies the data from the DMB into the receive buffer of the receiving socket application.

**DMB element (DMBE)**

The portion of a DMB that is associated with a specific TCP connection. Each DMB is partitioned into one or more DMBEs.

**IBM RoCE Express or Network Express feature**

A feature that enables Remote Direct Memory Access by managing low-level functions that the TCP/IP stack typically handles.

**IBM RoCE Express or IBM Network Express interfaces**

An interface that is dynamically created by TCP/IP that uses a particular port of a RoCE Express or Network Express feature with the corresponding port speed of that specific feature.

**Internal path**

The System z internal PCIe infrastructure for "RoCE" features. The internal path of a "RoCE" feature is determined based on how the feature is plugged into the System z I/O drawers.

**ISM device**

The System z firmware that facilitates the use of internal shared memory for SMC-D processing. An ISM device is identified by a unique PCIe function ID (PFID) and a virtual channel ID (VCHID). An ISM device is configured in the hardware configuration definition (HCD) and is associated with a single physical network ID.

**ISM interface**

An interface that is dynamically created by TCP/IP to represent an ISM device for SMC-D capable interfaces with the same physical network ID.

**Operating system images**

Logical partitions (LPARs) or guest virtual machines that operate in the same central processor complex (CPC).

**Physical channel ID (PCHID)**

A 2-byte hexadecimal value that is used to uniquely define a "RoCE" feature.

**PCIe function ID (PFID)**

A value that represents the SMC device.

For SMC-R, the PFID value is configured on the SMCR parameter of the GLOBALCONFIG statement in the TCP/IP profile to identify a "RoCE" feature. The PFID represents a physical "RoCE" feature and must match a FID value configured in the hardware configuration definition (HCD) for the PCHID value that identifies the feature. When the "RoCE" feature is installed on a System z that supports a shared RoCE environment, the same physical feature can be shared with other operating system images, and multiple PFID values specified on the same GLOBALCONFIG statement can represent different ports on the same physical "RoCE" feature.

For SMC-D, the PFID value is obtained during ISM interface activation that identifies an ISM device. The PFID value matches an FID value that is configured in the HCD for the VCHID value that represents the ISM device.

**Peripheral Component Interconnect Express (PCI Express, or PCIe)**

A local bus that provides the high-speed data path between the processor and an SMC device. For SMC-R, the device is an attached "RoCE" feature. For SMC-D, the device is the ISM device.

**Physical network ID (PNetID)**

A value that is defined to uniquely identify your physical layer 2 LAN fabric or physical broadcast domain. You can use this value to logically associate the System z features, adapters, and ports to be physically connected to your network. You specify the PNetID in a single step within the

hardware configuration definition (HCD), and all operating systems of all associated central processor complexes (CPCs) can dynamically learn and use this definition.

**RDMA network interface card (RNIC)**

"RoCE" feature that enables Remote Direct Memory Access by managing low-level functions that are typically handled by the TCP/IP stack.

**RDMA over Converged Ethernet (RoCE)**

An InfiniBand Trade Association (IBTA) standard that enables Remote Direct Memory Access over Converged Ethernet.

**Redundancy level**

For an SMC-R link group, this value indicates the level to which z/OS Communications Server can provide dynamic failover processing if there is a failure of an underlying "RoCE" interface or the associated network hardware.

**Reliable connected queue pair (RC QP)**

A logical connection between two virtual servers that enables that specific pair of servers to use RDMA communications between themselves.

**Remote Direct Memory Access (RDMA)**

A high-speed, low-latency network communications protocol in which data is transferred directly to the memory of a remote host with no involvement from the remote host processors or operating system.

**Remote memory buffer (RMB)**

Local memory that is used to receive inbound data over an SMC-R link. The remote peer places TCP socket application data directly into the RMB that the local peer assigns to receive data for the TCP connection. The local peer then copies the data from the RMB into the receive buffer of the receiving socket application.

**Rendezvous processing**

The sequence of TCP connection management flows that are required to establish SMC communications between two peers.

**RMB element (RMBE)**

The specific portion of an RMB that is associated with a specific TCP connection. Each RMB is partitioned into RMBEs.

***RoCE***

A generic term for *RoCE* shown in italics, indicating that the reference is not unique to a specific *RoCE* feature but is a general reference to *RoCE* capability that exists on all *RoCE* features

**RoCE Express or Network Express**

Generic terms for IBM RoCE features. When these terms are used, it is not necessary to include the specific bandwidth or level of the feature. When a reference is unique to a specific RoCE feature, then the specific full feature name will be used.

**Shared RoCE Environment**

Multiple operating system instances (LPARs) or TCP/IP stacks can concurrently use or share the same physical *RoCE* feature. *RoCE* features operate in a shared environment even if only one operating system instance is configured to use the feature.

**SMC-D link**

A logical representation of communication between two virtual servers that use SMC-D protocols. The concept of an SMC-D link exists primarily for operational consistency with SMC-R processing.

**SMC-R link**

A logical point-to-point link between two virtual servers that is used for SMC-R communications.

**SMC-R link group**

A logical grouping of equal SMC-R links between two communicating peers.

**Staging buffer**

Memory that the TCP/IP stack allocates for outbound SMC-R data. Staging buffers are not associated with specific SMC-R links or link groups, and are used by all TCP connections that traverse SMC-R links on this stack. Only local applications access the staging buffer storage.

**Virtual channel ID (VCHID)**

A 2-byte hexadecimal value that is used to uniquely define an ISM device.

## Using Shared Memory Communications

---

There are some configuration considerations and environment setup steps before you can configure and use Shared Memory Communications over RDMA (SMC-R) or Shared Memory Communications - Direct Memory Access (SMC-D).

**Tip:** You can use the SMC Applicability Tool (SMCAT) report to better understand the amount of your TCP workload that can use SMC communications. For more information about the SMCAT, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Configuration considerations for Shared Memory Communications

Before you configure Shared Memory Communications, consider the following factors:

- Decide whether to use VLANs. For more information, see [“VLANID considerations”](#) on page 546.
- Identify the physical connections between stacks and SMC devices. For more information, see [“Physical network considerations”](#) on page 547.
- Provide physical redundancy for high availability when using SMC-R. For more information, see [“SMC-R high availability considerations”](#) on page 550.
- Verify the system and network requirements.
  - For more information about system requirements for SMC-R, see [“System requirements for SMC-R using RoCE-Express”](#) on page 557, and [“Network requirements for SMC-R”](#) on page 558.
  - For more information about system requirements for SMC-D, see [“System requirements for SMC-D”](#) on page 559.

### VLANID considerations

The VLANID operand is optional on the following SMC capable interfaces:

- IPAQENET and IPAQENET6 INTERFACE statements with the OSD channel path ID type (CHPIDTYPE OSD)
- EQENET and EQENET6 INTERFACE statements with the OSH channel path ID type (CHPIDTYPE OSH)
- IPAQIDIO and IPAQIDIO6 INTERFACE statements (SMC-D support only)

On a specific OSA or HiperSockets interface basis, z/OS Communications Server enforces consistent VLAN definitions for INTERFACE statements that are associated with the same OSA or HiperSockets TRLE.

For example, when VLANs are not defined, the stack configuration allows only a single INTERFACE statement, and the VLANID operand is omitted on that INTERFACE statement. When VLANs are defined, multiple INTERFACE statements are allowed and each INTERFACE statement must specify a unique VLANID value.

The OSA VLAN attributes of the OSA interface are propagated to the "RoCE" interfaces (associated RNIC) or ISM interfaces (associated ISM) that have the same physical network identifier (PNetID) value. The HiperSockets VLAN attributes on the IPAQIDIO or IPAQIDIO6 interface are propagated to the ISM interfaces that have the same PNetID value. See [Physical network considerations](#) for more details on PNetID.

### SMC-R VLANID usage for RoCE features

Whether SMC-R communications use virtual LANs depends on the definition of the SMC-R capable OSA interfaces that are extended to the associated RoCE interfaces. The RoCE feature can be shared by TCP/IP stacks that are configured to use different VLAN ID definitions. The number of VLAN IDs you can configure per RoCE port depends on the generation of the feature. The 10 GbE RoCE Express feature supports up to

126 VLANs per port and up to 16 VLANs per virtual function (VF) or PFID. The number of unique VLAN IDs defined on the RoCE Express2, RoCE Express3 and Network Express features are not limited..

**Result:** Multiple VF representations of the same 10 GbE RoCE Express feature can use the same VLANID value, and only one of the available 126 VLANID values is used.

**Result:** If you define more unique VLANID values for one PNetID on the SMC-R capable INTERFACE statements than the 10 GbE RoCE Express feature can support, the VLANID values of the last INTERFACE statements to be activated are not registered with the 10 GbE RoCE Express feature. The IPAQENET or IPAQENET6 interfaces can start, but TCP connections that are established over these interfaces cannot use SMC-R communications. Netstat ALL/-A reports that display the TCP connections include the following diagnostic information for the connection:

```
SMCRSTATUS: INACTIVE
SMCREASON: 00005206 - VLAN ID NOT FOUND
```

## SMC-D VLANID usage

Whether SMC-D communications use virtual LANs depends on the definition of the SMC-D capable OSA or HiperSockets interfaces that are extended to the associated ISM interfaces. The ISM device can be shared by TCP/IP stacks that are configured to use different VLAN capabilities for the ISM device. Each TCP/IP stack, or virtual function (VF), can use up to 64 unique VLANID values per ISM interface.

**Result:** If you define more unique VLANID values for one PNetID on the SMC-D capable INTERFACE statements than the ISM device can support, the VLANID values of the last INTERFACE statements to be activated are not registered with the ISM device. The IPAQENET, IPAQENET6, EQENET, EQENET6, IPAQIDIO, or IPAQIDIO6 interfaces can start, but TCP connections that are established over these interfaces cannot use SMC-D communications. Netstat ALL/-A reports that display the TCP connections include the following diagnostic information for the connection:

```
SMCDSTATUS: INACTIVE
SMCREASON: 00005206 - VLAN ID NOT FOUND
```

The usage of VLAN IDs for ISM have changed for SMC Version 2. For details of the SMC-Dv2 VLAN ID usage for ISM, see [“SMC-Dv2 and ISM VCHID Association using PNetIDs” on page 570](#).

## Physical network considerations

The TCP/IP stack must be able to determine which physical network is connected to a particular "RoCE" or ISM interface, so that the interface can be associated with the SMC capable IPAQENET, IPAQENET6, EQENET, EQENET6, IPAQIDIO, and IPAQIDIO6 interfaces that connect to that same physical network.

[Figure 73 on page 548](#) shows an example of three distinct and physically separated networks accessed by separate physical adapters, OSA adapters for TCP/IP and RoCE adapters for SMC-R communications. This example illustrates the physical connectivity requirements and considerations when a separate RoCE card is required for SMC-R communications. A separate RoCE card is required for SMC-R when using OSA-Express for TCP/IP communications.

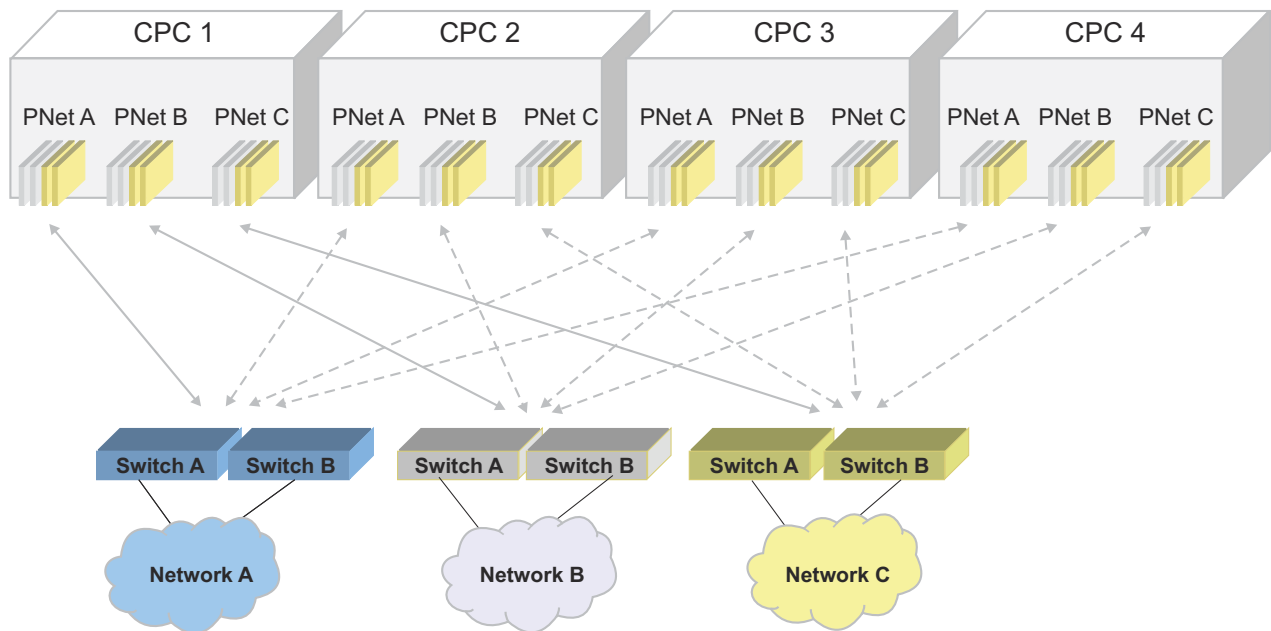

Figure 73. Physical networks for SMC-R

The concept of a physical network identifier (PNetID) was created to simplify this physical network configuration task. With the convention of a PNetID, you can define a value to represent the ID or name of your physical layer 2 LAN fabric or physical broadcast domain. The System z physical ports that are to be connected to the associated physical networks are then logically associated with their respective PNetIDs. The PNetID then becomes an attribute of the physical port of the feature or adapter, describing how this feature or adapter is physically connected to your data center network. You can specify the PNetID in a single step within the hardware configuration definition (HCD), enabling all operating systems of all associated CPCs to dynamically learn and use this definition.

**Guideline:** The TCP/IP stack does not validate the layer 2 physical network topology or broadcast domain. PNetIDs are values that you assign, and the operating systems learn and use these assigned values but cannot validate them within the Ethernet switched fabric. Therefore, the operating system does not assure or enforce any physical network separation or isolation across different physical networks. To physically isolate unique physical networks, you must ensure that traffic on PNet A cannot reach hosts on PNet B.

**Note:**

- When using Network Express for RoCE connectivity a PNetID is required for all RoCE use cases, when paired with OSA-Express (OSD) using multiple adapters or when used with Network Express (OSH) as a single adapter.
- The OSA PNetID is also used for configurations and use cases, such as SMC-D and HSCI. The requirements for PNetID can also change dynamically (e.g. during failover). Planning for and configuring a PNetID (HCD) for OSA is recommended.

You can use virtual LANs (VLANs) to logically separate a physical network. If you configure multiple PNetIDs for SMC-R or SMC-D, then you must ensure that each VLAN or subnet in your configuration does not span more than one PNetID.

**Rules:**

- The physical network that a PNetID represents can include multiple subnets, but each subnet must be completely contained within a specific PNetID.
- The physical network that a PNetID represents can include multiple VLANs, but VLANs do not span PNetIDs even if they have the same VLAN number. For example VLAN 400 on PNet A is not the same VLAN as VLAN 400 on PNet B.

SMC processing requires the use of subnet masks. For more information, see [“Configuring Shared Memory Communications over RDMA” on page 560](#) and [“Configuring Shared Memory Communications - Direct Memory Access” on page 562](#).

For more information about the HCD, see [z/OS HCD Planning](#) and [z/OS HCD User's Guide](#).

## **OSA-Express and SMC-R physical network considerations**

When using OSA-Express for TCP/IP communications, a physically separate "RoCE" feature is required to use RDMA over Converged Ethernet (RoCE) on Z<sup>®</sup>. This feature is used with the existing Ethernet connectivity that OSA provides. The "RoCE" feature provides access to the same physical Ethernet fabric that is used for traditional IP connectivity provided by OSA.

The operating systems must logically group the associated physical ports of both the "RoCE" and OSA adapters based on their required physical connectivity. Each central processor complex (CPC) connects to a physical network by using both OSA and "RoCE" ports. You can use two "RoCE" ports at most to connect to a physical network at a given time, but you can use as many OSA adapters as necessary for your network bandwidth or usage requirements. An example of this logical grouping, using two OSA adapters and two "RoCE" features, is shown in [Figure 73 on page 548](#).

One TCP/IP stack can define up to 16 Peripheral Component Interconnect Express (PCIe) function ID (PFID) values. Each PFID value must match a FID value configured in the hardware configuration definition (HCD). Each PFID represents a virtual function (VF) usage of a RoCE feature, RoCE Express or Network Express. Multiple PFID values can be associated with the same physical feature and port.

To match the "RoCE" features with the correct OSA SMC-R capable adapters, you must define a PNetID value for both the "RoCE" interface (physical port) and the corresponding OSA adapters (physical port) within the HCD. The OSA ports correspond to the stack IPAQENET and IPAQENET6 interfaces. VTAM and the TCP/IP stack then dynamically learn the PNetIDs for the "RoCE" interface and the OSA interfaces when the "RoCE" interface or the OSD interface is started. The "RoCE" interface is associated with only SMC-R capable OSA interfaces that have the same PNetID value defined.

## **Network Express and SMC-R physical network considerations**

With the z17 System, the Network Express feature supports both OSA (OSH CHPID) for the TCP/IP protocol and RoCE (NETH PFID) for the SMC-R protocol on a single adapter. The requirement for a separate RoCE card is eliminated when using Network Express as your OSA for TCP/IP connectivity. This single adapter system design simplifies the requirements for RoCE physical network connectivity. In this case, the example shown in [Figure 77 on page 553](#) would eliminate the need for additional RoCE cards.

However, on z17 the Network Express can also be paired with OSA to provide RoCE (NETH) connectivity for SMC-R for eligible TCP/IP connections.

For the cases in which a separate RoCE card is required for SMC-R, the associated RoCE feature used is based on the generation of System z:

- For Systems prior to z17, RoCE Express feature is used.
- For z17 and later, Network Express feature is used.

## **SMC-D Physical Network considerations**

The ISM device does not connect to the same Ethernet fabric that the SMC-D capable OSA interfaces use. However, the operating systems must still logically group the ISM device with the OSA or HiperSockets interfaces based on their required physical connectivity. When z/OS Communications Server activates the first SMC-D capable interface for a given physical network, it also attempts to activate an ISM interface for that same physical network. The Peripheral Component Interconnect Express (PCIe) function ID (PFID) value that represents the ISM device is obtained during activation processing. The possible PFID values to use for ISM devices are configured in the hardware configuration definition (HCD).

To match the ISM device with the correct SMC-D capable OSA or HiperSockets adapters, you must define a PNetID value for both the ISM device and the corresponding OSA or HiperSockets adapter within the

HCD. The OSA ports correspond to the stack IPAQENET, IPAQENET6, EQENET and EQENET6 interfaces, and the HiperSockets adapters correspond to the stack IPAQIDIO and IPAQIDIO6 interfaces. VTAM and the TCP/IP stack dynamically obtain the PNetIDs for the ISM, OSA, and HiperSockets interfaces when the interface is started. The ISM interface is associated with only SMC-D capable OSA or HiperSockets interfaces that have the same PNetID value defined.

**Restriction:** The same physical network cannot be used for OSA and HiperSockets interfaces. If you code the same PNetID for OSA and HiperSockets interfaces for SMC-D communications, the first interface to become fully active will be enabled for SMC-D communications and the second interface will not be able to participate in SMC-D communications.

The requirements for PNetIDs for ISM have changed for SMC Version 2. For details of the SMC-Dv2 PNetID requirements for ISM, see [“SMC-Dv2 and ISM VCHID Association using PNetIDs”](#) on page 570.

## SMC-R high availability considerations

Shared Memory Communications over RDMA (SMC-R) enables high-speed peer-to-peer connections over the RDMA over Converged Ethernet (RoCE) fabric between reliable connected queue pairs (RC QPs). SMC-R defines the RC QPs as an SMC-R link, and SMC-R links are logically grouped into SMC-R link groups. For more information, see [“SMC-R links”](#) on page 538 and [“SMC-R link groups”](#) on page 539.

"RoCE" features at each host are required for SMC-R communications. After a TCP connection dynamically and successfully switches to SMC-R, it cannot revert to standard TCP/IP communications. Therefore, to achieve network high availability for SMC-R, it is critical to provide redundant physical RoCE network connectivity.

If the underlying "RoCE" interface or the associated network hardware fails, the z/OS host provides dynamic failover processing that transparently moves the TCP connections from the SMC-R links that are using the failed "RoCE" interface to another SMC-R link in the link group. If no other SMC-R link in the link group is available at the time of failure, the TCP connections are lost. To have a second redundant SMC-R link within a link group, two "RoCE" interfaces must be defined and active.

Figure 74. Redundant SMC-R links in an SMC-R link group

## RoCE Express dual ports and redundancy

When using "RoCE Express" interfaces, an SMC-R link group might be considered redundant, even though the "RoCE Express" interfaces associated with SMC-R links use the same physical "RoCE Express" feature.

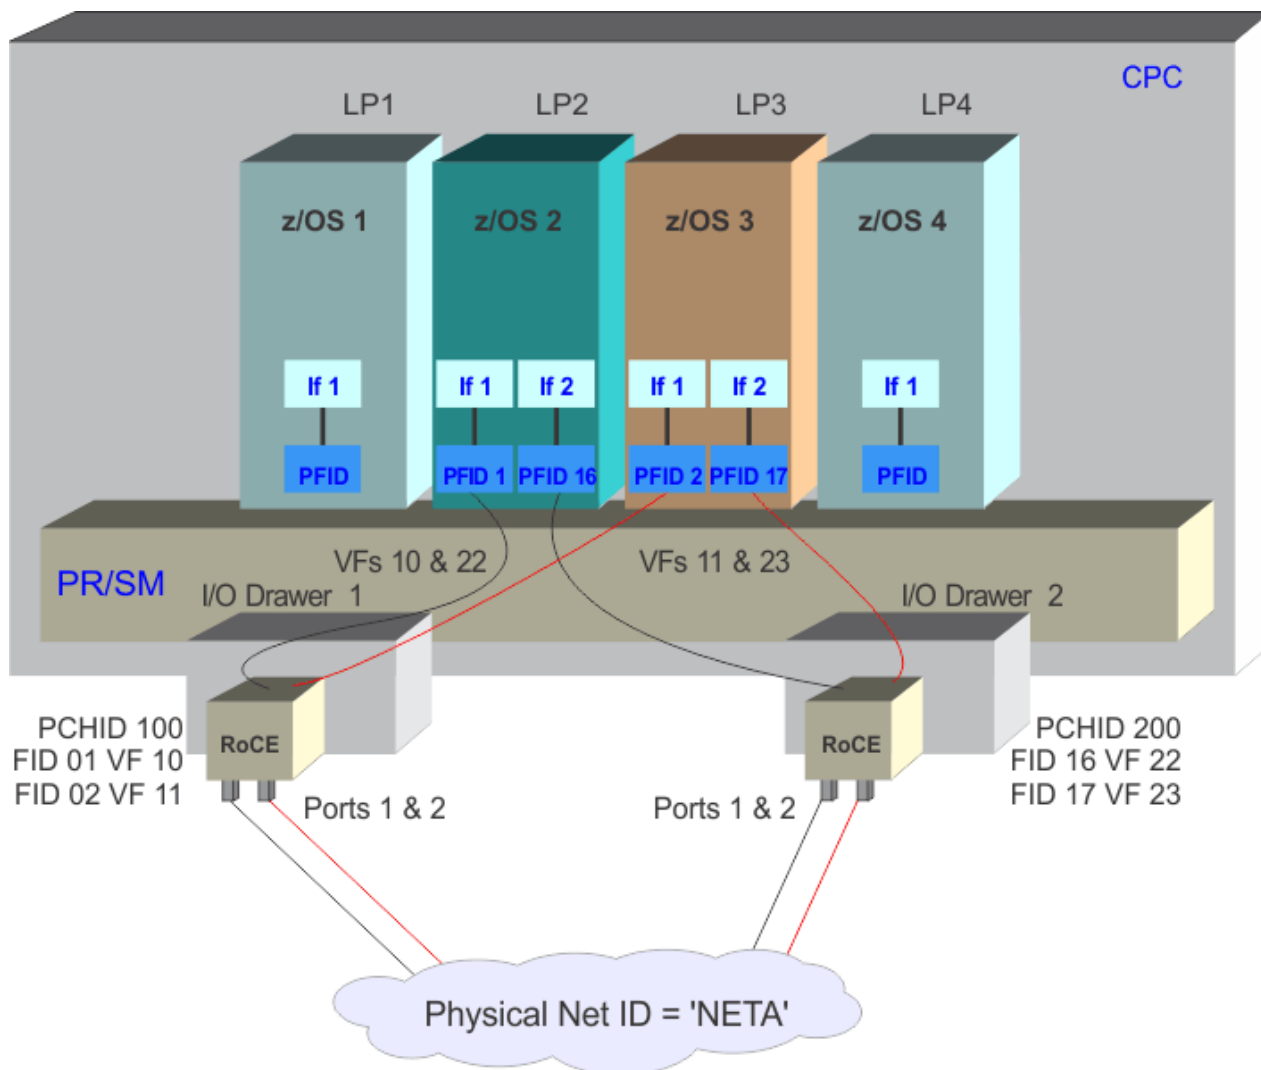

Figure 75. Misleading full redundancy configuration in a "RoCE Express" environment

For instance, in Figure 75 on page 551, z/OS 2 has multiple PFID values defined, but the PFID values represent different ports on the same "RoCE Express" feature. When TCP connections that use SMC-R are established in this configuration, an SMC-R link group, with two SMC-R links, is created. The two SMC-R links make this SMC-R link group appear to have full redundancy, but an failure involving the "RoCE Express" feature will result in failures of both PFIDs and all the associated interfaces. This in turn will cause failures for both SMC-R links within the SMC-R link group. As a result, dynamic failover processing will not occur, and TCP connections that use those SMC-R links will fail. A configuration of this type is identified by a value of "Partial (single local PCHID, unique ports)" in Netstat Devlinks/-d reports involving the SMC-R link group. For more information, see [Redundancy levels](#).

To ensure that a redundant path exists in a shared RoCE environment, you must design your connectivity to ensure that the PFID values used by a given TCP/IP stack represent physically different "RoCE Express" features. Two "RoCE Express" features are physically different if they are configured with different PCHID values.

## RoCE physical connectivity and redundancy

For achieving full physical redundancy, it is important to understand the physical differences in the RoCE Express and Network Express features. A feature represents a single point of failure. Users must define their RoCE configurations that result in the creation of SMC-R links over separate RoCE features.

For example:

- RoCE Express2 and RoCE Express3 features are a single PCHID with dual ports. The port numbers are configured in HCD.
- New Express features are logically divided and managed by the system into two separate PCHIDs. Each PCHID has single port. The port number is not configurable.

There are RoCE Express and Network Express configurations where you could be using separate RoCE physical ports, but the ports could be on the same physical feature. For full redundancy, this must be avoided (i.e. each port must be on separate features).

Figures Figure 76 on page 552 and Figure 77 on page 553 provide physical connectivity examples of RoCEv2 configurations of OSA and RoCE connectivity. Both figures provide examples of RoCEv2 configurations with full RoCE redundancy using RoCE-Express and Network Express. RoCEv2 provides “routable RoCE”. For additional information about RoCEv2, refer to “Shared Memory Communications multiple IP subnet support (SMCv2: SMC-Rv2 and SMC-Dv2)” on page 564.

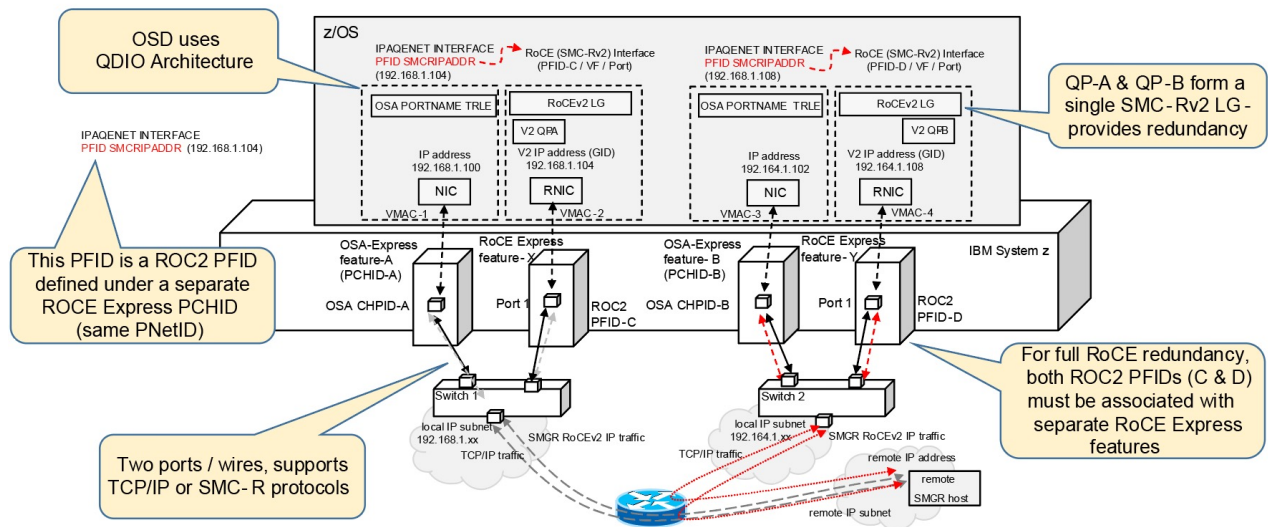

Figure 76. RoCE Express connectivity for full SMC-Rv2 Redundancy

This example illustrates full network redundancy for both OSA and RoCE using RoCE Express when configured for SMC-Rv2 / RoCEv2. A separate RoCE adapter is required when TCP/IP communications occur over OSA-Express. For this case, the SMC-R communication is provided by a separate RoCE card as follows:

- Prior to z17 a separate RoCE Express feature (ROC2 PFID) is required (as shown here)
- For z17 and after, a Network Express feature (NETH PFID) is required. For this case, you can use this same figure and substitute Network Express (NETH PFIDs) for the RoCE adapters.

**Note:** Matching PNetIDs are required (HCD) on both the OSD and RoCE PCHIDs.

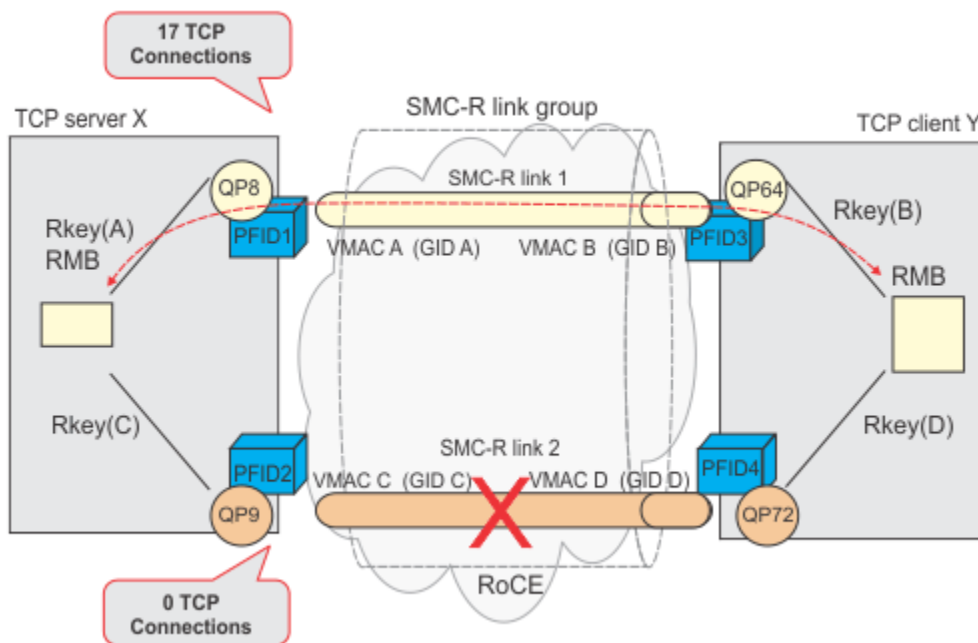

Figure 78. Failover processing within an SMC-R link group

Figure 74 on page 550 and Figure 78 on page 554 do not show the RoCE switches, but ideally, redundant physical switches are also present.

If both SMC-R peers do not have multiple active "RoCE" interfaces, then the SMC-R link group does not provide an ideal level of TCP connection resiliency. Figure 79 on page 554 is an example of a configuration where one peer (the server host) has two active "RoCE" interfaces, but the other peer (the client host) has just one. In this situation, the server still creates two SMC-R links, one per active interface, so the server can still move the TCP connections between SMC-R links if a "RoCE" interface fails. The client, however, cannot move the TCP connections if its "RoCE" interface fails because no alternative path exists. Because only one peer can provide recovery capability, this configuration has partial redundancy.

Figure 79. Partially redundant SMC-R links

If neither the server or the client has multiple active "RoCE" interfaces, as shown in Figure 80 on page 555, then the SMC-R link group is composed of a single SMC-R link. If a "RoCE" interface fails in this

configuration, the TCP connections cannot be recovered or moved, so they are all lost. This type of SMC-R link is called a single link, and the configuration has no redundancy capability.

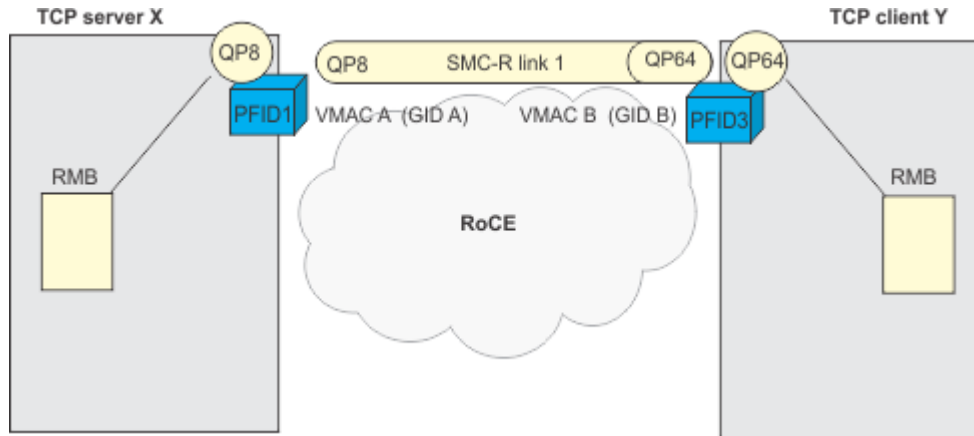

Figure 80. SMC-R link group with no redundant link

## Redundancy levels

System z also provides redundant internal Peripheral Component Interconnect Express (PCIe) hardware support infrastructures for the PCIe-based "RoCE" features. For simplicity, the System z internal PCIe infrastructure is referred to as the *internal path*. The RoCE Express feature requires a PCIe support partition. The Network Express feature does not require a PCIe support partition. The internal path of the "RoCE" features are determined based on how the features are plugged into the System z I/O drawers. To have full "RoCE" hardware redundancy on System z, each feature must have unique internal paths. For more information about the System z I/O drawer configurations and card plugging guidelines, see your IBM Service representative.

A complete high availability solution, therefore, requires the following setup between two SMC-R peers:

- Two unique physical "RoCE" features that use unique PCHIDs (see ["SMC-R high availability considerations" on page 550](#))
- Unique system PCIe support infrastructures, or internal paths, for the two features
- Unique physical RoCE switches

From the perspective of the local stack, the physical network topology and the internal path configuration at the remote system to the remote adapters are not visible. z/OS Communications Server can evaluate and report a redundancy level that is based only on the known local factors. If the local stack has two unique "RoCE" features that have unique internal paths, then an SMC-R link group with two redundant SMC-R links is considered to have full redundancy.

Table 28 on page 556 shows the reported redundancy levels with a description of each level. The values that are listed here represent the values that are displayed for an SMC-R link group in a Netstat DEVlinks/-d report. For an example of the [Netstat DEVlinks/-d report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

| Table 28. Redundancy levels                |                                       |                                                            |                                                                                                                                                                                                                                                                                                                                                  |
|--------------------------------------------|---------------------------------------|------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Redundancy level                           | SMC-R link group with redundant links | Unique "RoCE" features have unique physical internal paths | Description                                                                                                                                                                                                                                                                                                                                      |
| Full                                       | Yes                                   | Yes                                                        | Full local hardware redundancy<br><b>Rule:</b> Hardware redundancy must be verified at each host. The internal path at the remote host is not visible to the local host and therefore is not considered.                                                                                                                                         |
| Partial (single local internal path)       | Yes                                   | No                                                         | The local "RoCE" features share an internal System z PCIe adapter support infrastructure (hardware internal path). This hardware configuration provides a single point of failure, so full redundancy cannot be guaranteed.                                                                                                                      |
| Partial (single local PCHID, unique ports) | Yes                                   | No                                                         | The local "RoCE Express" features use the same PCHID but unique ports. The local "Network Express" features use the different PCHIDs but both PCHIDs are the same Network Express feature. Using the same PCHID (RoCE Express) or the same feature (Network Express) creates a single point of failure, so full redundancy cannot be guaranteed. |
| Partial (single local PCHID and port)      | Yes                                   | No                                                         | The local "RoCE" features use the same PCHID and port. Using the same PCHID and port creates a single point of failure, so full redundancy cannot be guaranteed.                                                                                                                                                                                 |
| Partial (single local RNIC)                | No                                    | N/A                                                        | The link group has only a single active feature on the local host, but multiple active features are available to the remote host.                                                                                                                                                                                                                |
| Partial (single remote RNIC)               | No                                    | N/A                                                        | The link group has only a single active feature on the remote host, but multiple active features on the local host.                                                                                                                                                                                                                              |
| None (single local and remote RNIC)        | No                                    | N/A                                                        | The link group has only a single active feature on both the local and the remote host.                                                                                                                                                                                                                                                           |

**Note:** The "Redundancy levels" apply to both RoCE Express and Network Express. In both cases to achieve full redundancy, it is necessary to configure two unique RoCE hardware features or adapters. Network Express simplifies the configuration requirements when using a single adapter for both OSA and RoCE functions.

### Associating OSA-Express and RoCE features

When OSA-Express is used for TCP/IP communications and SMC-Rv1 is configured (i.e. PFID is not defined on the OSD INTERFACE statement), the eligible RoCE features must be found and associated with each OSA-Express interface. The following topic describes this association processing as it applies to redundancy.

**Note:** SMC-Rv2 simplifies the OSA and RoCE association process by using the user defined PFID value on the IPAQENET INTERFACE statement.

A "RoCE" interface that is associated with an SMC-R capable interface because it has the same physical network ID is referred to as an *associated RNIC interface*. More than two "RoCE" interfaces can be defined with the same physical network ID, but the TCP/IP stack creates SMC-R link groups that use no more than two associated RNIC interfaces at any particular time. The "RoCE" interfaces are considered to be associated RNIC interfaces for IPAQENET and IPAQENET6 interfaces that match all of the following characteristics:

- The interfaces are active.
- The interfaces are defined by the INTERFACE statement with the OSD channel path ID type (CHPIDTYPE OSD).
- The interfaces are enabled for SMC-R communications.
- The interfaces have matching PNetID values.

Associated RNIC interfaces are displayed in the Netstat DEvlinks/-d OSD report. For an example of the Netstat DEvlinks/-d report, see [z/OS Communications Server: IP System Administrator's Commands](#).

Any additional "RoCE" interfaces that have the matching PNetID are started, but they are not used to provide for added link level load-balancing purposes. Instead, the extra "RoCE" interfaces are held in reserve for use if one of the associated RNIC interfaces fails.

For instance, in [Figure 78 on page 554](#), if "RoCE" interface 2 (shown as PFID2) on the server host fails, the TCP connections that were using SMC-R link 2 across interface 2 are switched to SMC-R link 1. The SMC-R link group loses its level of full link redundancy because only SMC-R link 1 is active. However, if another "RoCE" interface, call it PFID 5, were active on the server host, and PFID 5 had the same PNetID value as PFID 1 and PFID 2, the server can immediately activate new SMC-R links across PFID 5 to the client host to reestablish full link redundancy. If PFID 5 and PFID 1 have unique physical paths, then full redundancy is also restored. This new SMC-R link is used for TCP connections within the link group. If PFID 2 recovers, it now serves as a standby PFID and can be used if either PFID 1 or PFID 5 fails.

You can also use extra PFIDs for planned outages, such as to schedule an upgrade to the "RoCE" features.

## System and network requirements for Shared Memory Communications

Depending on what type of Shared Memory Communications (SMC) you will use, the system requirements are different. In addition, SMC-R imposes additional network requirements.

If you will use both SMC-R and SMC-D, you must ensure that the system and network requirements for each type of processing are met.

### **System requirements for SMC-R using RoCE-Express**

You need to ensure that your system meets the requirements to use Shared Memory Communications over RDMA (SMC-R) with "RoCE Express" features.

To use SMC-R with RoCE Express2 features, the minimum software requirements are:

- z/OS Version 2 Release 1 with APARs OA51949 and PI75199 applied
- z/OS Version 2 Release 2 with APARs OA51950 and PI75200 applied

To use SMC-R with RoCE Express3 features, the minimum software requirements are:

- z/OS Version 2 Release 3 and z/OS Version 2 Release 4 with APARs OA60855 and PH34117 applied

SMC-R requires RDMA over Converged Ethernet (RoCE) hardware and firmware support. The following minimum hardware requirements must be met to use SMC-R:

- If you use 10 GbE RoCE Express features, you must have IBM z13 (z13) or later systems.
- If you use RoCE Express2 features, you must have IBM z14® or later systems
- If you use RoCE Express3 features, you must have IBM z16 or later systems
- You must have one or more IBM 10 GbE RoCE Express, RoCE Express2, or RoCE Express3 features.

"RoCE Express" features are dual ports with short range (SR) optics and can be shared across multiple operating systems images or TCP/IP stacks in a central processor complex (CPC). RoCE Express3 features are also available with long range (LR) optics beginning with IBM z16.

**Guideline:** Provide two "RoCE Express" features per unique physical network. For more information, see ["RoCE network high availability" on page 559](#).

- You must have System z OSA-Express for traditional Ethernet LAN connectivity.

SMC-R does not impose any specific OSA requirements.

- You must have standard 10 GbE or 25 GbE switches.
- If you configure more than 24 Peripheral Component Interconnect Express (PCIe) devices, you must configure the IEASYSxx LFAREA parameter. The 24 PCIe devices include all z/OS Communications Server PCIe devices and other z/OS PCIe devices. In z/OS Communications Server, you can configure the following PCIe devices:
  - IBM 10 GbE RoCE Express features
  - RoCE Express2 features
  - RoCE Express3 features
  - Internal shared memory (ISM) devices

For more information about specifying the IEASYSxx LFAREA parameter, see [z/OS MVS Initialization and Tuning Guide](#).

### **System requirements for SMC-R using Network Express on IBM z17 or later environment**

You need to ensure that your system meets the requirements to use Shared Memory Communications over RDMA (SMC-R) with "RoCE Express" features.

To use the Network Express feature for OSA or SMC-R the minimum software requirements are::

- z/OS Version 2 Release 5 and z/OS Version 3 Release 1 with APARs OA64896 and PH54596
- One or more Network Express features. Network Express features are divided and managed by the system as two separate PCHIDs each with a single port. The PCHIDs can be shared across multiple operating systems images or TCP/IP stacks in a central processor complex (CPC).

**Guidelines:** Provide two Network Express features per unique physical network. For more information on RoCE network high availability, see [“Network requirements for SMC-R”](#) on page 558.

- Either an OSA-Express or Network Express feature for TCP/IP communications for traditional Ethernet LAN connectivity. SMC-R does not impose any specific OSA requirements.
- Standard 10 GbE or 25 GbE switches
- The IEASYSxx LFAREA parameter if you configure more than 24 Peripheral Component Interconnect Express (PCIe) devices. The 24 PCIe devices include all z/OS Communications Server PCIe devices and other z/OS PCIe devices. In z/OS Communications Server, you can configure the following PCIe devices:
  - Network Express features
  - Internal shared memory (ISM) devices

For more information about specifying the IEASYSxx LFAREA parameter, see [z/OS MVS Initialization and Tuning Guide](#).

### **Network requirements for SMC-R**

You need to ensure that your system meets the network requirements to use SMC-R with "RoCE" features.

This topic has unique considerations for SMC-Rv1. For additional information about the network requirement differences for SMC-Rv2, see [“Shared Memory Communications multiple IP subnet support \(SMCv2: SMC-Rv2 and SMC-Dv2\)”](#) on page 564.

z/OS Communications Server supports connectivity to multiple, distinct layer 2 networks through unique physical LANs. Each unique physical network is identified by existing Ethernet standards that are based on the physical layer 2 broadcast domain. You can define a physical network ID (PNetID) for each physical network. For more information, see [“OSA-Express and SMC-R physical network considerations”](#) on page 549.

For hosts to communicate by using SMC-Rv1, they must connect directly to the same Ethernet layer 2 LAN network. If VLANs are in use, each host must also have access to the same VLAN. For more information, see [“SMC-R VLANID usage for RoCE features”](#) on page 546.

There are restrictions on the physical distances that can be used to route RDMA frames. To understand these distance specifications and limitations, see *IBM z Systems Planning for Fiber Optic Links*.

## RoCE network high availability

This topic has unique considerations for SMC-Rv1. For additional information about the network requirement differences for SMC-Rv2, see [“Shared Memory Communications multiple IP subnet support \(SMCv2: SMC-Rv2 and SMC-Dv2\)”](#) on page 564.

Because RoCE connections do not use IP routing and the RDMA connections to remote hosts are direct point-to-point connections that use reliable connected queue pairs (RC QPs), there is no concept of an alternative IP route to the peer. SMC-R connectivity is possible with a single "RoCE Express" feature, but a loss in that single feature means that the associated TCP connections and workloads are disrupted. Therefore, redundant "RoCE Express" features on both the local and remote hosts are required to achieve network high availability with SMC-R. If your TCP workloads require high availability, redundant "RoCE Express" features and redundant Ethernet switches are required. The SMC-R protocol actively uses both features, rather than using one feature with the other in standby mode. For more information, see [“SMC-R high availability considerations”](#) on page 550.

"RoCE Express" features also have redundant internal PCIe support structures, or PCIe internal paths, as described in [“Redundancy levels”](#) on page 555. To avoid another single point of failure, install each "RoCE Express" feature that is managed by the same operating system with a unique internal path. For more information about how to install a "RoCE Express" feature to achieve full redundancy, see your IBM service representative.

## RoCE bandwidth

The "RoCE" features provide 10 and 25 GbE ports. When redundant features are defined, SMC-R link groups can be formed by using both features, resulting in a logical pipe with double the single adapter bandwidth (i.e. 20 or 50 GbE) to each physical network. z/OS Communications Server uses only two features within a link group at any time.

## System requirements for SMC-D

You need to ensure that your system meets the system requirements to use SMC-D.

To use Shared Memory Communications - Direct Memory Access (SMC-D), the minimum software requirement is z/OS Version 2 Release 2 with APARs OA48411 and PI45028 applied, and the minimum hardware requirement is IBM z13<sup>®</sup> GA2 or later systems.

If you configure more than 24 Peripheral Component Interconnect Express (PCIe) devices, you must configure the IEASYSxx LFAREA parameter. The 24 PCIe devices include all z/OS Communications Server PCIe devices and other z/OS PCIe devices. In z/OS Communications Server, you can configure the following PCIe devices:

- 10 GbE RoCE Express features
- RoCE Express2 features
- RoCE Express3 features
- Network Express features
- Internal shared memory (ISM) devices

For more information about specifying the IEASYSxx LFAREA parameter, see [z/OS MVS Initialization and Tuning Guide](#).

## Setting up the environment for Shared Memory Communications over RDMA

Before you configure Shared Memory Communications over RDMA (SMC-R), follow these steps to ensure that other components are configured.

### Before you begin

Review [“Configuration considerations for Shared Memory Communications”](#) on page 546.

## Procedure

Perform the following steps to prepare to use SMC-R:

1. Install and configure the "RoCE" features in the hardware configuration definition (HCD).  
Logical partition (LPAR) access lists must be provided for the "RoCE" features.
2. Assign physical network ID (PNetID) values, and configure the values in the HCD for both the "RoCE Express" ports and any OSA-Express devices that will use the "RoCE Express" ports for SMC-R communications.

**Note:** When using the Network Express feature for TCP/IP communications, then the same physical port configured as a NETH PFID also provides RoCE communications. PNetID must be configured in HCD for this case.

3. Provide for redundant system PCIe internal paths for the defined "RoCE" features.  
For more information, see [“Redundancy levels” on page 555](#).

4. Configure Ethernet switches for RDMA functionality.

RDMA processing requires standard 10 GbE switch support, and distance limitations might exist. Enable the global pause frame (a standard Ethernet switch feature for Ethernet flow control that is described in the IEEE 802.3x standard) on the switch. You might also need to configure the switch to indicate whether you use VLANs.

For more information, see [“Network requirements for SMC-R” on page 558](#).

## Configuring Shared Memory Communications over RDMA

Use these steps to configure and begin to use Shared Memory Communications over RDMA (SMC-R).

### Before you begin

See [“Setting up the environment for Shared Memory Communications over RDMA” on page 559](#).

## Procedure

Perform the following steps to configure SMC-R:

1. Configure the SMCR parameter on the GLOBALCONFIG statement in the TCP/IP profile. The SMCR parameter enables SMCR for the entire TCP/IP stack.

The SMCR parameter includes the following subparameters:

**Note:** The PFID subparameter (along with PORTNUM and MTU) are only required if you need to enable SMC-Rv1. SMC-Rv2 users define PFID on the OSA interface statements.

- PFID specifies the PCI Express (PCIe) function ID (PFID) value for a "RoCE" feature that this stack uses for SMC-Rv1 communications.

You must code at least one PFID subparameter for this stack to use SMC-Rv1, and two PFIDs per PNetID per stack for redundancy.

**Note:** The PFID parameter on GLOBALCONFIG enables SMC-Rv1 for the specified PFID(s). For enabling SMC-Rv2 communications (“Routable RoCE”) see the PFID subparameter on the IPAQENET or EQENET INTERFACE statements.

When a RoCE feature is shared, each TCP/IP stack that uses the same "RoCE" feature must have a unique PFID value, even if the TCP/IP stacks are defined on different LPARs.

- PORTNUM specifies the 10 GbE RoCE Express port number to use for each PFID.

**Guideline:** For RoCE Express2 or RoCE Express3, you do not have to code PORTNUM for a PFID. The port number is defined for the PFID in the HCD, and VTAM and the TCP/IP stack learns the port number during PFID activation.

**Rule:** For Network Express there is only a single physical port per PCHID. For Network Express PORTNUM is not applicable and not configurable in Communications Server or HCD.

Configure each PFID to use only a single port. The port number can be 1 or 2; 1 is the default port number.

- MTU specifies the maximum transmission unit (MTU) to be used for this PFID. The default value is 1024. For more information, see [“SMC-R RoCE maximum transmission unit” on page 583](#).
- FIXEDMEMORY specifies the total amount of memory, in megabytes, that can be used for the staging and remote memory buffers.

The default value is 256 MB.

- TCPKEEPMININTERVAL specifies the minimum time interval, in seconds, for sending keepalive probes for TCP connections that use SMC-R protocols to exchange data.

The default value is 300 seconds. For more information, see [“TCP keepalive” on page 582](#).

The following GLOBALCONFIG statement defines two RoCE features, PFID 0018 and PFID 0019 to be enabled for SMC-Rv1 communications. Port 2 is used on each feature, and the maximum amount of 64-bit private storage that can be used for SMC-R communications is 200 megabytes. The default values for both TCPKEEPMININTERVAL and MTU are used.

```
GLOBALCONFIG SMCR
 PFID 0018 PORTNUM 2
 PFID 0019 PORTNUM 2
 FIXEDMEMORY 200
```

If PFID 0018 and PFID 0019 represent RoCE Express2 or RoCE Express3 features, you do not need to specify PORTNUM on the GLOBALCONFIG definition. PORTNUM is not applicable to Network Express features and if PORTNUM is configured it is ignored.

```
GLOBALCONFIG SMCR
 PFID 0018
 PFID 0019
 FIXEDMEMORY 200
```

For more information about these and other SMCR subparameters on the [GLOBALCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

2. (Optional) Configure the SMCR parameter on the IPAQENET and IPAQENET6 INTERFACE statements with the OSD channel path ID type (CHPIDTYPE OSD) or on the EQENET or EQENET6 INTERFACE statements with the OSH channel ID type (CHPIDTYPE OSH). The SMCR parameter on the interface statement enables or disables SMC-R communications on a per interface basis.

**Note:** The SMCR parameter can also be used to enable an interface for SMC-Rv2 communications. For additional information, see [“Enabling SMC-Rv2” on page 573](#).

**Tip:** SMCR is the default setting on the IPAQENET, IPAQENET6, EQENET and EQENET6 INTERFACE statements.

**Guideline:** If you enable Multipath and the equal-cost interfaces are associated with different IP subnets, enabling SMC for some of, but not all, the interfaces can cause unpredictable SMC usage. You must specify either SMCR or NOSMCR on all equal-cost interfaces.

3. Associate the interfaces with the appropriate subnet or prefix.

- For an IPv4 interface to be eligible for SMC-R, you must configure a nonzero subnet mask on the INTERFACE statement in the TCP/IP profile.

**Result:** SMC-Rv1 is used only between peers whose interfaces have the same subnet value.

- For an IPv6 interface to be eligible for SMC-Rv1, the interface must have at least one prefix that is associated with it.

**Rule:** A prefix can be associated to an IPv6 interface in any of these ways:

- A prefix received on a router advertisement message from an attached router
- A prefix that is configured in OMPROUTE by using the PREFIX parameter on the IPV6\_OSPF\_INTERFACE, IPV6\_RIP\_INTERFACE, or IPV6\_INTERFACE statement

- A direct static prefix route that is configured over the interface on a ROUTE statement in a BEGINROUTES block in the TCP/IP profile

**Result:** SMC-Rv1 is used only between peers whose IPv6 interfaces have at least one prefix in common.

4. (Optional) If you are using VLANs for your SMC-R communications, configure the VLANID parameter on the IPAQENET and IPAQENET6 INTERFACE statements.

For more information, see [“VLANID considerations”](#) on page 546.

5. (Optional) If you have a server application that primarily uses short-lived TCP connections, you might want to avoid SMC-R rendezvous processing for TCP connections that are using that server port.

Configure NOSMC on the PORT statement or PORTRANGE statement for the server port or ports that this server application uses. For more information, see [z/OS Communications Server: IP Configuration Reference](#).

6. Start the IPAQENET, IPAQENET6, EQENET and EQENET6 interfaces.

When the first SMC-R capable OSA interface becomes active, z/OS Communications Server automatically starts all PFIDs that are defined in the GLOBALCONFIG statement for SMC-Rv1 communications, and associates the "RoCE" interfaces with the OSA interfaces that have matching physical network IDs (PNet IDs). For more information about PNet IDs, see [“OSA-Express and SMC-R physical network considerations”](#) on page 549.

## What to do next

For information about how SMC-R interacts with other functions, see [“SMC interactions with other z/OS Communications Server functions”](#) on page 580.

For information about managing SMC-R communications, see [“Managing SMC communications”](#) on page 583.

## Setting up the environment for Shared Memory Communications - Direct Memory Access

Before you configure Shared Memory Communications - Direct Memory Access (SMC-D), follow these steps to ensure that other components are configured.

### Before you begin

Review [“Configuration considerations for Shared Memory Communications”](#) on page 546.

### Procedure

Assign physical network ID (PNetID) values, and configure the values in the HCD for both the ISM devices and any OSA or HiperSockets devices that will use the ISM device for SMC-D communications.

## Configuring Shared Memory Communications - Direct Memory Access

Use these steps to configure and begin to use Shared Memory Communications - Direct Memory Access (SMC-D).

### Before you begin

See [“Setting up the environment for Shared Memory Communications - Direct Memory Access”](#) on page 562.

### Procedure

Perform the following steps to configure SMC-D:

1. If you are using IPv4 IPAQIDIO DEVICE, LINK, and HOME definitions, convert them to INTERFACE definitions.

SMC-D processing is provided for only HiperSockets interfaces that are configured with INTERFACE definitions. For more information about converting IPv4 IPAQIDIO DEVICE, LINK, and HOME definitions to INTERFACE definitions, see [“Steps for converting from IPv4 IPAQIDIO DEVICE, LINK, and HOME definitions to the IPv4 IPAQIDIO INTERFACE statement”](#) on page 96.

2. Configure the SMCD parameter on the GLOBALCONFIG statement in the TCP/IP profile.

The SMCD parameter includes the following subparameters:

- FIXEDMEMORY specifies the total amount of memory, in megabytes, that can be used for the direct memory buffers. The default value is 256 MB.
- TCPKEEPMININTERVAL specifies the minimum time interval, in seconds, for sending keepalive probes for TCP connections that use SMC-D protocols to exchange data. The default value is 300 seconds. For more information, see [“TCP keepalive”](#) on page 582.

For more information about SMCD subparameters on the GLOBALCONFIG statement, see [z/OS Communications Server: IP Configuration Reference](#).

3. (Optional) Configure the SMCD parameter on the IPAQENET, IPAQENET6 EQENET, and EQENET6 INTERFACE statements.

**Tip:** SMCD is the default setting on the IPAQENET, IPAQENET6, EQENET and EQENET6 INTERFACE statements.

**Tip:** When the EZAZCX and EZ6ZCX interfaces are automatically generated to support IPv4 or IPv6 zCX instances, these interfaces are enabled for SMC-Dv2 communications by default.

**Guideline:** If you enable Multipath and the equal-cost interfaces are associated with different IP subnets, enabling SMC for some of, but not all, the interfaces can cause unpredictable SMC usage. You must specify either SMCD or NOSMCD on all equal-cost interfaces.

4. (Optional) Configure the SMCD parameter on the IPAQIDIO and IPAQIDIO6 INTERFACE statements.

**Tip:** SMCD is the default setting on the IPAQIDIO and IPAQIDIO6 INTERFACE statements.

**Guideline:** If you enable Multipath and the equal-cost interfaces are associated with different IP subnets, enabling SMC for some of, but not all, the interfaces can cause unpredictable SMC usage. You must specify either SMCD or NOSMCD on all equal-cost interfaces.

5. Associate the interfaces with the appropriate subnet or prefix.

- For an IPv4 interface to be eligible for SMC-D, you must configure a nonzero subnet mask on the INTERFACE statement in the TCP/IP profile.

**Result:** SMC-D is used only between peers whose interfaces have the same subnet value. SMC-Dv2 supports SMC-D across multiple IP subnets. For more information, see [“Shared Memory Communications multiple IP subnet support \(SMCv2: SMC-Rv2 and SMC-Dv2\)”](#) on page 564.

- For an IPv6 interface to be eligible for SMC-D, the interface must have at least one prefix that is associated with it.

**Rule:** A prefix can be associated to an IPv6 interface in any of these ways:

- A prefix that is received on a router advertisement message from an attached router
- A prefix that is configured in OMPROUTE by using the PREFIX parameter on the IPV6\_OSPF\_INTERFACE, IPV6\_RIP\_INTERFACE, or IPV6\_INTERFACE statement
- A direct static prefix route that is configured over the interface on a ROUTE statement in a BEGINROUTES block in the TCP/IP profile

**Result:** SMC-Dv1 is used only between peers whose IPv6 interfaces have at least one prefix in common. SMC-Dv2 supports SMC-D across multiple IPv6 prefix values. For more information, see [“Shared Memory Communications multiple IP subnet support \(SMCv2: SMC-Rv2 and SMC-Dv2\)”](#) on page 564.

6. If you use VLANs for your SMC-D communications, configure the VLANID parameter on the IPAQENET, IPAQENET6, EQENET and EQENET6 INTERFACE and on the IPAQIDIO and IPAQIDIO6 INTERFACE statements.

For more information, see [“VLANID considerations”](#) on page 546.

7. If you have a server application that primarily uses short-lived TCP connections, you might avoid SMC-D rendezvous processing for TCP connections that are using that server port.

Configure the NOSMC parameter on the [PORT](#) statement or [PORTRANGE](#) statement for the server port or ports that this server application uses. For more information, see [z/OS Communications Server: IP Configuration Reference](#).

8. Start the IPAQENET, IPAQENET6, EQENET and EQENET6 interfaces, or the IPAQIDIO and IPAQIDIO6 interfaces.

When the first SMC-D capable OSA or HiperSockets interface becomes active for a given physical network ID (PNetID), z/OS Communications Server automatically looks for an available ISM device with a PNetID value that matches the PNetID value of the OSA or HiperSockets interface. If a matching ISM device is available, VTAM activates the ISM device and provides the associated PFID to the TCP/IP stack. For more information about PNetIDs, see [“Physical network considerations”](#) on page 547. For details of the SMC-Dv2 PNetID requirements for ISM, see [“SMC-Dv2 and ISM VCHID Association using PNetIDs”](#) on page 570.

### What to do next

For information about how SMC interacts with other functions, see [“SMC interactions with other z/OS Communications Server functions”](#) on page 580.

For information about managing SMC communications, see [“Managing SMC communications”](#) on page 583.

## Shared Memory Communications multiple IP subnet support (SMCv2: SMC-Rv2 and SMC-Dv2)

---

The initial version of SMC was limited to TCP/IP connections over the same layer 2 network and therefore was not routable across multiple IP subnets. The associated TCP/IP connection was limited to hosts within a single IP subnet requiring the hosts to have direct access to the same physical layer 2 network (i.e. same Ethernet LAN over a single VLAN ID). The scope of eligible TCP/IP connections for SMC was limited to and defined by the single IP subnet.

SMC Version 2 (SMCv2) provides support for SMC over multiple IP subnets for both SMC-D and SMC-R and is referred to as SMC-Dv2 and SMC-Rv2. SMCv2 requires updates to the underlying network technology. SMC-Dv2 requires ISMv2 and SMC-Rv2 requires RoCEv2.

In some of the following topics it will be necessary to distinguish the SMC-Dv2 or SMC-Rv2 support from the initial SMC-D or SMC-R support. For this reason, the initial version of SMC support is now referred to as SMC-Dv1 or SMC-Rv1. The SMCv2 protocol is downward compatible allowing SMCv2 hosts to continue to communicate with SMCv1 down-level hosts.

Many architectural aspects of SMCv2 apply to both SMC-Dv2 and SMC-Rv2. The common SMCv2 topics are described first, followed by the topics that are unique to SMC-Dv2 and SMC-Rv2. While SMCv2 changes the SMC connection protocol enabling multiple IP subnet support, SMCv2 does not change how actual user TCP socket data is transferred, which preserves the benefits of SMC to TCP workloads.

TCP/IP connections that require IPsec are not eligible for any form of SMC.

### SMC Enterprise ID

With SMCv2, the IP subnet no longer defines the scope of eligible TCP/IP connections. With the multiple IP subnet support, the SMCv2 administrator will require a new means for defining or limiting the scope of hosts that are eligible for SMC over multiple IP subnets. The SMC Enterprise ID (EID) defines a group of hosts that are allowed to communicate using SMCv2.

SMCv2 supports the concept of allowing the SMCv2 administrator to define a single unique ID that represents a group of systems. Systems means OS instances (z/OS or Linux), potentially many systems

or the group could be a smaller set of systems. For SMC-D, the systems must all reside (execute) on the same CPC.

While SMCv2 extends the reach of SMC to additional workloads, the objective of SMCv2 is optimizing workloads within your enterprise data center. SMC-Dv2 connections must execute on systems within the same CPC. SMC-Rv2 is not targeting long distance connections over the WAN. For SMC-Rv2, the physical proximity of and distance between your systems are key considerations.

In addition to Enterprise IDs (EIDs), SMCv2 offers administrators a more granular form of controlling SMC connection eligibility with SMC filters. SMC filters apply to all versions and types of SMC (SMC-Dv1, SMC-Dv2, SMC-Rv1, and SMC-Rv2). See [“SMC filters” on page 567](#) for more details.

## EID Concepts

Systems that are eligible to connect using SMCv2 must define a common EID. The systems could span many IP subnets. The IP subnet of the peer host's IP interface is not evaluated when determining SMCv2 connection eligibility.

The EID is a user defined identifier or UEID (User defined EID) that is defined once and then used (configured) among all systems within the group. A System EID or SEID is also available for SMC-Dv2 only and is described below.

The administrator would first identify the systems where SMC would be deployed across multiple IP subnets within their Enterprise. This could be a single group or it could be multiple groups of systems. SMC groups (EIDs) are not directly associated with other clustering technologies such as Sysplex. Instead, the SMC group is simply a group of heterogenous systems where SMC is to be permitted across multiple IP subnets.

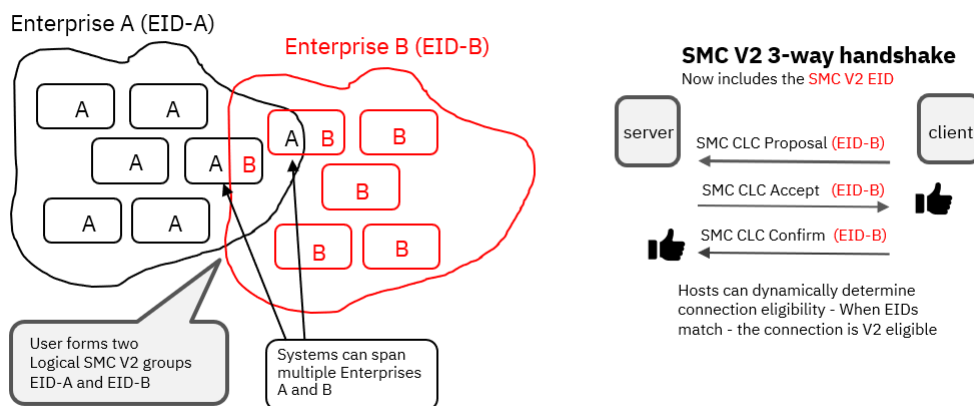

Figure 81. SMCv2 EID concepts

Each group (or groups) of systems within an Enterprise would be defined with a unique EID. The EID is an SMC configuration parameter describing a group of systems (within the Enterprise) eligible to connect over multiple IP subnets using SMCv2. The EID is not intended to represent authorization, it is not encrypted or encoded in any way. Existing TCP connection level authentication protocols such as TLS are used to control connection level authentication.

Defining globally unique user defined EIDs is important for avoiding potential conflicts with other systems, particularly systems outside your control.

The EID attributes are summarized here:

- An EID is a single ID (per unique group of systems) representing an SMC group of systems.
- The EID applies to the entire TCP/IP stack for both IPv4 and IPv6.<sup>4</sup>
- The EID is not associated to specific IP interfaces, IP networks, or IP subnetworks.

<sup>4</sup> SMC-Dv2 supports both IPv4 and IPv6. SMC-Rv2 supports IPv4 only.

- The EID is a software attribute associated with the SMCv2 protocol. The EID is not a network hardware attribute.
- The EID is exchanged within the SMCv2 connection protocol where the EIDs are dynamically evaluated during the connection setup process to determine eligibility.

## EID Format

The EID is a fixed length 32-byte character data that is a user defined ID. The EID is converted to ASCII characters when used within SMC protocol messages. The UEID supports any valid combination of the valid ASCII characters (ASCII 4) described in the EID definition below with no spaces or blanks.

The valid ASCII characters allowed for the EID are upper case A-Z, 0-9, hyphen, and dot. The first character of the EID cannot be a special character and the EID cannot contain consecutive dots.

The EID format defined by the SMCv2 wire protocol is described as follows:

|                                                                                                  |  |
|--------------------------------------------------------------------------------------------------|--|
| EID Format                                                                                       |  |
| EID: 32 ASCII character bytes                                                                    |  |
| ASCII encoding: A-Z upper case, 0-9, and delimiters (special characters) hyphen "-" and dot ".". |  |

## User Defined EID (UEID)

User defined EIDs allow administrators to create meaningful user defined Enterprise IDs that are easily recognizable. This can be helpful when performing various administrative tasks when managing and monitoring data center networks. Users can establish unique enterprise wide EID naming conventions (e.g. A400-PRODCLUSTER4, CC29-DEVCLUSTER18 etc.). The hyphen and dot allows users to compose EIDs using elements of their IT infrastructure, such as Company-Loc-Group, BusinessLine-Group, Plex®-Cluster-Type, etc.

It is recommended that all 32 characters be defined by the user. When fewer than 32 characters are defined by the administrator, the EID is padded with trailing character blanks to form a full 32-byte EID. When the EID is exchanged within SMC connection setup messages, it must be fixed length 32 bytes. Once the user initially defines the EID, the same EID must be configured in each OS that will be permitted to communicate using SMCv2 over multiple IP subnets within the same SMC group. For more information about defining the UEID, see the SMCEID parameter on the TCP/IP profile [GLOBALCONFIG statement](#) in [z/OS Communications Server: IP Configuration Reference](#).

### Tip:

In use cases in which instances of z/OS are moved between different sites (e.g. DR sites), the UEID value can be sensitive to the current physical location of the site. For this case, users should consider setting UEID based on using z/OS System Symbolics.

## Multiple EIDs

In some use cases, a single EID will be sufficient for your entire enterprise data center. In this use case, there is no recognized need to separate systems using SMCv2. There are also valid use cases where it would be beneficial to separate the systems by defining multiple SMC groups. For example, users might want to separate and control the usage based on business lines, security zones, test versus production systems or other variations. In this case, where the systems form a more homogenous grouping, a user would define each unique group across their enterprise with a unique UEID.

Typically each z/OS system would be defined with a single UEID and belong to a single SMC group. However, there are also use cases in which a z/OS system needs to reside within multiple groups supporting multiple EIDs. z/OS Communications Server allows each TCP/IP stack to define up to four user-defined EIDs. The SMCv2 protocol permits the exchange of multiple UEIDs. If a common EID is exchanged between the client and server, the TCP connection is eligible to use SMCv2.

## System EID (SEID)

SMC-Dv2 supports TCP/IP connections spanning multiple IP subnets. However, SMC-Dv2 communications are restricted to within the same CPC. Hosts must also share a common ISM VCHID. For example, two z/OS systems executing on the same CPC could establish a TCP/IP connection over OSA traversing one or more IP networks or IP router hops. The TCP connection (spanning multiple IP subnets) could be eligible to communicate internally using SMC-Dv2.

Given that SMC-Dv2 communications are restricted to a CPC, SMC-Dv2 also provides support for a system generated EID called a System EID (SEID). The SEID is automatically defined representing the CPC. The format of the SEID is consistent with the user defined EIDs. The SEID value is not defined by the user. SEID is a self-defined constant value generated by the OS encoded with system serial/type. There is a single unique SEID per CPC. The format and value of the SEID is based on IBM internal definitions described by the SMC-Dv2 protocol specifications. For more information about defining the SEID, see the `SYSTEMEID/NOSYSTEMEID` parameter on the TCP/IP profile `GLOBALCONFIG` statement in [z/OS Communications Server: IP Configuration Reference](#).

Using the SEID provides benefits in terms of ease of use by reducing the SMC-Dv2 deployment time. The SEID allows users to enable and start using SMC-Dv2 within a CPC with minimal software configuration requirements. The System EID is applicable to an entire Z CPC and it is applicable to SMC-Dv2 and ISMv2 only. In many SMC-Dv2 use cases, a single EID will be sufficient. Using the System EID enables all SMC-Dv2 capable hosts within the same CPC that also specify the SEID to communicate using SMC-Dv2.

For more information about defining SMC EIDs, see the `GLOBALCONFIG` statement in [z/OS Communications Server: IP Configuration Reference](#).

### Result:

Users should be aware that defining UEID or SEID enables SMCv2 for the stack. Defining UEID enables both SMC-Rv2 and SMC-Dv2. Defining SEID enables only SMC-Dv2 (if not already enabled by UEID).

## Using UEID or SEID

In some cases, the SEID could be too broad or too general for the various types of systems executing within the same CPC. Users who have a need for separation or isolation by creating multiple SMC groups within a CPC or who need a greater level control for other reasons have the following options:

1. Use the SEID (single EID per CPC) and then create separation of unique groups by assigning unique ISM VCHIDs to each group.
2. Use a unique UEID for each unique group allowing UEID to create the internal separation. Users who require greater levels of control can refrain from using the System EID and elect to only use UEIDs. Each unique group can either share a single ISM VCHID or each group can also use unique VCHIDs. Unique UEIDs with unique ISM VCHIDs provide the strongest form of separation.
3. Options 1 and 2 could be combined to meet your requirements for separation. Users can elect to use both UEIDs in combination with SEID.

**Tip:** You can verify the EIDs defined for your TCP/IP stack using the `Netstat Config` command. You can also determine if your TCP connections are using SMC-Dv2 and the EIDs used for the TCP connections using the `Netstat All` command.

## SMC filters

In addition to organizing your SMCv2 eligible systems within groups with a common UEID, users also have the ability to control SMC connectivity at a more granular level. SMC filters are provided in the form of SMC Permit and Exclude filters. SMC filters are not restricted to SMCv2 connections. SMC filters apply to all versions and types of SMC (SMC-Dv1, SMC-Dv2, SMC-Rv1, and SMC-Rv2).

When the SMC filters are defined, they are applied to the remote host's IP address or IP subnet associated with the TCP/IP connection. The filters are not applied to the remote RoCEv2 IP address. The filters control all SMC connectivity by permitting or excluding connectivity by controlling the SMC support indication in the TCP SMCR options flag exchanged during the TCP/IP connection 3-way handshake. When

connections are not permitted or specifically excluded by the SMC filters, the peer hosts view the TCP/IP connection as not eligible for SMC.

Use of SMC filters is optional. For some use cases, the base SMC connection eligibility criteria (IP subnet for SMCv1 and EID for SMCv2) is too broad. Users who need more granular control over the SMC connection eligibility can choose to exploit the SMC filters.

Before defining SMC filters, it is important to understand a couple of the key implications of using SMC filters.

**Results:**

- When adding your first or a single SMC Permit Filter, the default Permit behavior must be understood. With no SMC Permit Filters defined, by default all peer hosts are permitted to use SMC. However, once the first Permit Filter is added, only peer hosts that match the single (current) permit filter(s) will be permitted to use SMC.
- When your SMC Permit and Exclude Filters overlap, the Exclude Filter takes precedence over the Permit Filter, regardless of which filter is more specific.

## Using SMC filters

Some examples of using SMC Permit Filters are provided here.

The SMC Permit Filters allow the following options:

- New SMC users to gradually increase the scope of SMC exploitation
- Existing users to assert more granular control on their current usage
- All users to enable specific hosts by targeting specific workloads
- Users to avoid exposing the SMC option to unknown hosts
- SMCv2 users who frequently move z/OS systems to different sites can combine EIDs with z/OS symbols and SMC filters to assure connections over the WAN are not eligible for SMCv2

The SMC Exclude Filters allow the following options:

- The exclusion of a specific IP address or set of IP addresses within a large IP subnet or site
- Overriding your Permit Filters
- The exclusion of a specific IP address that exhibits undesirable behavior
- The exclusion of a specific IP address on a temporary basis

**Tips:**

- SMC filters must be evaluated during the TCP/IP connection processing. When defining your SMC filters administrators should give this aspect consideration. To achieve the required level of SMC connection eligibility control, users should strive to use the minimum number of SMC filters.
- Users who must create SMC filters that also have a need to share the filters among several z/OS instances, or who frequently change their filters should consider using the z/OS Network Configuration Assistant (NCA) TCP/IP Profile technology to share and manage their SMC filter definitions.

**Rule:**

Users can configure up to a maximum of 256 Permit and 256 Exclude filters per IP version.

## Dynamic selection of SMC version and SMC type

The SMC protocol uses the TCP 3-way handshake to dynamically select the SMC version and type by the TCP server. The selection is based on the client and server SMC configuration and other criteria. The TCP client can offer a single SMC version and type or up to all four SMC versions / types. The TCP server will favor SMCv2 over SMCv1 and SMC-D over SMC-R. The SMC type is dynamically selected by the server in the following order of preference:

1. SMC-Dv2

2. SMC-Dv1
3. SMC-Rv2
4. SMC-Rv1

**Result:**

SMCv2 is used even when client and server hosts are attached to the same IP subnet.

## SMC-Dv2

SMC-Dv2 hosts must continue to be on the same CPC and have access to the same ISM VCHID. However, the associated TCP/IP connection can now span multiple IP subnets crossing multiple "IP router hops". This also means that the IP connection through OSA or HiperSockets to a network used by each peer host is not limited to a single physical layer 2 network or VLAN.

There are additional simplification advantages in using SMC-Dv2. For this reason, when SMC-Dv2 is enabled by both peers and the TCP connection does not cross multiple IP subnets, SMC-Dv2 will be preferred or used when possible.

## ISMv2

IBM System Z Internal Shared Memory (ISM) technology provides the internal communications capability required for SMC-D. The initial version of SMC-D inherited the host's IP connection's (OSA or HiperSockets) layer 2 attributes, such as PNetID (physical network) and VLAN ID to form SMC-D connectivity.

SMC-Dv2 connections are no longer bound to a single IP subnet. This allows all hosts to span multiple IP subnets connecting over multiple IP hops. SMC-Dv2 connectivity is not based on or restricted to layer 2 connectivity. The System Z Internal Shared Memory (ISM) technology is updated to support this new form of ISM Layer 3 connectivity. This update is referred to as ISMv2 and is provided with IBM z15® at GA1.5 level or later systems.

The changes in SMC-Dv2 and ISMv2 are transparent to z/VM. z/VM 7.1 or higher is required to support all versions of SMC-D.

Like SMC-Dv1, SMC-Dv2 does not build, use, or exchange IP packets. ISMv2 does not use any form of IP routing. Instead, ISMv2 creates a unique internal ISM L3 connection that is isolated from existing L2 traffic defined by the System Z ISM architecture and the SMC-Dv2 protocol.

## Enabling SMC-Dv2

To understand the base SMC-D setup requirements, see [“Setting up the environment for Shared Memory Communications - Direct Memory Access”](#) on page 562.

When an EID is defined, with either the SEID or UEID specified in the TCP/IP profile on the Global Configuration statement, then this step also enables SMC-Dv2 for this TCP/IP stack for both IPv4 and IPv6. Once SMC-Dv2 is enabled, as new TCP/IP connections are created, they become eligible for SMC-Dv2 (enables SMC-D across multiple IP subnets).

In order for a TCP/IP connection to be eligible for SMC-Dv2, the following conditions must all be true, both the TCP client and the server must:

- Support and be enabled for SMC-Dv2 (exchanged in SMC connection setup)
- Be configured with the same EID (either SEID or UEID, exchanged in the SMC connection setup)
- Execute on the same CPC that supports ISMv2 (dynamically evaluated in the SMC connection setup processing)
- Have access to a common ISM VCHID (exchanged in the SMC connection setup)
- Not be prevented from SMC connectivity due to the presence of an SMC filter
- Not require IPsec encryption (for the associated TCP/IP connection)

When connecting with SMC-Dv2, the IP topology of the associated TCP/IP connection is not relevant and is not evaluated. This means that the physical networks, the IP subnets and the VLANs are not part of the SMC-Dv2 connection eligibility criteria and are not evaluated. The TCP/IP connection will set up across the IP network potentially over multiple IP hops and the SMC-Dv2 socket application communications occur internally over ISMv2.

**Tip:**

Some firewalls can be configured to drop TCP options. The SMC protocol requires TCP option 254 to flow on the TCP/IP 3-way handshake. It is recommended that you verify that your firewalls permit TCP option 254 to flow. For more information about the SMC protocol, see RFC 7609.

## SMC-Dv2 and ISM VCHID Association using PNetIDs

With the initial version of SMC-D, the ISM connectivity was based on the layer 2 IP connectivity provided by OSA or HiperSockets. To allow ISM to inherit the L2 attributes, the ISM VCHID was required to be associated with an IP device such as your OSA or HiperSockets physical layer 2 network. The association was accomplished by defining the same PNetID on both ISM and OSA or HS.

With SMC-Dv2, the layer 2 network requirements are no longer part of the SMC connection criteria. This key difference means that to connect with SMC-Dv2, your ISM VCHID is not required to be associated with any IP network device, meaning ISM does not require a PNetID definition.<sup>5</sup>

Users who plan to exploit SMC-Dv2 have the following ISM VCHID system configuration options to consider for defining their SMC-Dv2 and ISMv2 environment:

- **ISM VCHIDs with PNetID**

Define ISM VCHIDs with a PNetID in HCD that matches your OSA or HiperSockets PNetID definitions. This method is referred to as associated ISM devices (FIDs), meaning the ISM FIDs are directly associated with an IP device (OSA or HiperSockets) and are only used by those IP devices with the same PNetID. This method is required for SMC-Dv1. In cases in which your z/OS system supports SMC-Dv2 but it will also communicate with down-level hosts (that do not support SMC-Dv2), then you will need to define your ISM VCHID with a PNetID to meet the layer 2 connectivity requirements. You might also choose to only use associated ISM devices if you would like to continue to control the traffic flowing over the various ISM devices, as in SMC-Dv1. The interface related to an associated ISM FIDs are activated when the associated OSA or HiperSockets interface is activated.

Figure 82. SMC-Dv2 and ISMv2 with PNetID

- **ISM VCHIDs without PNetID**

<sup>5</sup> The ISM PNetID could still be required to communicate with down-level hosts.

Define ISM VCHIDs without a PNetID in HCD. This method is referred to as unassociated ISM devices (FIDs), meaning the ISM FIDs are not associated with any IP devices and therefore can be used by any SMC-D eligible IP device regardless of whether a PNetID was specified for that IP device or not. Note that this also means that traffic for IP devices without a PNetID, which was not eligible for SMC-D in the past, is now eligible for SMC-Dv2. In cases in which your z/OS system supports SMC-Dv2 and will only communicate with up-level systems that also support SMC-Dv2, then you don't require an ISM PNetID. The layer 2 attributes are not associated with ISM and therefore not required to meet the SMC-Dv2 connection criteria. z/OS also supports multiple (up to four) unassociated ISM VCHIDs. Using multiple ISM VCHIDs permits the system administrator to separate and isolate unique users on unique ISM VCHIDs (e.g. unique business groups). Once the first OSA or HiperSocket interface has been started, unassociated ISM FIDs are automatically activated when the unassociated FID comes online.

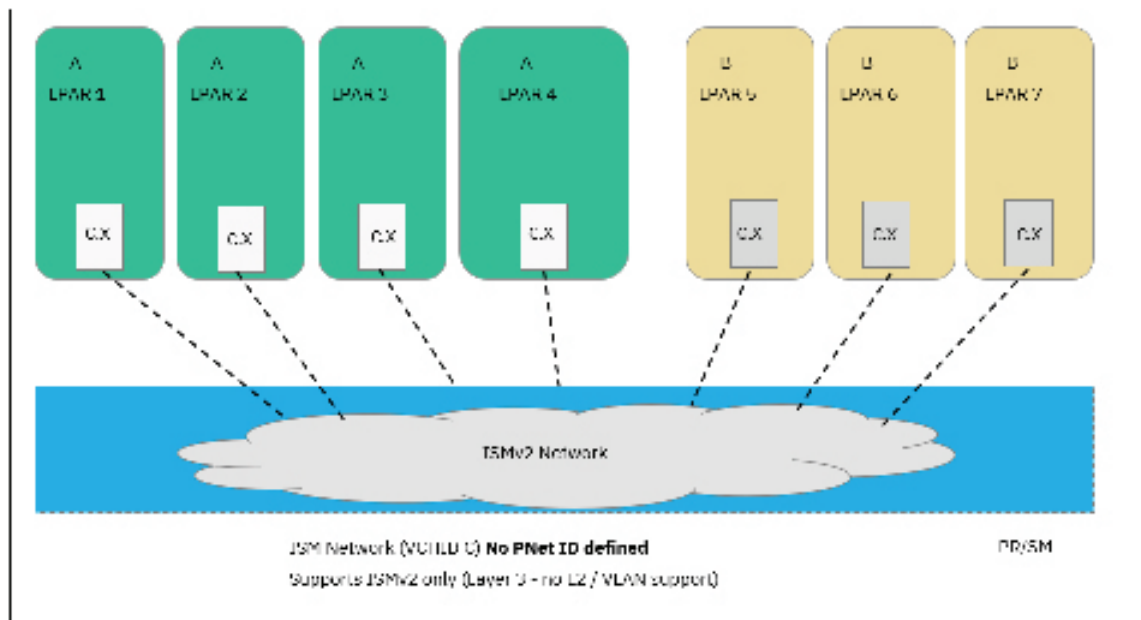

Figure 83. SMC-Dv2 and ISMv2 without PNetIDs

- **Combination of ISM VCHIDs with and without PNetID**

Users can also combine both of the methods described above. Users can use ISM with a PNetID to communicate with down-level systems and provision a separate ISM VCHID (or multiple ISM VCHIDs) without a PNetID used for communicating with up-level systems. Note that SMC-D eligible IP devices with a PNetID can use either ISM VCHIDs with a matching PNetID or ISM VCHIDs without a PNetID, but will prefer the ISM VCHID with the matching PNetID if the SMC partner has access to that same ISM VCHID.

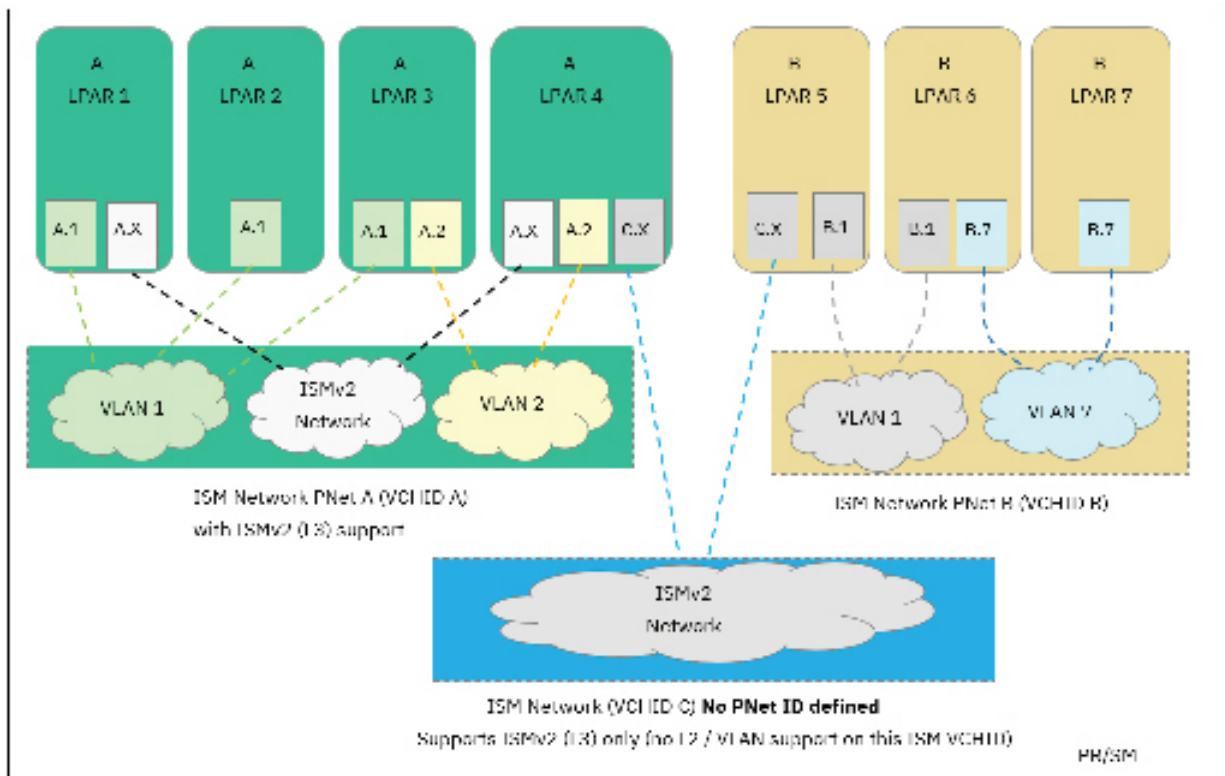

Figure 84. SMC-Dv2 and ISMv2 With and Without PNetIDs

While both (associated or non-associated) ISM configuration methods can be used to exploit SMC-Dv2 connectivity (enabling SMC-D over multiple IP subnets), the administrator must consider the entire set of systems that are required to communicate over the same ISM VCHID. When any system in this set is down-level, method 1 (associated VCHIDs) is required (or at least combined as in method 3). While method 2 offers improvements in usability, it requires that all systems are up-level supporting SMC-Dv2.

## SMC-Rv2

SMC-Rv2 defines the updates to the SMC-R protocol allowing SMC-Rv2 enabled hosts to connect and communicate over multiple IP subnets. SMC-Rv2 uses the RoCEv2 protocol also known as "routable RoCE". SMC-Rv2 connection eligibility is defined by the Enterprise ID. SMC-Rv2 peer hosts must define a common EID. SMC-Rv2 preserves many of the architectural concepts of SMC-R, such as supporting TCP sockets, dynamically creating SMC-Rv2 connections from the TCP/IP connection and preserving many of the related TCP quality of services such as the network administrative model, TCP connection load balancer compatibility, and TCP connection (TLS) security.

Some of the key differences of SMC-Rv2 are related to IP connectivity, such as provisioning an IP address to the RoCE interface and the reliance on your IP routing definitions (static or dynamic) and your IP topology (IP routes, routers, firewalls, etc.). In most cases your existing IP routing definitions will be sufficient. For high availability, it is strongly recommended that users define multiple equal cost routes between hosts exploiting SMC-Rv2.

Your RoCEv2 network high availability reuses your existing IP network high availability methodology. SMC-Rv2 continues to provide high availability through the SMC-Rv2 link group architecture using multiple links for load balancing and high availability.

SMC-R does not support IPSec. TCP connections that require IPSec are not eligible for SMC-Rv2 or SMC-Rv1. SMC-R network traffic supports connection level security such as TLS or AT-TLS.

## RoCEv2

RoCEv2 defines the updates to the RoCE standards that enable "Routable RoCE". RoCEv2 encapsulates RoCE network traffic in UDP/IP packets using reserved UDP port 4791. RoCEv2 packets are not processed by z/OS.<sup>6</sup> All packet level processing is performed by the RoCE feature. The IBM RoCE Express2 feature on the IBM z15 or later system provides the RoCEv2 support required by SMC-Rv2. All RoCE features after RoCE Express2 also support RoCEv2. RoCEv2 is supported on both the 10 and 25 GbE RoCE features.

The changes in SMC-Rv2 and RoCEv2 are transparent to z/VM. z/VM 7.1 or higher is required to support all versions of SMC-R.

### Tip:

The z/OS administrator will not be required to reserve RoCEv2 UDP port 4791. When the administrator provisions a RoCEv2 (SMCR) IP address for the RoCEv2 interface in the OSA INTERFACE statement, the IP address is used exclusively by the RoCE Express hardware feature for RoCEv2 IP communications. Although the RoCEv2 IP address is provisioned and managed by the z/OS administrator, it is not used by z/OS. For this reason, the RoCEv2 IP address and UDP port will not conflict with a traditional z/OS IP address and port.

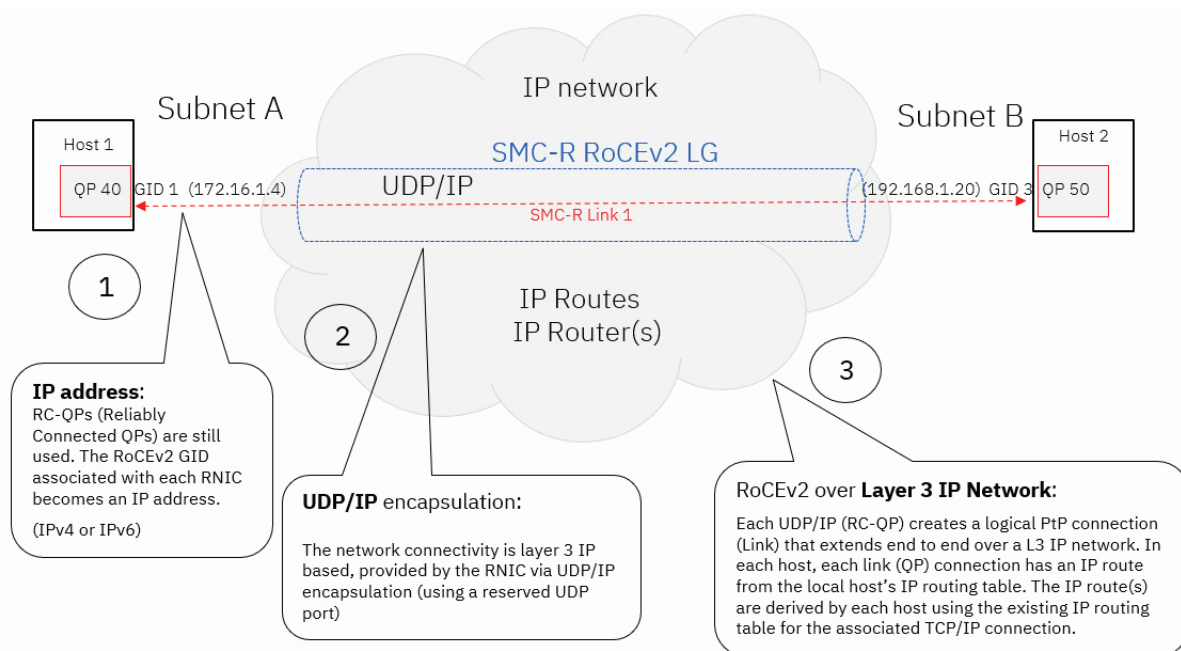

Figure 85. SMC-Rv2 connectivity concepts

## Enabling SMC-Rv2

To understand the base SMC-R setup requirements, see [“Setting up the environment for Shared Memory Communications over RDMA”](#) on page 559.

Enabling SMC-Rv2 involves the following two z/OS TCP/IP profile configuration steps:

### 1. Defining an Enterprise ID

When the administrator defines EID in the TCP/IP profile on the GlobalConfig statement, it enables SMC-Rv2 for this TCP/IP stack for IPv4.<sup>7</sup>

### 2. Defining IP interfaces for RoCEv2

<sup>6</sup> z/OS can process UDP/IP RoCEv2 packets when the z/OS TCP/IP stack is acting as an IP router (datagram forwarding enabled) in the IP network path between RoCEv2 endpoints.

<sup>7</sup> SMC-Rv2 does not support IPv6.

The administrator must enable the applicable OSA (IPAQENET or EQENET) interfaces for RoCEv2. When an EID is defined, enabling a single OSA interface can create SMC-Rv2 connections with SMC-Rv2 peer hosts. For high availability, it is recommended that at least two OSA interfaces are enabled for SMC-Rv2. See [“SMC-Rv2 resilience, high availability with RoCEv2 and IP routing”](#) on page 578 for more information.

The required SMC-Rv2 definitions on the OSA INTERFACE<sup>8</sup> statement under the SMCR parameter are:

- a. PFID: PCI function ID that references the RoCE Express feature that supports RoCEv2 to be associated with this OSA IP interface. The PFID is defined in HCD.

**Rule:** When defining the PFID for an EQENET interface, the PFID value must reference a PFID on the same OSH PCHID (physical port).

- b. SMCRIPADDR: SMC-Rv2 IP address (RoCEv2 IP Address) that is to be used by the RoCE feature for RoCEv2 network traffic. This IP address must be the same IP version as this OSA and must be provisioned within the OSA IP subnet.

Note that the SMCRMTU (RoCEv2 MTU) is an optional parameter.

**Tip:**

Careful consideration should be given to changing the default SMCRMTU size of 1 K. Increasing the SMCRMTU to a value greater than 1 K (e.g. 2 K or 4 K) requires that the entire IP network path, which can be multiple IP subnets, supports jumbo frames.

The above two steps (EID and INTERFACE) can be performed in either order. Once SMC-Rv2 is enabled in the stack with an EID and an eligible IP interface is active, then as new TCP/IP connections are created over this OSA IP interface, the TCP/IP connections become eligible for SMC-Rv2 when connecting with SMC-Rv2 enabled peer hosts sharing a common EID.

In order for a TCP/IP connection to be eligible for SMC-Rv2, the following conditions must all be true for the TCP client and the server, both hosts must:

- Be enabled for SMC-Rv2 (exchanged in SMC connection setup)
- Be configured with the same user-defined EID (exchanged in the SMC connection setup)
- Have IP routes defined over the associated OSA IP interfaces that are SMC-Rv2 enabled
- Not be prevented from SMC connectivity due to the presence of an SMC filter
- Not require IPsec for the associated TCP/IP connection

**Tip:**

Some firewalls can be configured to drop TCP options. The SMC protocol requires TCP option 254 to flow on the TCP/IP 3-way handshake. It is recommended that you verify that your firewalls permit TCP option 254 to flow. For more information about the SMC protocol, see RFC 7609.

**Tip:**

It is also recommended that you verify that UDP port 4791 (RoCEv2) is open in your firewalls.

## Network Express and RoCEv2 device association and physical connectivity

The Network Express feature simplifies the physical connectivity requirements for RoCE by converging the IP and SMC-R (RDMA) protocols to the same physical port. With Network Express, users can exploit SMC-R without requiring a separate RoCE adapter (RNIC), physical port and the corresponding switch port. Although the physical connectivity is simplified by Network Express, to the z/OS administrator,

---

<sup>8</sup> The OSA INTERFACE statement must meet all existing OSA INTERFACE definition requirements and all existing SMC-R definition requirements, such as defining a subnet mask. The associated OSA-Express and RoCEv2 PFID (RoCE Express or Network Express) must both have a matching PNetID (HCD). When OSA is provided by Network Express (OSH), a single PNetID must be defined (HCD) that is used for both OSA (OSH) and RoCEv2 with NETH PFIDs

the network IP configuration and usage of SMC-Rv2 (RoCE) are virtually identical to OSA-Express. The physical connectivity topic in this section is unique to exploiting SMC-Rv2 on the Network Express feature

The OSH EQENET INTERFACE statement defines the specific physical OSA adapter using the OSA INTERFACE device number parameter which references a specific OSH CHPID. The configured SMCR RoCEv2 PFID parameter must reference a specific NETH PFID (defined in HCD) for this same physical adapter or PCHID. The TCP/IP communications are provided by the EQDIO architecture (OSH) and the related SMC-Rv2 / RoCEv2 communications are provided by the NETH PFID using native PCIe architecture for the same physical adapter and port.

**Rule:** The OSH PNetID is required in HCD.

The OSA INTERFACE VLAN ID definition is inherited by the RoCE PFID. When the OSA port is configured in access mode (VLAN ID is not known by the host), the RoCE port must also be configured in access mode.

**Rule:** The RoCEv2 VLAN ID must match the VLAN ID of any adjacent (next hop) IP routers used by IP routes for RoCEv2 traffic. The RoCEv2 VLAN ID is inherited from the associated OSA interface and is either:

- Zero, unknown by z/OS and is untagged (switch port is in access mode) or
- A specific value (matching the switch port that is configured in trunk mode)

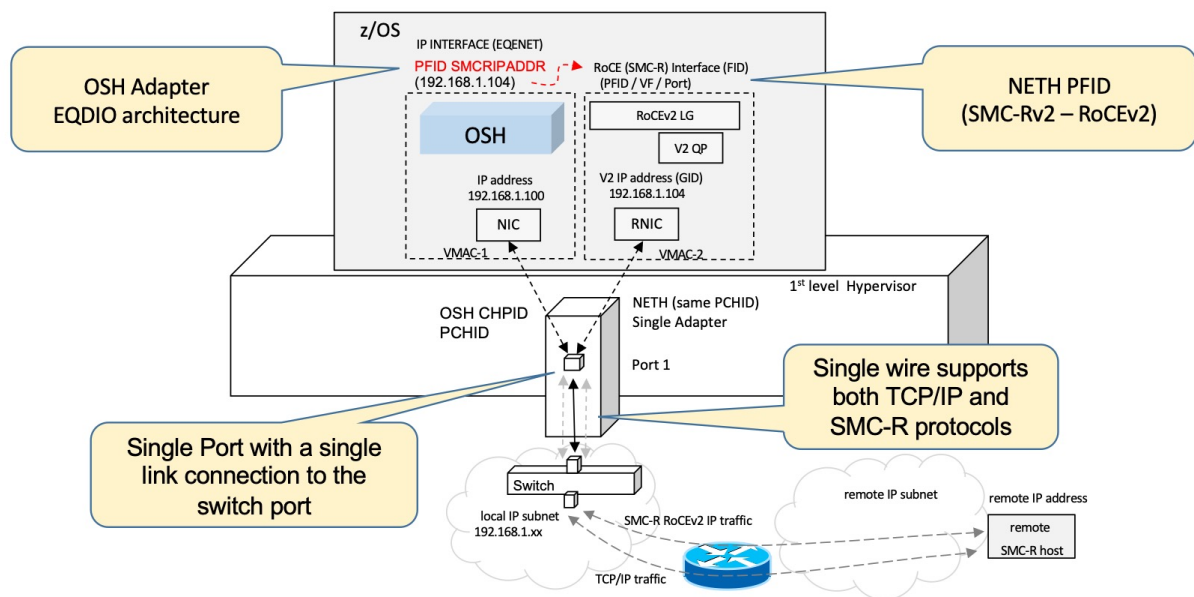

Figure 86. Network Express SMC-Rv2 and RoCE relationship

Some of the key concepts of the Network Express converged adapter support illustrated here are:

- A single physical adapter and port support both IP and RDMA protocols.
- The OSH CHPID is used for EQENET and NETH is used for the PFID.
- The EQENET INTERFACE statement uses the existing parameters PFID and SMC RIPADDR to dynamically create the SMCR interface.
- The value used on the PFID parameter must reference the same physical adapter or PCHID as device number (DEVNUM parameter).

## OSA and RoCEv2 device association and physical connectivity

The physical connectivity differs based on the OSA feature that provides the TCP/IP communication. When you use OSA (IPAQENET) for TCP/IP communications, a separate physical adapter is required

for RoCEv2, either a RoCE Express or Network Express feature. OSA and RoCEv2 communications are described in this section.

The OSA INTERFACE statement defines the specific physical OSA through the OSA interface port statement which references a VTAM TRLE. The OSA SMCR RoCEv2 PFID parameter defines the specific RoCE feature. The OSA INTERFACE SMCR RoCEv2 parameters (PFID and SMCRIPADDR) logically bond the two adapters together. The TCP/IP communications is provided by OSA and the related SMC-Rv2 / RoCEv2 communications are provided by the RoCE adapter. The IP routes that will be reused for RoCEv2 connectivity will be associated with the OSA IP interfaces.

Both the OSA and associated RoCE features must:

- Have their physical ports defined with the same PNetID in HCD.
- Both physical ports must be attached on the same physical LAN (typically the same physical switch).
- Both physical Ethernet switch ports must be defined with the same VLAN ID (when in trunk mode).

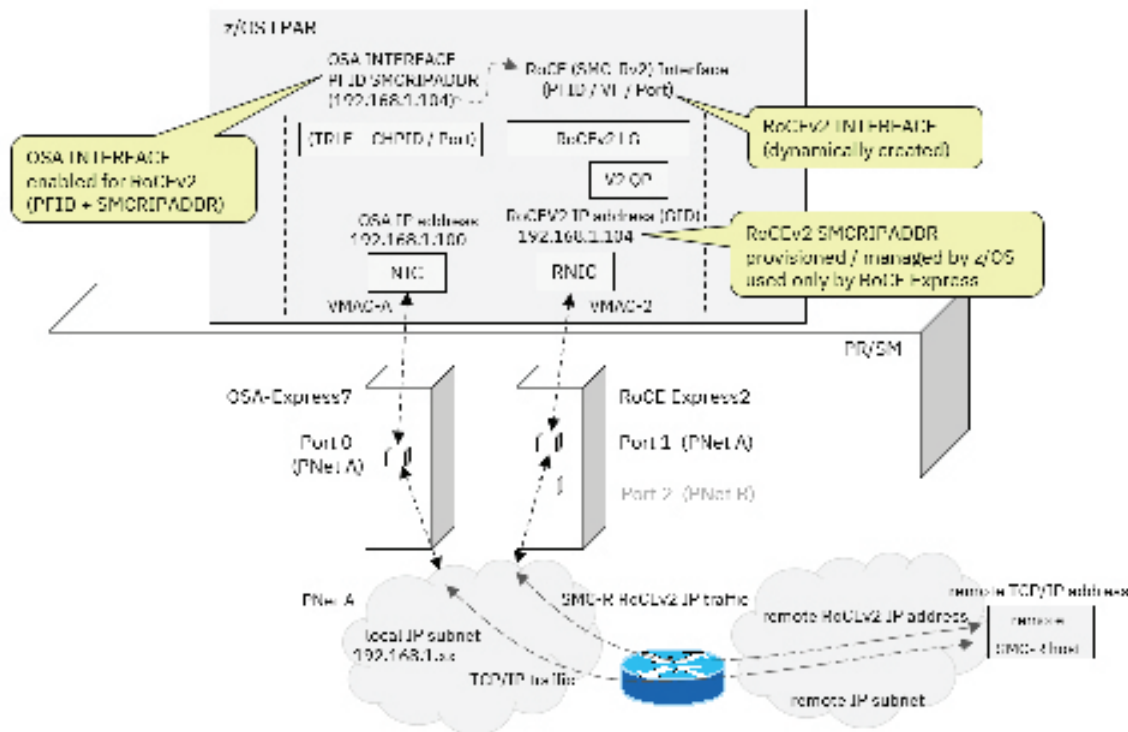

Figure 87. SMC-Rv2 OSA and RoCE relationship

The figure shows OSA and RoCE Express features. This figure also applies to OSA when using Network Express for RoCEv2 (NETH PFIDs). The non-converged RoCE support shown here (using two adapters) is also used for the case when OSA is used for TCP/IP and Network Express (NETH) is used for RoCE connectivity. The IPAQENET INTERFACE SMC-Rv2 configuration requirements are the same for both RoCE Express and Network Express except when using Network Express for TCP/IP (OSA) the defined PFID value must be associated with a Network Express NETH PFID for the same OSH PCHID.

## RoCEv2 Common Network Connectivity Considerations

The RoCEv2 network connectivity considerations in this section are common to and applicable to both OSA-Express (OSD) and Network Express (OSH) configurations.

Some common RoCE external network configuration concepts to note are:

- The IP routes that will be reused for RoCEv2 connectivity will be associated with the OSA IP interface.
- The PFID configured on the OSA INTERFACE statement is used for SMC-Rv2 communications.

- When SMC-Rv1 communications are also required, configuring the same PFID on the GLOBALCONFIG statement enables this PFID for SMC-Rv1. However, the VLAN definition for the OSA INTERFACE statement impacts the SMC-Rv1 communications capability.

The OSA INTERFACE VLAN ID definition is inherited by the RoCE PFID. When the OSA port is configured in access mode (VLAN ID is not known by the host), the RoCE port must also be configured in access mode (N/A for Network Express, where a single port is used).

**Rule:** The RoCEv2 VLAN ID must match the VLAN ID of any adjacent (next hop) IP routers used by IP routes for RoCEv2 traffic. The RoCEv2 VLAN ID is inherited from the associated OSA interface and is either:

- Zero, unknown by z/OS and is untagged (switch port is in access mode) or
- A specific value (matching the switch port that is configured in trunk mode)

The PFID configured on the OSA INTERFACE statement is used for SMC-Rv2 communications. When SMC-Rv1 communications are also required, configuring the same PFID on the GLOBALCONFIG statement enables this PFID for SMC-Rv1. However, the VLAN definition for the OSA INTERFACE statement impacts the SMC-Rv1 communications capability as follows:

- When VLAN is configured on the OSA INTERFACE statement (trunk mode), this PFID can also be used for SMC-Rv1 communications. For this case, configuring this same PFID on the GLOBALCONFIG statement enables SMC-Rv1 connectivity.
- When VLAN is not configured on the OSA INTERFACE statement (access mode), this PFID can conditionally be used for SMC-Rv1 connectivity described as follows:
  - When the OSA interface and all RoCE PFIDs on the PNET that are to be used for SMC-Rv1 connectivity are all defined in the associated switch ports with a single VLAN ID, SMC-Rv1 connectivity is supported. For this case, the PFID should be configured on the GLOBALCONFIG statement.

**Restriction:** When the OSA interface and all RoCE PFIDs on the PNET that are to be used for SMC-Rv1 connectivity are not defined in the associated switch ports with a single VLAN ID, SMC-Rv1 connectivity is not supported. When enabling SMC-Rv2 communications in this access mode configuration the PFID must not be configured on the GLOBALCONFIG statement.

**Result:** Configuring PFID on the GLOBALCONFIG statement for this case could result in connection hangs with SMC-Rv1 link timeouts.

**Tip:**

- To accommodate adapter sharing and various virtualization use cases, it is recommended that both the OSA-Express and RoCEv2 ports are configured in trunk mode. Network Express uses a single port to be configured in trunk mode. SMC-Rv2 does support access mode but limits your ability to share adapters and cannot provide the same level of SMC-R support as trunk mode. See the above restriction.
- SMC-Rv2 RoCEv2 traffic is encapsulated in UDP/IP by the "RoCE" feature. The "RoCE" feature is also responsible for managing the UDP network flow control by making adjustments to the UDP congestion management algorithms. The "RoCE" feature uses various network indications to adjust the network flow control algorithms. One such indication is defined by the Explicit Congestion Notification (ECN) standard.

ECN is an existing industry standard congestion control mechanism applicable to the IP protocol. ECN provides notification (within the IP header) when IP packets are traversing an IP network path that is experiencing congestion. The notifications provided by ECN allow the network endpoints ("RoCE" feature) to make adjustments to the flow control algorithms. The "RoCE" feature supports ECN by default. There is no action required on the z/OS host.

## SMC-Rv1 migration considerations

z/OS SMC-Rv2 users can control the use of SMC-Rv1 communications. Users who must continue to communicate with down-level SMC-R peer hosts which only support SMC-Rv1 (over the same IP subnet) must also configure the same FID value defined on OSA INTERFACE SMCR PFID parameter on the

GlobalConfig SMCR statement to enable base SMC-R support. When the RoCE PFID is not configured on the GlobalConfig statement, SMC-Rv1 communications are disabled.

**Result:**

SMC-Rv2 enabled peers that are attached to the same IP subnet will use SMC-Rv2 / RoCEv2 on the same subnet.

## Sharing or reusing resources: SMCRIPADDR and PFID

In some configurations, it is beneficial to reuse or share the SMCRIPADDR and the RoCEv2 PFID.

The SMCRIPADDR (RoCEv2 IP address) can be shared among multiple OSA interfaces associated with unique physical OSAs when the following conditions are true of all OSA INTERFACE statements:

1. Define the same subnet mask and
2. Define the same PFID value (reuse the same RoCEv2 adapter) and
3. Are associated with physical OSAs with ports attached to the same physical LAN (each OSA is defined with the same PNetID)

**Rule:**

The same RoCEv2 IP address cannot be shared among multiple OSA INTERFACE statements associated with the same physical OSA. In this case each INTERFACE requires a unique OSA IP address, subnet, and VLAN ID.

**Rule:**

The SMCRIPADDR (RoCEv2 IP address) is owned by a single z/OS TCP/IP stack. The same RoCEv2 IP address cannot be defined in (shared by) multiple TCP/IP stacks or used by any other LPARs.

The RoCEv2 FID can be shared among multiple OSA INTERFACE statements when the associated OSA ports are on the same physical LAN (each OSA is defined with the same PNetID). In the FID sharing case, the OSA INTERFACE statements can be associated with the same physical OSA or unique physical OSAs.

**Tip:**

A RoCE PFID allows unique users, typically LPARs, stacks or guests, to share (virtualize) the same physical adapter. There is no known reason or benefit for provisioning multiple PFID values associated with the same RoCE adapter and port to the same z/OS TCP/IP stack. This practice is not checked, prevented, or disallowed but it is not recommended.

## SMC-Rv2 resilience, high availability with RoCEv2 and IP routing

SMC-Rv2 and RoCEv2 connectivity requires and is based on your IP routing definitions and your IP topology. Your IP routes can be statically or dynamically defined. Dynamic routing offers many significant advantages. SMC-Rv2 does not require unique IP routing design. Defining multiple equal cost IP routes is recommended. The SMC-Rv2 protocol reuses your existing TCP/IP connection IP routes. IP routes must be defined over one or more of your OSA IP interfaces.

## SMC-Rv2 link groups

SMC-Rv2 preserves the network resiliency for workloads with the SMC-R link group architecture which has been adapted to RoCEv2. SMC-Rv2 LGs attempt to create two links (connections) over unique RoCEv2 adapters. When this can be achieved at both peers the LG is considered to be a symmetric LG. Symmetric LGs provide full redundancy when the connections are over unique adapters. The LG is created during the first TCP connection setup and it is reused for all subsequent TCP connections between the same two hosts having the same TCP client and server roles and when both hosts use the same RoCEv2 IP addresses. The TCP server is responsible for managing the LG.

For the most part, your RoCEv2 network resiliency is achieved by reusing your existing IP network resiliency model. In order to achieve full SMC-Rv2 redundancy at each host and within the IP network, the following must be provided:

- Two OSA INTERFACE statements that are enabled for SMC-Rv2 (RoCEv2) with a PFID and SMCRIPADDR
- Each OSA INTERFACE statement is defined and associated with a unique physical RoCE adapter (PFID). Network Express uses a single physical port for both OSA and RoCE.
- Two or more distinct equal cost IP routes to the peer SMC-Rv2 hosts over the OSA IP interfaces and
- Each IP route is designed to have some form of hardware redundancy for your IP routing paths (e.g. redundant switches and IP routers).

**Rule:**

The IP routes used to create the SMC-R2 Link Groups come from the TCP/IP stack routing table. SMC-Rv2 does not use policy-based routes or the policy-based routing table to form v2 LGs.

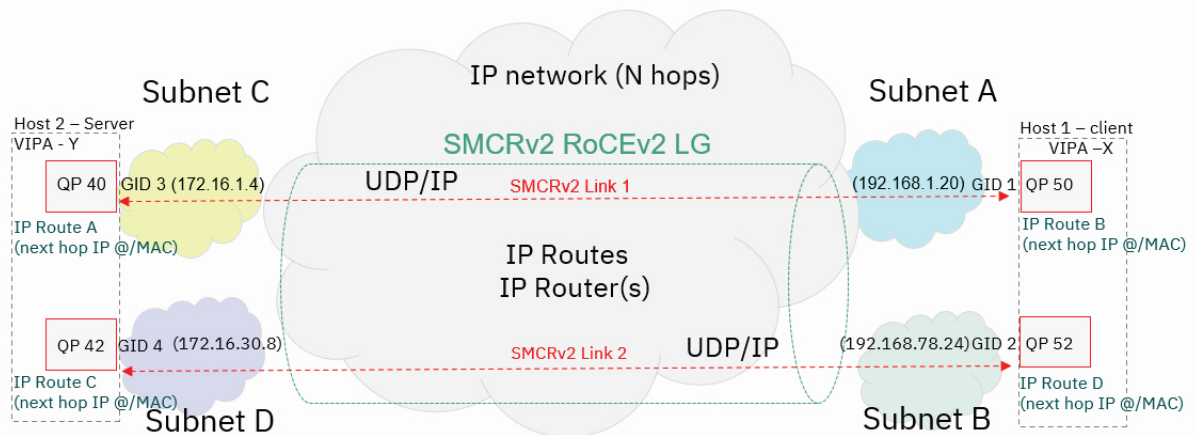

Figure 88. SMC-Rv2 link group

Although the OSA IP interfaces are not shown in Figure 88 on page 579, each OSA interface would be within the same IP subnets associated with each of the RoCEv2 links (QPs). This figure illustrates a typical IP network configured for high availability. By reusing the IP network configuration, the SMC-Rv2 symmetric Link Group is dynamically formed to provide RoCEv2 high availability.

**Tip:**

The SMC-Rv2/RoCEv2 resiliency is dependent on both provisioning redundant hardware and your IP network configuration. TCP/IP NetStat link group display provides the level of redundancy for an SMC-Rv2 link group. The redundancy level is based on the host's local view of the RoCEv2 hardware (two SMC-Rv2 links having unique adapters, adapters are in unique I/O drawers and the LG type, such as symmetric versus asymmetric). See Netstat SMC-R LG report for more details.

**Rule:**

When only a single IP interface, a single IP route or a single RoCEv2 capable adapter is available, TCP/IP will create an SMC-Rv2 LG as either a single LG or an asymmetric LG. The TCP server will then periodically attempt to add a second link transitioning the LG to full redundancy (symmetric).

**Rule:**

When a direct route to a peer host can be found, it is preferred. When hosts are attached to the same IP subnet and both peers are SMC-Rv2 enabled, then SMC-Rv2 protocol is used. This is defined as an SMC-Rv2 direct link within the LG.

Similar to SMC-Rv1, SMC-Rv2 also provides for keep-alive support for both the TCP/IP connection and the RoCEv2 connection. In most use cases, the TCPMINKEEP setting on the GlobalConfig statement will be sufficient. For SMC-Rv2 indirect (multi-hop) links the TCP keep alive setting is set to 5 minutes, and for direct links the v1 TCPMINKEEP value is used.

**Tip:**

When SMC is used, the associated TCP connection stays active but idle. Some users exploit idle disconnect timers in their IP routers or firewalls. When SMC-Rv2 is used for multiple hop TCP/IP connections, the TCPMINKEEP setting should be set lower than your router disconnect timers.

## SMC interactions with other z/OS Communications Server functions

SMC interacts with the following functions:

- “Sysplex distributor” on page 580
- “Security functions” on page 581
- “Intrusion detection services (IDS)” on page 581
- “TCP keepalive” on page 582
- “TCP application data transfer options” on page 582
- “Packet trace” on page 583
- “SMC-R RoCE maximum transmission unit” on page 583

### Sysplex distributor

You can use Shared Memory Communications (SMC) with the sysplex distributor function with no additional configuration requirements. TCP connections are set up as normal through the sysplex distributor node, and the connection endpoints exchange SMC rendezvous information as described in “Rendezvous processing” on page 535. The sysplex distributor node examines information that is passed in the rendezvous exchange to select the optimum server application for SMC protocols. After the TCP connection is established to the server application, rendezvous processing continues to determine whether SMC communications are possible, and to establish an SMC link if necessary. After the TCP connection switches to SMC communications, the data does not flow through the sysplex distributor node, as shown in Figure 89 on page 580. This bypassing of the distributor node represents a performance improvement for the sysplex distributor function when SMC protocols are used.

Figure 89. Sysplex distributor and SMC-R interaction

## Security functions

You can use Application Transparent Transport Layer Security (AT-TLS) with SMC with no restriction. The negotiation of AT-TLS support for a TCP connection takes place after the SMC rendezvous exchange, and after that the encryption and decryption of the data occur as normal.

Generally, security functions that require TCP/IP to examine TCP packets cannot be used with SMC communications because data that is sent over SMC links is not converted into TCP packets. The following security functions do not interoperate with SMC:

- IPSec when the TCP connection requires tunneling
- IP filters when the filter would deny a packet for the TCP connection
- Multilevel security when the connection requires packet tagging (that is, when the source and destination zones are both SYSMULTI)

All of the above functions can be activated dynamically through profile changes, with the expectation that the change applies to current active TCP connections. If TCP connections are currently traversing SMC links when such a profile change is made, then the stack stops the TCP connections that are not compatible with the new security profiles.

## Intrusion detection services (IDS)

Intrusion detection services (IDS) provides the following support:

- Scan detection and reporting
- Traffic regulation for TCP connections and UDP receive queues
- Attack detection, reporting, and prevention

The first two services involve checks that occur during TCP connection setup that do not interact directly with SMC communications.

The last service covers a range of checks. Most of the checks occur for inbound TCP packets, which means they are not applicable for SMC communications. The following two checks that are included in this service apply to TCP connections that traverse SMC links:

- TCP queue size events

You can use IDS policy to detect when the send or receive queue for a TCP connection that traverses an SMC link becomes constrained because of the amount or age of the data on the queue. When a queue becomes constrained, you can reset the TCP connection or continue to monitor the condition until the queue is no longer constrained.

Send or receive queues can be constrained for TCP connections that traverse SMC links:

- The send queue is considered to be constrained when data is available to be sent but cannot be sent, or when data is stored into the peer remote memory buffer (RMB) or direct memory buffer (DMB) that is not acknowledged for more than 30 seconds.
- The receive queue is considered to be constrained when data is available to be delivered but the application does not receive the data for more than 30 seconds.
- When either queue becomes constrained, the TCP connections are monitored or stopped based on the IDS policy in effect.

- Global TCP stall events

You can use IDS to detect attacks that are designed to consume system resources by creating many TCP connections and causing them to stall, making them unable to send data. A global stall condition is in effect when at least 50% of the active TCP connections are stalled and at least 1000 TCP connections are active. You can reset stalled connections, or continue to monitor the condition.

TCP connections that traverse SMC links are considered for global TCP stall events. A TCP connection that traverses an SMC link is treated as a stalled connection when the TCB is write-blocked.

## TCP keepalive

Some intermediate nodes (for instance, load balancers or firewalls) use data traffic as an indication that the TCP connection is still alive. If no data flows across the TCP path for a long enough period, the intermediate node might reset the connection. TCP keepalive processing periodically sends packets over the TCP connection to prevent the connection from being reset.

The rendezvous negotiations to use SMC communications occur over the TCP connection. After the decision to switch to SMC protocols is made, the TCP connection remains active, but only termination messages flow over the TCP connection as needed. The application socket data flows out of band by using RDMA or ISM protocols. Thus, a TCP connection that is using SMC can be viewed as using two paths:

- A TCP path that is used for non-data packets, including the initial three-way handshake packets, FIN packets, and RST packets.
- An SMC path that is used for data.

Because the TCP connection does not use the TCP path to exchange data packets, intermediate nodes might consider the connection to be idle for long periods. For TCP connections over SMC, keepalive processing must ensure that both the TCP path and the SMC path remain operational.

For traditional TCP connections, the time interval that is used to send keepalive probes is determined by using the following sequence:

1. The value of the `TCP_KEEPAIVE` `setsockopt()` option, if specified by the application
2. The value of the `INTERVAL` parameter on the `TCPCONFIG` statement

For a TCP connection that is traversing an SMC link, the time interval that is used to send keepalive probes on the SMC path is determined by using the same method because the SMC path is where the actual data flows. For these connections, however, use of this same method for the TCP path can generate excessive keepalive probe traffic, so a separate method is used to determine the keepalive time interval for the TCP path.

- For TCP connections that use SMC-R communications, this method uses the larger of the `GLOBALCONFIG SMCR TCPKEEPMININTERVAL` value, the `TCPCONFIG INTERVAL` value, and the `TCP_KEEPAIVE setsockopt()` value.
- For TCP connections that use SMC-D communications, this method uses the larger of the `GLOBALCONFIG SMCD TCPKEEPMININTERVAL` value, the `TCPCONFIG INTERVAL` value, and the `TCP_KEEPAIVE setsockopt()` value.

For example:

- `SO_KEEPAIVE` is specified by the application, `TCPCONFIG INTERVAL` is 120 minutes, and `GLOBALCONFIG SMCR TCPKEEPMININTERVAL` value is 5 minutes.

In this case, the time interval for both the SMC-R path and the TCP path is 120 minutes.

- `SO_KEEPAIVE` is specified by the application, `TCPCONFIG INTERVAL` is 10 minutes, `TCP_KEEPAIVE setsockopt()` is specified by the application with a value of 5 minutes, and the `GLOBALCONFIG SMCD TCPKEEPMININTERVAL` value is 15 minutes.

In this case, the time interval for the SMC-D path is 5 minutes, but the time interval for the TCP path is 15 minutes.

## TCP application data transfer options

The SMC protocol is transparent to and fully compatible with TCP socket applications. A wide range of functions are available through the API interfaces that z/OS Communications Server provides. The use of SMC protocols for exchanging application socket data is not apparent to the applications. Thus, socket API functions such as `MSGWAITALL`, `MSG_PEEK`, `Accept` and `Receive (ANR)`, and `Urgent Data` can still be used by the applications, even when SMC communications are used.

## Packet trace

Packet trace provides a mechanism for capturing the contents of TCP packets as they are sent and received. Even though SMC does not create TCP packets for data that is sent over SMC links, the data is captured as part of packet trace processing. This data includes all TCP connection data that is sent across the SMC link, and any SMC-R Link Layer Control (LLC) messages that the TCP/IP stack generates to manage the link or the associated memory buffers.

For information about formatting the SMC data in the packet trace, see [z/OS Communications Server: IP Diagnosis Guide](#).

## SMC-R RoCE maximum transmission unit

RDMA protocols, including SMC-R, define a unique set of supported maximum transmission unit (MTU) sizes. SMC-R protocols support MTU sizes of 256, 512, 1024, 2048, and 4096 bytes, but z/OS Communications Server requests an MTU size of at least 1024 bytes. When an SMC-R link is initially established between two peer hosts, the MTU size is exchanged and negotiated to the lowest value for both hosts. The negotiated MTU size must account for transport headers and cyclic redundancy check (CRC) information that is used by the underlying RoCE protocols.

### Guidelines:

- The default MTU value for Communications Server is 1024, which can be used for most z/OS application workloads.
- In some cases, such as streaming or bulk data transfer, you can improve throughput by using an MTU setting of 2048 or 4096. You can configure the MTU value on the PFID subparameter of the GLOBALCONFIG statement.
- If you set the MTU size to 2048 or 4096, you must also enable jumbo frames on all switches in the path for all peer hosts.
- Define the same MTU size for all PFIDs that are associated with the same physical network (PNetID).

## Managing SMC communications

---

You can use the VARY command to manage your "RoCE Express" and ISM interfaces, and the Netstat command to display Shared Memory Communications (SMC) information. You can use various tools to monitor SMC information, and VTAM DISPLAY commands to display information about "RoCE Express" and ISM interfaces. You can stop SMC at a stack-wide level.

- [“Managing your GLOBALCONFIG RoCE interfaces” on page 583](#)
- [“Managing your ISM interfaces” on page 585](#)
- [“Displaying SMC information” on page 585](#)
- [“Monitoring SMC information” on page 587](#)
- [“VTAM displays and tuning statistics” on page 588](#)
- [“Stopping SMC-R” on page 589](#)
- [“Stopping SMC-D” on page 589](#)

## Managing your GLOBALCONFIG RoCE interfaces

This section describes how to manage RoCE Interfaces created from the PFIDs configured on the GLOBALCONFIG statement and SMCR parameter. The PFIDs defined on the GLOBALCONFIG statement are used for SMC-Rv1 only. SMC-Rv2 RoCE Interfaces are created by the PFIDs defined on the OSA INTERFACE statements and are managed along with the OSA interface. To understand how to define and manage SMC-Rv2 RoCE interfaces, see [“Enabling SMC-Rv2” on page 573](#).

The TCP/IP stack dynamically creates "RoCE" interfaces for each configured PCI Express function ID (PFID). The stack activates all the configured "RoCE" interfaces when the first SMC-R capable IPAQENET or IPAQENET6 interface is started. After the "RoCE" interfaces are started, they remain active even

when all SMC-R capable IPAQENET, IPAQENET6, EQENET and EQENET6 interfaces are stopped. You can explicitly stop a "RoCE" interface by using the VARY TCPIP,,STOP command. The name of the dynamically created "RoCE" interfaces is in the form EZARIUT

pf

, where *p* is the port number and *fff* is the PFID.

**Restriction:** If you manually stop a "RoCE" interface, you must later restart that interface by using the VARY TCPIP,,START command. The stack does not automatically restart the "RoCE" interface when the next SMC-R capable interface is started.

In addition to stopping and starting the "RoCE" interface, you can dynamically add or delete PFIDs from your TCP/IP profile by using the VARY TCPIP,,OBEYFILE command.

## Steps for dynamically adding a "RoCE Express" interface

Use these steps to dynamically add a "RoCE Express" interface.

### Procedure

Perform the following steps:

1. Install and configure the "RoCE Express" feature in the hardware configuration definition (HCD). Configuration includes the physical network ID (PNetID) for the "RoCE Express" port. For more information, see ["Physical network considerations"](#) on page 547.
2. Add the new PCI Express function ID (PFID) to the GLOBALCONFIG SMCR parameter in the TCP/IP profile data set.

**Rule:** In addition to the PFID that you are adding, you must also specify all currently configured PFIDs on the GLOBALCONFIG SMCR parameter. When you update the configured PFIDs on the GLOBALCONFIG SMCR parameter, you are completely replacing the configured PFID information.

3. Issue the VARY TCPIP,,OBEYFILE command and specify the updated TCP/IP profile data set.

### Results

If any SMC-R capable IPAQENET and IPAQENET6 interfaces were ever active, the "RoCE Express" interface that the added PFID represents is automatically started. Otherwise, the interface is started when the first SMC-R capable interface is started.

### What to do next

For more information about [GLOBALCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Steps for dynamically removing a GLOBALCONFIG "RoCE" interface

Use these steps to dynamically remove a "RoCE" interface.

### Procedure

Perform the following steps:

1. Issue the VARY TCPIP,,STOP command for the "RoCE" interface to be deleted.  
**Result:** If no alternative SMC-R link exists for connections that are using this "RoCE" interface, the connections are reset.
2. Remove the PCI Express function ID (PFID) value from the GLOBALCONFIG SMCR parameter in the TCP/IP profile data set.
3. Issue the VARY TCPIP,,OBEYFILE command and specify the updated TCP/IP profile data set.

### What to do next

For more information about [GLOBALCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Managing your ISM interfaces

The TCP/IP stack dynamically creates and activates an internal shared memory (ISM) interface for a specific physical network ID (PNetID) when both of the following conditions are true:

- The first SMC-D capable IPAQENET, IPAQENET6, EQENET, EQENET6, IPAQIDIO, or IPAQIDIO6 interface is started for that PNetID.
- An ISM device with the same PNetID value is found.

After the ISM interface is started, it remains active even when all SMC-D capable interfaces are stopped. You can explicitly stop an ISM interface by using the VARY TCPIP,,STOP command. The name of the dynamically created associated ISM interfaces is in the form of EZAISMxx, where xx is a value from 01 to 28. Up to four unassociated ISM interfaces might be dynamically created and activated when the first SMC-D capable interface is activated.

**Restriction:** If you manually stop an ISM interface, you must later restart that interface by using the VARY TCPIP,,START command. The stack does not automatically restart the ISM interface when the next SMC-D capable interface is started. If you stop and then restart the ISM interface, z/OS Communications Server might assign a different Peripheral Component Interconnect Express (PCIe) function ID (PFID) to the ISM interface, depending on the availability of ISM devices that are associated with this PNetID.

## Displaying SMC information

You can use the Netstat command and the DISPLAY TCPIP,,STOR command to display Shared Memory Communications (SMC) information.

For more information about these commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

### Netstat ALL/-A report

You can use the Netstat ALL/-A report to determine whether a TCP connection is using SMC communications. You can filter the report by using the SMCID/-U filter and specifying an SMC-R link group ID, SMC-R link ID, or SMC-D link ID value as the filter. When a filter is specified, only those TCP connections that traverse the specified link group or link are displayed.

### Netstat ALLConn/-a and Netstat CConn/-c reports

You can use the Netstat ALLConn/-a and Netstat CConn/-c reports to obtain TCP connection information. You can filter the reports by using the SMCID/-U filter and specifying an SMC-R link group ID, SMC-R link ID, or SMC-D link ID value as the filter. When a filter is specified, only those TCP connections that traverse the specified link group or link are displayed.

### Netstat CONFIG/-f report

You can use the Netstat CONFIG/-f report to display the settings on the GLOBALCONFIG statement, which includes the SMCR and SMCD parameters and subparameters.

### Netstat DEvlinks/-d report

You can use the Netstat DEvlinks/-d report to display the following information about interfaces:

- Whether an IPAQENET, IPAQENET6, EQENET or EQENET6 interface is eligible for SMC-R, and if so, information about the associated "RoCE" interfaces, also known as associated RNIC interfaces, that are in use.
- Whether an IPAQENET, IPAQENET6, EQENET, EQENET6, IPAQIDIO, or IPAQIDIO6 interface is eligible for SMC-D, and if so, information about the associated or unassociated internal shared memory (ISM) interface that is in use.

The physical network ID (PNetID) is also displayed, which can be useful in determining why "RoCE" or ISM interfaces are not associated with the OSA or HiperSockets interface.

You can also use the Netstat DEvlinks/-d report to display information about SMC links and link groups:

- You can display the SMC-R links and SMC-R link groups that traverse a "RoCE" interface, including the redundancy level for the link group as described in [“SMC-R high availability considerations” on page 550](#).
- You can display the SMC-D links that traverse an ISM link.

To obtain information about SMC links and link groups, you must specify the SMC modifier on the Netstat command.

You can filter the Netstat report by using the SMCID/-U filter and specifying an SMC-R link ID or link group ID as the filter:

- When an SMC-R link ID is specified, information about that SMC-R link is displayed, in addition to information about the SMC-R link group that contains the link.
- When an SMC-R link group ID is specified, information about the SMC-R link group and all SMC-R links within the group is displayed.
- When an SMC-D link ID is specified, information about that SMC-D link is displayed.

You can display information about interfaces based on the PNetID value that is assigned to the interface by using the PNETID modifier on the Netstat command.

- To display all interfaces that have a PNetID value, specify PNETID=\* as the modifier value.
- To display all interfaces that have a specific PNetID value, specify PNETID=*physical network ID* as the modifier value.

For more information, see [z/OS Communications Server: IP System Administrator's Commands](#).

### Netstat PORTList/-o report

You can use the Netstat PORTList/-o report to display the settings of the NOSMC and SMC parameters for the defined TCP port or range of ports.

### Netstat STATS/-S report

You can use the Netstat STATS/-S report to display SMC-R and SMC-D usage statistics.

- In some cases, the statistics are a subset of the overall TCP statistics of the same name. For example, a value for the field `Current Established Connections` is displayed under `TCP Statistics`, `SMCR Statistics`, and `SMCD Statistics`. To determine the number of current connections that do not traverse an SMC link, subtract the total of SMC-R and SMC-D statistics from the total of TCP statistics.
- In other cases, the statistics represent information that is applicable to SMC-R or SMC-D processing only. For instance, the field `Active SMC Links Opened` has no corresponding TCP statistics value.
- For information about which SMC statistics fit in which category in the [Netstat STATS/-S report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

### DISPLAY TCPIP,,STOR output

You can use the DISPLAY TCPIP,,STOR command to display current SMC-R and SMC-D storage usage.

- SMC-R values are displayed for remote memory buffers (RMBs), denoted as `SMC-R RECV MEMORY`, and staging buffers, denoted as `SMC-R SEND MEMORY`. This storage is limited by the setting of the `FIXEDMEMORY` subparameter on the `GLOBALCONFIG SMCR` parameter. The SMC-R information is displayed only when the SMC-R function is enabled or was previously enabled for this TCP/IP stack.
- SMC-D values are displayed for direct memory buffers (DMBs), denoted as `SMC-D FIXEDMEMORY`. This storage is limited by the setting of the `FIXEDMEMORY` subparameter on the `GLOBALCONFIG SMCD` parameter. The SMC-D information is displayed only when the SMC-D function is enabled or was previously enabled for this TCP/IP stack.

## Monitoring SMC information

z/OS Communications Server provides various tools that you can use to monitor Shared Memory Communications (SMC) information:

- [“Network Management Interface” on page 587](#)
- [“SMF records” on page 587](#)
- [“SNMP” on page 588](#)

### Network Management Interface

Several TCP/IP callable NMI (EZBNMIFR) requests include information about SMC in general and specifics about "RoCE Express" and ISM interfaces:

- The GetConnectionDetail request provides information about active TCP connections, including SMC information for TCP connections that traverse SMC-R or SMC-D links.
- The GetGlobalStats request provides TCP/IP stack global statistics for IP, ICMP, TCP, UDP, SMC-R, and SMC-D processing.
- The GetIfs request provides TCP/IP stack interface attributes and IP addresses, including information about "RoCE Express" and ISM interfaces.
- The GetProfile request provides profile information, including GLOBALCONFIG information for SMC-R and SMC-D.

In addition, the following NMI requests that are specific to SMC-R information are available:

- The GetRnics request, which provides interface statistics and VTAM tuning statistics that are related to "RoCE Express" interfaces. This request provides similar information to what is returned on the GetIfStats and GetIfExtendedStats requests for traditional interfaces.
- The GetSmcLinks request, which provides statistics about active SMC-R link groups and the SMC-R links within the link groups.

In addition, the following NMI requests that are specific to SMC-D information are available:

- The GetIsms request, which provides interface statistics that are related to ISM interfaces. This request provides similar information to what is returned on the GetIfStats and GetIfExtendedStats requests for traditional interfaces.
- The GetIsmLinks request, which provides statistics about active SMC-D links.

For specifics about these [EZBNMIFR](#) requests, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

### SMF records

Several SMF 119 records include information about SMC in general and specifics about "RoCE Express" interfaces or ISM interfaces:

- The TCP connection termination SMF record (subtype 2) notifies the user when a TCP connection terminates. The record includes SMC information for TCP connections that traverse SMC-R or SMC-D links.
- The TCP profile event SMF record (subtype 4) notifies the user of changes to the TCP/IP profile. The records include GLOBALCONFIG and SMFCONFIG information for SMC-R and SMC-D, and IPCONFIG and IPCONFIG6 information for SMC-D.
- The TCP/IP statistics SMF record (subtype 5) provides statistics for a variety of TCP/IP functions. The records include global statistics and storage usage statistics that are related to SMC-R and SMC-D processing.

In addition, SMF type 119 records that are specific to SMC-R processing are available:

- The SMC-R link state start (subtype 42) and SMC-R link state end (subtype 43) SMF records notify the user when an SMC-R link is activated or deactivated. These SMF records serve a similar purpose for SMC-R links as the TCP connection start and TCP connection end records serve for TCP connections.
- The SMC-R link group statistics SMF record (subtype 41) provides statistics for all active SMC-R link groups on an interval basis. This SMF record includes information pertinent to both SMC-R link groups and the individual SMC-R links that comprise the link group.
- The RNIC interface statistics SMF record (subtype 44) provides interface statistics for "RoCE Express" interfaces on an interval basis. This SMF record serves the same purpose for "RoCE Express" interfaces that the interface statistics SMF record (subtype 6) serves for other interfaces.

In addition, SMF type 119 records that are specific to SMC-D processing are available:

- The SMC-D link state start (subtype 39) and SMC-D link state end (subtype 40) SMF records notify the user when an SMC-D link is activated or deactivated. These SMF records serve a similar purpose for SMC-D links as the TCP connection start and TCP connection end records serve for TCP connections.
- The SMC-D link group statistics SMF record (subtype 38) provides statistics for all active SMC-D link on an interval basis.
- The ISM interface statistics SMF record (subtype 45) provides interface statistics for ISM interfaces on an interval basis. This SMF record serves the same purpose for ISM interfaces that the interface statistics SMF record (subtype 6) serves for other interfaces.

For more information about [Type 119 SMF records](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

## SNMP

The Simple Network Management Protocol (SNMP) TCP/IP subagent provides Shared Memory Communications information, such as SMC eligibility and the associated physical network ID (PNetID) for IPAQENET, IPAQENET6, EQENET, EQENET6, IPAQIDIO, IPAQIDIO6, RNIC, and ISM interfaces. SNMP also reports basic information about "RoCE" and ISM interfaces. The following SNMP MIB tables contain the information:

- `ibmTcpiMvsIfTable`
- `ibmTcpiMvsPortTable`

All the MIB objects that are supported by Communications Server functions are listed in the [MIB objects](#) appendix in [z/OS Communications Server: IP System Administrator's Commands](#).

## VTAM displays and tuning statistics

When a "RoCE" or internal shared memory (ISM) interface is first started, VTAM dynamically creates a transport resource list element (TRLE) to represent it.

- For a RoCE Express2 or RoCE Express3 and Network Express (NETH) interface interface, the TRLE name is in the form of `IUTpffff`, where *p* is the port number and *ffff* is the PCI-Express function ID (PFID). The Network Express port number is always 1.
  - For a 10 GbE RoCE Express feature, if you specify `GLOBALCONFIG SMCR PFID 0018 PORTNUM 1`, the TRLE name is `IUT10018`.
  - For a RoCE Express2 or RoCE Express3 feature, if you specify `GLOBALCONFIG SMCR PFID 0055`, the TRLE name will be `IUT10055` or `IUT20055`. It depends on the port number defined for PFID 55 in the Hardware Configuration Definition (HCD). VTAM learns the port number when the PFID is activated.
  - For a Network Express feature, if you specify `GLOBALCONFIG SMCR PFID 0055`, the TRLE name will be `IUT10055`. The port number is always 1 and is not configurable.

**Tip:** The PFID can also be defined on the OSA INTERFACE statement for creating an SMC-Rv2 interface. The dynamically created TRLE for the RoCE interface uses the same naming conventions as described above for the GLOBALCONFIG SMCR Pf Ids.

- For an ISM interface, the TRLE name is in the form of IUT0ffff, where *ffff* is the PFID that is associated with the ISM device that VTAM selects to use with this physical network. For example, if the PFID value is 0024, the TRLE name is IUT00024.

You can use the VTAM DISPLAY TRL and DISPLAY ID commands to display information about the TRLE representation of the "RoCE" or ISM interface, including information about the physical network ID (PNetID), and which TCP stacks use the interface.

VTAM tuning statistics are managed differently for "RoCE" interfaces and ISM interfaces:

- VTAM collects tuning statistics for "RoCE" interfaces when requested by using the TNSTAT start option or the MODIFY TNSTAT command. Tuning statistics that represent processing at a "RoCE" interface level and statistics at a user or TCP/IP stack level are both maintained. The TCP/IP stack level statistics are also provided on the GetRnics request. For more information, see ["Network Management Interface" on page 587](#).
- ISM interfaces are not affected by the MODIFY TNSTAT command or the TNSTAT start option. VTAM collects a minimal set of tuning statistics for the ISM interface, and these statistics are included on the Netstat DEvlinks/-d report and the GetIsms request. For more information, see ["Network Management Interface" on page 587](#).

For more information about the VTAM commands, see [z/OS Communications Server: SNA Operation](#).

For more information about [Gathering tuning statistics](#), see [z/OS Communications Server: SNA Network Implementation Guide](#).

## Stopping SMC-R

You can stop Shared Memory Communications over RDMA (SMC-R) at a stack-wide level.

### Procedure

Perform the following steps to stop SMC-R:

1. Modify the GLOBALCONFIG statement in the TCP/IP profile data set to include the NOSMCR parameter.
2. Issue the VARY TCPIP,,OBEYFILE,*profile\_data\_set* command.

### Results

The TCP/IP stack does not immediately stop all existing SMC-R processing after the VARY TCPIP,,OBEYFILE command is processed. Existing TCP connections that are using existing SMC-R links are unaffected and continue to use SMC-R communications until they end or are stopped. However, no new SMC-R link groups or links are created, and no TCP connections that are established after this point use the existing SMC-R links.

### What to do next

When you are restarting SMC-R after a stop, the previous SMCR parameter settings are used when they are not explicitly configured in the OBEYFILE data set. For more information about [GLOBALCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Stopping SMC-D

You can stop Shared Memory Communications - Direct Memory Access (SMC-D) at a stack-wide level.

### Procedure

1. Modify the GLOBALCONFIG statement in the TCP/IP profile data set to include the NOSMCD parameter.
2. Issue the VARY TCPIP,,OBEYFILE,*profile\_data\_set* command.

## Results

The TCP/IP stack does not immediately stop all existing SMC-D processing after the VARY TCPIP,,OBEYFILE command is processed. Existing TCP connections that are using existing SMC-D links are unaffected and continue to use SMC-D communications until SMC-D links end or are stopped. However, no new SMC-D links are created, and TCP connections that are established after this point do not use the existing SMC-D links.

## What to do next

When you restart SMC-D after a stop, the previous SMCD parameter settings are used if they are not explicitly configured in the OBEYFILE data set. For more information about [GLOBALCONFIG statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

---

## Part 2. Server applications

## Chapter 11. Accessing remote hosts using Telnet

Telnet is a terminal emulation protocol. With Telnet, users can log on to remote host applications as though they were directly attached to that host. Telnet protocol requires that the user have a Telnet client that emulates a type of terminal that the host application can understand. The client connects to a Telnet server, which communicates with the host application. The Telnet server acts as an interface between the client and host application. A PC can support several clients simultaneously, each with its own connection to any Telnet server. This topic describes how to set up and use the following kinds of Telnet servers:

- TN3270E Telnet server

Provides access to z/OS VTAM SNA applications on the MVS host using Telnet TN3270E, TN3270, or linemode protocol

- z/OS UNIX Telnet server

Provides access to z/OS UNIX shell applications on the MVS host using Telnet linemode protocol

You can use the same port for both Telnet servers. For an overview of port management, see [“Port management overview”](#) on page 46. For more specific information about the PORT BIND statement, see [“Setting up reserved port number definitions in PROFILE.TCPIP”](#) on page 286.

### The TN3270E Telnet server

The TN3270E Telnet server (Telnet) provides access to z/OS VTAM SNA applications on the MVS host using Telnet TN3270E, TN3270, or linemode protocol. Telnet acts as an interface between IP and SNA networks. End users in an IP network connect to Telnet, which is also a VTAM application. Telnet activates one SNA application minor node logical unit (LU) to represent each Telnet IP client. The Telnet application LU establishes a session with a VTAM host application (for example, CICS or TSO), simulating a terminal (LU0 or LU2) or a printer (LU1 or LU3). To enable connections, you must modify the VTAM and Telnet configuration data sets with Telnet statements. These statements describe Telnet server characteristics, the Telnet LUs, a listening port, and the characteristics of that port. After Telnet is started, you can use VARY and DISPLAY commands that are specifically related to Telnet to alter the state of Telnet or to display information about Telnet. For more information about these command sets, see [z/OS Communications Server: IP System Administrator's Commands](#).

Figure 90. Telnet connectivity

### Steps for starting the TN3270E Telnet server

Use these steps for the minimum information that you need to start the TN3270E Telnet server. The steps refer to more specific information about customizing your server.

#### Before you begin

You need to know how to create VTAM definition data sets; specifically, you need to know how to define VTAM application LUs. You need to set up and know how to use a TN3270E client emulator. A maximum of eight Telnet servers can be active at any time.

## Procedure

Perform the following steps to start the TN3270E Telnet server:

1. Create a new data set member in your procedure library for the TN3270E Telnet server JCL.  
A sample procedure is in SEZAINST(EZBTNPRC). The only valid parameter that can be passed in from the JCL (using the PARM= keyword on the EXEC JCL statement) is the component trace options parmlib member name.
2. Define security for a user ID and associate the user ID with the Telnet procedure name; see [“Steps for defining security for a user ID and associating the user ID with the Telnet procedure name” on page 595](#).
3. Customize the VTAM configuration data set to define VTAM application LUs for Telnet to use; see [“Steps for customizing the VTAM configuration data set for Telnet” on page 597](#).
4. Customize the TCP/IP configuration data set.  
Reserve your Telnet ports by using the PORT *num tnproc* statement in the TCP/IP startup profile. If you do not code the PORT *num tnproc* statement, another application might use the port before the Telnet application can claim it.
5. Customize the TN3270E Telnet server configuration data set; see [“The TN3270E Telnet server configuration data set” on page 598](#) and [“Steps for customizing the TN3270E Telnet server configuration data set” on page 599](#).
6. Set the component trace options (CTRACE).  
Component trace options are set in a separate parmlib data set member. The sample procedure JCL points to a sample parmlib member, CTIEZBTN, in SYS1.PARMLIB, which starts a minimum trace. Use this member unless you need to turn on other options to debug a Telnet problem.  
  
To change the component trace options, specify a new parmlib member in the JCL. The member has the form CTIEZBxx. For more information about setting up trace options, see [“Telnet CTRACE” on page 601](#).
7. Set up the resolver input file.  
Use the default search order unless there are special circumstances that require you to use unique parameters. For example, if there are parameters that are to be used only when the resolver is called by Telnet, you need to define those unique parameters. Define the unique parameters in a data set that is specified on the SYSTCPD DD statement in the Telnet procedure JCL. For more information about resolvers and resolver configuration files, see [Chapter 13, “The resolver,” on page 753](#).
8. Start Telnet by issuing START *tnproc*, where *tnproc* is the Telnet procedure member name.

## Results

You should now see message EZZ6003I *tnproc* LISTENING ON PORT *nnnnn*. To verify your configuration, connect to the Telnet port from your Telnet client emulator; Telnet uses the first Telnet LU that is available. A solicitor screen or USSMSG10 screen prompts you to enter an application. Enter the name of any valid SNA application to log on to that SNA application. If an error occurs during session initiation, the MSG07 statement causes an error message to be sent to the client. If you do not code the MSG07 statement, then the connection is dropped.

### Tips:

- To help avoid any unnecessary IPL, specify REUSASID=YES on the START command to ensure that the address space identifier (ASID) associated with the Telnet address space can be reused. The Telnet address space provides PC-entered services that must be accessible to all address spaces, so a system linkage index (LX) is obtained. Unless you specify REUSASID=YES on the START command, the ASID associated with the Telnet address space will be nonreusable when the address space is stopped or restarted. If the Telnet address space is stopped enough times and REUSASID=YES is not specified when started, all available ASIDs could be exhausted, preventing the creation of a new address space on the system. In this case, an IPL is required. For more information about tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in [z/OS MVS Initialization and Tuning Reference](#).

- The default MVS program properties table (PPT) entry sets Telnet to be a non-cancelable application. As a non-cancelable application, a TCP/IP stack should not automatically start Telnet using the AUTOLOG function. If the TCP/IP stack is recycled, the stack tries to cancel and restart all AUTOLOG applications. A non-cancelable application does not end and the following messages are issued repeatedly:

```
N 0140000 SA6I 2005147 04:59:27.69 STC07087 00000084 EZZ0621I AUTOLOG FORCING IBMTNSI0, REASON: TCP/IP HAS BEEN RESTARTED
NR0000000 SA6I 2005147 04:59:27.71 STC07087 00000080 IEE838I IBMTNSI0 NON-CANCELABLE - ISSUE FORCE ARM
```

If you want to set the priority for Telnet in the PPT, change the priorities by assigning the job name to another service class in the STC subsystem.

The default settings are: Privileged, non-swappable, non-cancelable, running in key 6, and system task. With these settings, Telnet and the TCP/IP stack have the same priority. The privileged or system task setting causes the started job to be assigned to the SYSSTC service class.

- To change the IPv6 or INET environments, you must recycle the Telnet procedure. Telnet checks for changes in the environment each time a port is activated. If Telnet detects a change in the environment, then the port is not activated. If you change from an IPv4 environment to an IPv6 environment, from an IPv6 environment to an IPv4 environment, from an INET environment to a CINET environment, or from a CINET environment to an INET environment, then results are unpredictable on existing ports.

## Steps for defining security for a user ID and associating the user ID with the Telnet procedure name

Before you can start Telnet, you must define security for a user ID and associate it with the Telnet procedure name. These steps use RACF as the example security subsystem. If you are using another security product, see the documentation for that product to determine the appropriate procedure.

### Before you begin

- You need to know the name of the Telnet procedure that you are using.
- Ensure that the MAXSOCKETS value is large enough to support the anticipated number of sockets that will be used by the system. If your system is IPv6 enabled, Telnet listening sockets are IPv6; set the IPv6 MAXSOCKETS value appropriately.
- Ensure that the file descriptor limit for a process is large enough to support the anticipated number of sockets that will be used by Telnet. If your system MAXFILEPROC limit is adequate, you do not need to make a change. If you need a larger limit, you can configure a higher limit for Telnet using the FILEPROCMAX attribute in the OMVS SAF options for the Telnet user ID. If the Telnet user ID is a superuser ID or has READ access to the BPX.SUPERUSER resource, Telnet will dynamically increase its file descriptor limit to the maximum allowed by z/OS UNIX System Services, currently 524,287. For more information about MAXFILEPROC, see [z/OS UNIX System Services Planning](#).

## Procedure

Perform the following steps to define security for a user ID and to associate it with the procedure name.

### 1. Use an existing user ID or create a new user ID:

- Define a user ID with a nonzero UID value and do not permit it to the BPX.SUPERUSER resource. You will see message EZZ6049I *tnproc* NON-ZERO OMVS UID IN EFFECT, indicating that you associated Telnet to a user ID that does not have superuser authority. The number of connections allowed on a single port will be the MAXFILEPROC value. The number of connections can be overridden on the ALTUSER command with the FILEPROCMAX option. For example, you can allow 150,000 connections using the following command:

```
ALTUSER TN3270E DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(23) FILEPROCMAX(150000)
HOME('/'))
```

If connection failures occur (EZZ6012I *tnproc* BPX1AI0 ACCEPT FAILED, RC = 0000007C RSN = 050B0146) followed by a port quiesce (EZZ6003I *tnproc* QUIESCED ON PORT 23), the MAXFILEPROC value has been reached.

**Tip:** If your MAXFILEPROC value is less than your expected number of Telnet connections on a single port, you should use superuser authority or the FILEPROC MAX option on the RACF ALTUSER command. The FILEPROC MAX value will override the MAXFILEPROC value for processes associated with the user ID. If you do not use the FILEPROC MAX option and you do not give the associated user ID superuser authority by permitting the user ID to the BPX.SUPERUSER resource, Telnet is not able to increase the MAXFILEPROC value on the listener socket and will support the number of connections specified by the MAXFILEPROC value instead of the OMVS maximum.

- Permit a user ID with a nonzero UID value to the BPX.SUPERUSER resource in the FACILITY class:
  - a. Add the user to RACF:

```
ADDUSER TN3270E
```

- b. Permit the user ID:

- i) Create a BPX.SUPERUSER FACILITY class profile:

```
RDEFINE FACILITY BPX.SUPERUSER
```

- ii) If this is the first class profile, activate the FACILITY class:

```
SETOPTS CLASSACT(FACILITY)
SETOPTS RACLIST(FACILITY)
```

- iii) Permit the user to the class:

```
ALTUSER TN3270E DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(23) HOME('/'))
PERMIT BPX.SUPERUSER CLASS(FACILITY) ID(TN3270E) ACCESS(READ)
```

In this example, the user ID is TN3270E and the UID is 23. The UID can be any nonzero number. UID 23 was used to match the well-known Telnet port number.

- iv) Refresh the FACILITY class:

```
SETOPTS RACLIST(FACILITY) REFRESH
```

This example uses TN3270E for the user ID, but you can use any name.

**Tip:** You can combine the ADDUSER and ALTUSER commands into one command by putting the OMVS parameter on the ADDUSER command line. The ADDUSER and ALTUSER commands are performed separately in case the user ID already exists. Even if the ADDUSER command fails, the ALTUSER command is successful.

- Use an existing superuser ID to associate with the job name.
- Define a superuser ID to associate with the job name.

To define a superuser ID, add a user ID to RACF and alter it to superuser status:

```
ADDUSER TN3270E
ALTUSER TN3270E DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
```

Sample statements for defining a superuser ID are in SEZAINST(EZARACF). For more information, see [z/OS UNIX System Services Planning](#), [z/OS Security Server RACF Security Administrator's Guide](#), and [z/OS Security Server RACF Command Language Reference](#).

2. Add the procedure name to the RACF STARTED class and associate the user ID from step 1 with the name.

For example, code the following statements:

```
RDEFINE STARTED TELNET*.* STDATA(USER(TN3270E))
SETOPTS RACLIST(STARTED) REFRESH
```

Sample statements for adding the procedure to the STARTED class are in SEZAINST(EZARACF). For more information, see [z/OS UNIX System Services Planning](#), [z/OS Security Server RACF Security Administrator's Guide](#), and [z/OS Security Server RACF Command Language Reference](#).

3. If you are using secure Telnet connections, make sure that the user ID that runs Telnet has access to the SSL key ring and certificates.  
Take one of the following actions:
  - Create a new key ring and certificate that is owned by the user ID that runs Telnet.
  - Share the existing key ring and certificates with Telnet. For more information about [Implementation scenarios](#), see [z/OS Security Server RACF Security Administrator's Guide](#).
4. If you are using hardware encryption, ensure that the Telnet user ID has read access to the RACF CSFSERV class resources. For details, see [“Encryption algorithms” on page 1362](#).

## Results

You know you are done when you can start Telnet without receiving errors.

If your job ends abnormally with system completion code EC6 and a register 15 value of 0F01C008, you did not associate a valid user ID with the started job name.

## Steps for customizing the VTAM configuration data set for Telnet

Telnet uses application LUs that are defined in VTAM application (APPL) major nodes to represent clients.

### Before you begin

You can code LU definitions in the data set members of your choice. You must include the data set that contains your member updates in the list of data sets that is specified on the VTAMLST DD statement in the procedure that is used to start VTAM. Including this data set in the list ensures that the LUs are available for activation after VTAM is started.

## Procedure

Perform the following steps to customize the VTAM configuration data set:

1. Automatically activate the application definition deck by including it in ATCONxx.
2. Define the LUs in a VTAM data set member.

A sample VTAM configuration data set is in SEZAINST(IVPLU).

**Tip:** In the VTAM configuration data set, you can define Telnet LUs that represent either terminal or printer emulators with a wildcard character instead of coding individual Telnet application LU statements. The Model Application Names function enables you to code a model APPL name with an asterisk (\*) or a question mark (?) (see [z/OS Communications Server: SNA Resource Definition Reference](#) for more information). Use \* as a wildcard character to replace a character string. For example, if you need Telnet LUs in the range TCPABC01-TCPABC99, then you can add a single VTAM application definition statement to the sample configuration data set. The definition statement has the Telnet application minor node (Telnet LU) name TCPABC\*, which supports all 99 LUs.

3. Use the default value YES for the SESSLIM parameter.

Telnet server LUs do not support multiple concurrent sessions.

4. Code LOSTERM=IMMED on all target (PLU) applications that will have a SNA session with Telnet.

If you do not code this value, CLOSEACB might stop while it is waiting for UNBIND RESPONSE if the target (PLU) application does not issue CLSDST when the LOSTERM exit is processed.

5. Code EAS=1 to minimize Common Service Area (CSA) storage use.

If you use the default value for EAS, excessive CSA storage will be used.

6. Use the default VTAM value NO for PARSESS.

You should not use parallel sessions with Telnet LUs.

## Results

When you are done, start VTAM. Put the LUs in a connectable state by activating the APPL major node that represents the Telnet LUs. Issue the D NET,MAJNODES command or the D NET,ID=*appl\_major\_node\_name* command to verify that your APPL major node is active.

## The TN3270E Telnet server configuration data set

Telnet configuration statements are processed during the initialization of the TN3270E Telnet server or when you issue the VARY TCPIP,*tnproc*,OBEYFILE command to update the Telnet configuration data set. (For information about using the VARY TCPIP,*tnproc*,OBEYFILE command to update the Telnet configuration data set, see [“Using the VARY TCPIP,\*tnproc\*,OBEYFILE command to update Telnet configuration” on page 603](#)). The Telnet configuration statements enable the following definition and session setup:

- Define Telnet server characteristics
- Define connection characteristics
- Define LU names to represent Telnet clients
- Facilitate session setup with MVS host VTAM applications

**Requirement:** When configuration data sets are processed, the TELNETPARMS and BEGINVTAM blocks are required for each port that you start or modify.

You use the following statement blocks to configure Telnet:

### TELNETGLOBALS and ENDTELNETGLOBALS

An optional statement block that contains Telnet parameter statements. The parameters define connection characteristics for all ports.

### TELNETPARMS and ENDTELNETPARMS

A required statement block that contains Telnet parameter statements. You must create a unique TELNETPARMS block for each port and for each qualified port. The parameters define connection characteristics for the specified port. A TELNETPARMS block is required for each port that you start or modify using the VARY TCPIP,*tnproc*,OBEYFILE command.

### BEGINVTAM and ENDVTAM

A required statement block that contains Telnet mapping statements. The mapping statements define how applications and LU names are mapped (assigned) to clients. Each port that you start or modify using the VARY TCPIP,*tnproc*,OBEYFILE command must have a BEGINVTAM block. You can use one BEGINVTAM block for all ports, you can use one BEGINVTAM block for some of your ports and another BEGINVTAM block for the remaining ports, or you can use a unique BEGINVTAM block for each of your ports.

### PARMSGROUP and ENDPARMSGROUP

An optional parameter group statement in the BEGINVTAM block that contains Telnet parameter statements. The parameters define connection characteristics for the mapped clients.

See [z/OS Communications Server: IP Configuration Reference](#) for the exact syntax rules for these statement blocks. See [“Using the VARY TCPIP,\*tnproc\*,OBEYFILE command to update Telnet configuration” on page 603](#) for information about profile processing.

Telnet initially sets all connection parameters to default values. These connection parameter values are arranged hierarchically, as shown in [Figure 91 on page 599](#).

Figure 91. Telnet parameter placement

You can change these parameter values at any of the levels in the hierarchy, depending on how you want the changes to be applied to successive connection levels. Parameters that you code in the TELNETGLOBALS block are applied to all connections on all ports, unless these values are overridden by parameters in either the TELNETPARMS block or the PARMSGROUP block. Parameters that you code in the TELNETPARMS block are applied to all connections on the specified port, unless these values are overridden by parameters in the PARMSGROUP block. Parameters that you code in the PARMSGROUP block are applied to connections with clients that are mapped to that PARMSGROUP block. For a complete list of Telnet parameters, see [z/OS Communications Server: IP Configuration Reference](#).

Eleven mapping statements are available in the BEGINVTAM block. These mapping statements map objects to client identifiers that are specified on the port. Five statements are related to application setup, four are related to LU name assignment, one maps connection parameters, and one maps monitoring rules. After a connection request is accepted, Telnet uses the mapping statements to map, or assign, as many of the eleven objects to the client as possible. This set of objects is used for the duration of the connection. For more information, see [“Mapping Objects to Client Identifiers”](#) on page 629.

The sample profile in SEZAINST(TNPROF) contains additional statements that are included as comments. These statements provide examples of advanced functions. Many of these statements are installation-specific; you need to modify these statements to suit your installation.

## Steps for customizing the TN3270E Telnet server configuration data set

You can customize the TN3270E Telnet server by defining server, connection, and other configuration characteristics.

### Before you begin

You need to create the data set in which you will put the configuration information. You must also specify the profile data set name on the PROFILE DD statement in the procedure JCL that is used to start Telnet. The data set must be defined with format fixed block, and must have a record length of 56-256. The block size must be evenly divisible by the record length.

If you are using multiple TN3270E Telnet servers, ensure that each server uses unique LU names, or define shared LU name groups. If you do not use unique LU names or create shared LU name groups, then the second server that uses the same LU name will not be able to establish a session; either the OPEN ACB request will fail or the cross-domain session request will fail.

For information about updating Telnet configuration, see [“Using the VARY TCPIP,tproc,OBEYFILE command to update Telnet configuration”](#) on page 603.

## Procedure

Perform the following steps to customize the TN3270E Telnet server configuration data set. A sample configuration is in SEZAINST(EZBTNPRF).

1. Define Telnet server characteristics.

The minimum required definition is the TELNETPARMS block with the PORT statement. The following functions are optional:

- To associate Telnet with one TCP/IP stack, see [“Associating Telnet with one TCP/IP stack”](#) on page 609.
- To set up Telnet in a sysplex to share LU names, see [“Shared LU name groups for Telnet servers”](#) on page 610.
- To qualify a port with the destination IP address or link name to differentiate between Telnet services, see [“Qualified ports”](#) on page 613.
- To use multiple Telnet ports, see [“Multiple ports”](#) on page 615.
- To reduce ECSA storage use when supporting a large number of connections, see [“Reducing demand for ECSA storage”](#) on page 677.

2. Define connection characteristics at the server or port level.

- To determine the connection type, see [“Connection mode choices”](#) on page 616.
- For security, see [“Connection security”](#) on page 621.
- For persistence, see [“Connection persistence”](#) on page 627.

3. Understand the concept of mapping Objects to Client Identifiers.

To understand the concept of mapping Objects to Client Identifiers, see [“Mapping Objects to Client Identifiers”](#) on page 629.

4. After you identify all the clients in your network, determine which clients have unique characteristics (for example, a particular client should use a certain LU name) and need to remain exact Client Identifiers, and which clients can be combined into Client Identifier groups using wildcard values.

5. Use LU name mapping statements to assign LU names to connections based on the Client Identifier. This step is required. See [“LU name mapping statements”](#) on page 640.

6. Use application mapping statements to facilitate session setup based on the Client Identifier. See [“Application mapping statements”](#) on page 644.

7. Use the connection parameters mapping statement to change connection parameters based on specific Client Identifiers. To extend connection mode, security, and persistence choices to Client Identifiers, see [“Connection parameters mapping statement”](#) on page 647.

8. Consider advanced topic features for additional Telnet functions.

- [“Advanced LU name mapping topics”](#) on page 647
- [“Advanced application topics”](#) on page 657
- [“Device types and logmode considerations”](#) on page 666
- [“Using the Telnet solicitor or USS logon screen”](#) on page 667
- [“SMF”](#) on page 671
- [“Connection monitoring mapping statement”](#) on page 672

## Results

You know you are done when you do not receive errors after you apply the profile.

## Telnet CTRACE

Telnet uses the TCP/IP stack component name SYSTCPIP. Telnet CTRACE with only the Telnet option specified provides complete information about Telnet processes. You do not need other CTRACE options for debugging most Telnet problems.

A sample Telnet component trace is supplied. The member name is CTIEZBTN in SYS1.PARMLIB. You set up tracing for Telnet in the same way that you set up tracing for the TCP/IP stack; however, there are fewer trace options needed for Telnet. You can change the component trace in the JCL by specifying a new parmlib member in the form CTIEZBxx. For a complete description of the trace options and for information about how to set up tracing, see the [TCP/IP services traces and IPCS support information](#) in *z/OS Communications Server: IP Diagnosis Guide*.

The following subset of trace options is available in the SYSTCPIP component when it is set up for Telnet:

- ALL (excludes SERIAL, STORAGE, and TIMER)
- INIT (includes OPCMDS and OPMSGGS)
- MESSAGE
- MIN or MINIMUM (includes INIT, OPCMDS, and OPMSGGS)
- MISC
- NONE (or OFF)
- OPCMDS (includes INIT and OPMSGGS)
- OPMSGGS (includes INIT and OPCMDS)
- SERIAL
- STORAGE
- TELNET
- TIMER
- WORKUNIT

## Managing Telnet

This topic describes information needed to manage Telnet, such as command and port information.

### Telnet commands

Telnet commands are TCP/IP commands. You must specify the procedure name on all commands; otherwise, the command is processed by the default TCP/IP stack instead of by the Telnet procedure. For example, assuming that the Telnet procedure name is TN3270E, the profile display command is as follows:

```
D TCPIP,TN3270E,PROFILE
```

If the procedure does not exist or if you incorrectly type the TCPIP keyword, then the command is assumed to be a TCP/IP command and a TCP/IP error message is displayed.

You use the following VARY and DISPLAY commands to change and monitor Telnet functions and to debug problems. Telnet VARY and DISPLAY commands are described in [z/OS Communications Server: IP System Administrator's Commands](#).

- Use Telnet VARY commands to change the state of Telnet ports, enable or disable the use of certain Telnet LU names, and manage diagnostic tools.
  - VARY TCPIP,*tnproc*,QUIESCE,PORT blocks any new connection requests but allows existing connections to continue activity.
  - VARY TCPIP,*tnproc*,RESUME,PORT ends the quiesce state and allows new connection requests.
  - VARY TCPIP,*tnproc*,STOP,PORT ends connections on the port and closes the port.

- VARY TCPIP,*tnproc*,OBEYFILE starts, restarts, or changes a port by updating the Telnet profile. Use the VARY TCPIP,*tnproc*,STOP and VARY TCPIP,*tnproc*,OBEYFILE commands to stop a Telnet port and then restart that port or start a new port without stopping the TCP/IP stack. You can also use these commands to increase the level of participation in the Telnet XCF group. A Telnet server that has joined the group becomes a standby LUNS, even if you used an OBEYFILE command to specify it to be a primary LUNS.
- Tip:** When you issue a VARY TCPIP,*tnproc*,OBEYFILE command, the TELNETPARMS and BEGINVTAM blocks are required for each port that you start or modify.
- VARY TCPIP,*tnproc*,ACT,*luname* activates LUs for use by the Telnet server. Specify ALL for *luname* to activate all inactive LUs with one command. This command has no effect on the VTAM state of the LU.
- VARY TCPIP,*tnproc*,INACT,*luname* deactivates LUs for use by the Telnet server. If an LU is already in use, the command fails. This command has no effect on the VTAM state of the LU.
- VARY TCPIP,*tnproc*,DEBUG,OFF turns off all debug activity that might have been turned on to debug a problem.
- VARY TCPIP,*tnproc*,ABENDTRAP sets an abend trap based on unique Telnet return codes set in Telnet modules.
- Use Telnet VARY commands to change the state of a LUNS, and to enable or disable the use of certain LU names by a LUNS.
  - VARY TCPIP,*tnproc*,LUNS,START starts the takeover process by which a standby LUNS becomes the active LUNS.
  - VARY TCPIP,*tnproc*,LUNS,QUIESCE instructs a standby LUNS to stop monitoring the active LUNS. In case of a LUNS failure, this Telnet server will not be a takeover candidate. The Telnet server must be a takeover candidate for you to make changes to the LUNS using the OBEYFILE command.
  - VARY TCPIP,*tnproc*,LUNS,RESUME ends the quiesce state and instructs a LUNS to resume monitoring the active LUNS. In case of a LUNS failure, this Telnet will be a takeover candidate.
  - VARY TCPIP,*tnproc*,LUNS,ACT,*luname* activates LUs for use by the LUNS. Specify ALL for *luname* to activate all inactive LUs with one command. This command has no effect on the VTAM state of the LU.
  - VARY TCPIP,*tnproc*,LUNS,INACT,*luname* deactivates LUs for use by the LUNS. If an LU is already in use, the command fails. This command has no effect on the VTAM state of the LU.
- Use Telnet DISPLAY commands to review classic Telnet information.
  - D TCPIP,*tnproc*,PROFile displays summary or detail information about parameter statements from the TELNETGLOBALS or TELNETPARMS blocks.
  - D TCPIP,*tnproc*,OBJect displays summary or detail information about mapping statements from the Object perspective.
  - D TCPIP,*tnproc*,CLientID displays summary or detail information about mapping statements from the Client Identifier perspective.
  - D TCPIP,*tnproc*,CONN displays summary or detail information about client connections.
  - D TCPIP,*tnproc*,INACTLUS displays all LUs that were deactivated by the operator or by Telnet as a result of OPEN ACB or multilevel security problems.
  - D TCPIP,*tnproc*,STOR displays the maintenance level of a module or the amount of storage used by Telnet.
- Use Telnet DISPLAY commands to review information about Telnet in an XCF group.
  - D TCPIP,*tnproc*,XCF<,GRoup> displays the status of all members of the Telnet XCF group.
  - D TCPIP,*tnproc*,XCF,STats displays the performance status of the XCF Telnet server. If the Telnet server is a LUNS, the performance statistics between it and all LUNRs are reported.
- Use Telnet DISPLAY commands to review information about Telnet performing as a LUNS.
  - D TCPIP,*tnproc*,LUNS,OBJect displays summary or detail information about shared LUNR Objects on the LUNS.
  - D TCPIP,*tnproc*,LUNS,INACTLUS displays all the LUs that are inactive on the LUNS.

## Using the VARY TCPIP,*tnproc*,OBEYFILE command to update Telnet configuration

When you use the VARY TCPIP,*tnproc*,OBEYFILE command to update Telnet configuration, new profile statements create a new configuration that is used by all connections that are accepted after you updated the file. Existing connections continue to use the configuration that was in effect when those connections were accepted. The TELNETPARMS and BEGINVTAM blocks are required for each port that you start or modify. The new configuration that you create is not a cumulative update from the previous profile. If you need to make only one change in the new profile, change the old profile or copy the profile to another data set member and make the change.

After you have updated the Telnet configuration file and the VARY TCPIP,*tnproc*,OBEYFILE command processing is completed, the new profile is labeled as the current profile, and the replaced profile becomes profile 0001. If you make another update, the new update becomes the current profile and the replaced profile becomes profile 0002. If you updated the profile for a subset of the active ports, the ports that you did not update remain unchanged. You can suppress profile debug messages by coding DEBUG OFF or DEBUG SUMMARY in the TELNETGLOBALS block and then placing the TELNETGLOBALS block in front of all other Telnet statement blocks.

New connections are associated with the current profile and use the mappings and parameters that are defined by that profile for the life of the connection. Even if you issue a VARY TCPIP,*tnproc*,OBEYFILE command to update the port, existing connections remain associated with the same profile. The statements of profiles that are not the current profile remain in effect and continue to support all connections that were established when that profile was the current profile. When all connections that are associated with a non-current profile have ended, the storage for the non-current profile mapping rules is freed and the profile is considered inactive.

The structural layout of the profiles and how connections are associated with profiles are shown in [Figure 92 on page 604](#).

Figure 92. Telnet profiles and connections

## OMVS shutdown

The TN3270E Telnet server application uses UNIX System Services; when OMVS is shut down, Telnet services are no longer available. To prevent Telnet from abnormally ending, Telnet is automatically stopped prior to OMVS shutdown, and can be restarted after OMVS is restarted.

Telnet automatically registers with OMVS; because of this registration, OMVS notifies Telnet when OMVS shutdown is requested, and OMVS waits for Telnet to stop. When Telnet is notified of the OMVS shutdown, it immediately begins to stop, as if the MVS STOP command had been issued. After Telnet is stopped, OMVS shutdown is no longer blocked by the Telnet server.

If you plan to shut down OMVS, be sure your Telnet users are logged off before you shut down OMVS.

## Telnet diagnostic tools

In addition to general diagnostic tools such as CTRACE and dumps which are described in [z/OS Communications Server: IP Diagnosis Guide](#), there are several Telnet-specific diagnostic tools available.

### DEBUG messages

Telnet-specific debug messages can be turned on or off to diagnose Telnet problems related to client connections, Telnet tasks, or configuration processing. Several types of debug messages are available.

- Exception messages indicate that a problem was detected and are issued for connection, task, and configuration processing. Exception level debug is the default level.
- Summary messages indicate important status changes and are available for connection processing.

- Detail messages are issued when an important event occurs other than an error and are available for connection and task processing.
- Trace messages show detail data that is coming into and out of Telnet and are available for connection and configuration processing.

Message generation is controlled with the DEBUG statement. For information about the DEBUG statement, see [z/OS Communications Server: IP Configuration Reference](#).

Connection processing debug options are as follows:

- Exception

The DEBUG CONN EXCEPTION statement issues a message at the time of failure that displays the client IP address and port, connection ID, Telnet LU name, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to you and others will be helpful to IBM service. For message [EZZ6035I](#) return code details, see [z/OS Communications Server: IP Messages Volume 4 \(EZZ, SNM\)](#).

The DEBUG CONN EXCEPTION statement causes the CONN DROP message to be issued only for error conditions and inactivity reasons. DEBUG CONN EXCEPTION is the default. If more than one connection is dropped for the same reason within 15 seconds, a single message with LU name MULTIPLE will be issued. For example, if MSG07 is not coded in the DEBUG CONN DETAIL example, the connection will be dropped after the lookup failure. The CONN DROP message will include the return code and indicate that an error caused the connection drop. The following message will be produced whether or not DEBUG was coded because of the error condition.

```
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 CONN DROP ERR 3012
IP..PORT: 1.12.13.14..456 EZBTPGLU
```

- Summary

The DEBUG CONN SUMMARY statement provides tracking for the status of a connection. A summary message is written when:

- A connection request is accepted by Telnet.
- Connection negotiation is complete.
- A session is established with the host application.
- A session is dropped.
- A connection is dropped.

LU name, Connection ID, and client IP address and port are included in each message. In the example below a user connects to port 23. The connection is negotiated as a TN3270E connection and a session with TSO is established. The session is dropped because of client disconnect (CLNTDISC) and then the connection is dropped because of client disconnect.

```
EZZ6034I TNSERV11 CONN 00000011 LU **N/A** ACCEPTED 23
IP..PORT: 1.12.13.14..456
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 NEGOTIATED TN3270E
IP..PORT: 1.12.13.14..456
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 IN SESSION TS00001
IP..PORT: 1.12.13.14..456
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 SESS DROP CLNTDISC
IP..PORT: 1.12.13.14..456
EZZ6034I TNSERV11 CONN 00000011 LU TCPM1001 CONN DROP CLNTDISC
IP..PORT: 1.12.13.14..456
```

In addition to tracking major state changes and providing key information, the statements can be used for diagnostic purposes. For example, a user might be attempting a connection and something is not working. The ACCEPTED, NEGOTIATED, and IN SESSION messages are major connection milestones. Using the information provided and knowing whether or not these messages are displayed can provide many clues about the connection request. The SESS DROP and CONN DROP messages give a variety of reasons about why the drop occurred.

- Detail

You can use the DEBUG CONN DETAIL statement if the DEBUG CONN SUMMARY messages do not provide enough information to solve a problem. In addition to the summary messages, the DEBUG CONN DETAIL statement issues a message at the time of failure that displays the client IP address and port, connection ID, Telnet LU name, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to the system administrator and others will be helpful to IBM service. For message EZZ6035I return code details, see [z/OS Communications Server: IP Messages Volume 4 \(EZZ, SNM\)](#).

In the example below the user specified an application not in the Telnet profile and then disconnected at the client emulator.

```
EZZ6035I TNSERV11 DEBUG DETAIL CONN DETAIL
IP..PORT: 1.12.13.14..456
CONN: 00000011 LU: TCPM1001 MOD: EZBTPLU
RCODE: 3012-00 Application name is invalid.
PARM1: 00000000 PARM2: 00000000 PARM3: 00000000

EZZ6035I TNSERV11 DEBUG DETAIL CONN DETAIL
IP..PORT: 1.12.13.14..456
CONN: 00000011 LU: TCPM1001 MOD: EZBTTRCV
RCODE: 1001-02 Client disconnected from the connection.
PARM1: FFFFFFFF PARM2: 00000461 PARM3: 00000000
```

- Trace

The DEBUG CONN TRACE statement generates messages that contain data that was sent to and from the client, sent to and from VTAM, and sent to and from an LU name exit for a single connection. The TRACE option allows you to quickly see why a client is not connecting or why a session hangs. Be careful where you specify DEBUG CONN TRACE. Every connection that maps to the statement generates many messages. DEBUG CONN TRACE should be specified in a PARMSGROUP block that is mapped to only a few connections. Even when DEBUG CONN TRACE is specified in a PARMSGROUP block, it could flood the message console quickly if the connection is very active.

```
EZZ6034I TNSERV11 CONN 00000080 LU **N/A** ACCEPTED
IP..PORT: 9.14.6.42..36484
EZZ6035I TNSERV11 DEBUG CONN TRACE

CONN: 00000080 LU: MOD: FRM CLNT
-C-> FFFB28
PARM1: 00000003 PARM2: 00000000 PARM3: 00000000
EZZ6035I TNSERV11 DEBUG CONN TRACE
IP..PORT: 9.14.6.42..36484
CONN: 00000080 LU: MOD: TO CLNT
<-C- FFFA2808 02FFF0
PARM1: 00000007 PARM2: 00000000 PARM3: 00000000
```

Task processing debug options are as follows:

- Exception

The DEBUG TASK EXCEPTION statement issues a message at the time of a failure that displays the task, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to you and others will be helpful to IBM service. For message EZZ6035I return code details, see [z/OS Communications Server: IP Messages Volume 4 \(EZZ, SNM\)](#). DEBUG TASK EXCEPTION is the default for task processing debug.

The following exception message indicates that Telnet failed to join the XCF group because the group already contains the maximum number of members allowed.

```
EZZ6035I TLUNR1 DEBUG TASK EXCEPTION
TASK: XCF MOD: EZBTXXCF
RCODE: A006-01 Telnet failed to join the XCF group.
PARM1: 0000000C PARM2: 00000004 PARM3: MAX GROUPS OR MEMBERS
```

- Detail

The DEBUG TASK DETAIL statement issues a diagnostic message at certain event points that displays the task, detecting module name, unique return code and brief explanation, and additional parameters if relevant. The Detail option shows event milestones for different scenarios, enabling you to see some events of interest other than errors. Some messages will be helpful to the system administrator and others will be helpful to IBM service. For message EZZ6035I return code details, see [z/OS Communications Server: IP Messages Volume 4 \(EZZ, SNM\)](#).

The following detail message indicates that an outstanding receive failed for job TLUNR1 on MVS023.

```
EZZ6035I TLUNR1 DEBUG TASK DETAIL
TASK: XCFRECV MOD: EZBTXRCV
RCODE: A014-01 LUNS/LUNR receive failed.
PARM1: 00000000 PARM2: 00000000 PARM3: MVS023 TLUNR1
```

Configuration processing debug options are as follows:

- Exception

The DEBUG CONFIG EXCEPTION statement issues a message at the time of a failure that displays the line number, detecting module name, unique return code and brief explanation, and additional parameters if relevant. Some messages will be helpful to you and others will be helpful to IBM service. For message EZZ6035I return code details, see [z/OS Communications Server: IP Messages Volume 4 \(EZZ, SNM\)](#). DEBUG CONFIG EXCEPTION is the default for configuration processing debug.

The following message indicates that the value for scaninterval on line 35 is outside of the acceptable range.

```
EZZ6035I TLUNS1 DEBUG CONFIG EXCEPTION
LINE: 35 MOD: EZBTMPRP
RCODE: 805B-00 Value outside acceptable range for statement.
PARM1: PARM2: SCANINTE PARM3:
```

- Trace

The DEBUG CONFIG TRACE statement generates a statement message listing all words associated with the statement and a formatted control block message for each Telnet statement. This option can flood the message console if you have a very large configuration file. The CONFIG messages can be limited to a smaller, specified set of statements. If you specify a subset of statements, DEBUG CONFIG messages are issued only from those statements. If a large amount of CONFIG data is required, you can suppress the DEBUG messages by specifying the CTRACE option on the DEBUG statement. With the CTRACE option, the messages will be in the CTRACE but will not flood the console or joblog. CTRACE is the default option.

The sample below shows data sent to the console for profile statement LUGROUP:

```
DEBUG CONFIG TRACE,LUGROUP CONSOLE

EZZ6035I TNSERV11 DEBUG CONFIG TRACE
LINE: 82 MOD: EZBTMPRF
LUGRP1 TCPM1094 TCPM1102
PARM1: 00000003 PARM2: 00000052 PARM3: LUGROUP

EZZ6035I TNSERV11 TNSERV11 DEBUG CONFIG TRACE
LINE: 82 MOD: EZBTMPRF
E3C5D3C3 00000000 00000058 00005502 | TELC.....|
00000036 00000000 00000052 00000000 ||
00000000 00000000 00000000 00000000 ||

E3C3D7D4 F1F1F0F2 | TCPM1102 |
PARM1: 00000058 PARM2: 00000036 PARM3: LUGROUP
```

The DEBUG OFF statement ensures that all debug messages are suppressed , including the exception CONN DROP messages.

The DEBUG CONN parameter can cause flooding of the operator's console. Console flooding concerns can be dealt with in several ways.

- Most DEBUG messages are, by default, assigned to routing code 11, the JOBLOG. The DEBUG option JOBLOG can be used for the same effect. However, the master console also receives routing code 11 messages by default. To stop the messages from going to the master console, issue VARY CN(01),DROUT=(11), which drops routing code 11 from the console. Another DEBUG option, CONSOLE, will direct the messages to the master console, routing code 2, and the teleprocessing console, routing code 8. The CTRACE option suppresses messages completely while continuing tracing at the debug level.
- If DEBUG messages are being used primarily for problem diagnosis, the VARY TCPIP,*tnproc*,OBEYFILE command can be used to keep the number of messages low. Start Telnet initially without DEBUG coded. When a problem appears, issue a VARY TCPIP,*tnproc*,OBEYFILE command for a Telnet profile that includes the DEBUG statement. Only new connections to the new profile will produce messages. After data is obtained, issue another VARY TCPIP,*tnproc*,OBEYFILE command for a Telnet profile that omits the DEBUG statement.
- If the Client Identifier of the client having the problem is known, include DEBUG in a PARMSGROUP statement. Using PARMSMAP, map that group to the client. Debug messages for only that client will be issued.

The VARY TCPIP,*tnproc*,TELNET,DEBUG,OFF command can be issued to turn off DEBUG for all connections associated with all profiles, including the current profile. It will also turn off TASK and CONFIG DEBUG messages. To turn on DEBUG again, issue a VARY TCPIP,*tnproc*,OBEYFILE command with the Debug option specified in the Telnet profile. Summary messages for CONN DROP due to errors or time-outs will also be suppressed. Use DEBUG EXCEPTION to retain these messages.

## MSG07

The MSG07 parameter is very helpful when diagnosing problems. It allows Telnet to send a message to the client indicating an error occurred and what the error was. Something simple like a mistyped application name can be corrected by the user without additional help. Even for more difficult problems, MSG07 provides a good starting point. It is recommended that MSG07 always be coded unless there are reasons not to send error messages to the client.

## Abend trap

The VARY TCPIP,*tnproc*,TELNET,ABENDTRAP,*module*,*rcode*,*instance* command can be used to set up an abend based on the variables specified. Abend trap has three variables:

*module* is required. It is the module detecting the error. It can have a wildcard value by using asterisk (\*) at the end. If a single \* is used, any module reporting the specified return code will cause an abend. The module name "OFF" turns off an active trap.

*rcode* is optional. It is the return code reported and cannot have a wildcard value.

*instance* is optional. It is the instance of the return code and cannot have a wildcard value.

Below is an example setting the abend trap and then issuing a profile display to verify the trap is set. In the example, when EZBTTRCV reports an error code of 1001, Telnet will issue an abend with reason code '3133'x. The state of the trap changes from "ACTIVE" to "TRIPPED". No more abends will be issued. After being tripped, the abendtrap command must be issued again to activate the trap. While the trap is active, the abend trap can be turned off by specifying "OFF" as the module name. An active trap cannot be changed directly. The current trap must be tripped or turned off before a new command is accepted.

```
V TCPIP,TCPCS6,T,ABENDTRAP,EZBTTRCV,1001
EZZ6038I TCPCS6 COMMAND ABENDTRAP EZBTTRCV COMPLETE

D TCPIP,TCPCS6,T,PROF
EZZ6060I TCPCS6 PROFILE DISPLAY
 PERSIS FUNCTION DIA SECURITY TIMERS MISC
 (LMTGQAK) (OATSKQSWHT) (DRF) (PCKLECXN) (IKPSTS) (SMLT)

 LM*R*P* **TSBQ*WHT TJ* SSH*ESX* ***STS SDD*

 PORT: 23 ACTIVE PROF: CURR CONNS: 1

```

## TESTMODE

You can use the TESTMODE parameter statement in a TELNETPARMS block to allow a port to be processed by Telnet but then dropped before the statements for that port become active. Using TESTMODE ensures that LU assignments, security levels, and other Telnet parameters are not compromised due to syntax errors.

## Displays

Use the DISPLAY commands to verify that the configuration is what you thought it was, that connections are mapping to the correct parameters and Objects, and to check XCF Telnet LUNS and LUNR status and performance. For details about the commands available, see [“Managing Telnet” on page 601](#) and [z/OS Communications Server: IP System Administrator's Commands](#).

## Tracing

If you cannot resolve a problem using the available tools, IBM service will likely need a CTRACE with option Telnet. For details, see [“Telnet CTRACE” on page 601](#). You might also need to activate one of the following additional traces:

- Full data trace

If the problem is data related, use the FULLDATATRACE statement to trace all the data coming into and leaving Telnet rather than tracing only the first 64 bytes of data. FULLDATATRACE will cause a trace-wrap condition more quickly so it should be set only if needed. It should be set in PARMSGROUP instead of TELNETPARMS if a subset of clients can be identified.

- Telnet subagent trace

For Telnet SNMP subagent problems, use the TNSATRACE keyword on the TNSACONFIG statement in PROFILE.TCPIP at startup. This will generate trace points throughout Telnet subagent processing, in addition to tracing data passed between the Telnet subagent, Telnet, and the TCP/IP stack. Subagent tracing can also be enabled after Telnet has been started by using the VARY TCPIP,*tnproc*,OBEYFILE command. To enable tracing using the VARY TCPIP,*tnproc*,OBEYFILE command, the subagent must first be disabled and then re-enabled with the TNSATRACE keyword. Trace data is written to the syslog daemon. Subagent tracing can be disabled using the NOTNSATRACE keyword.

- DBCS trace

If the problem is with a DBCS connection, use the DBCSTRACE statement in the TELNETPARMS block or in the PARMSGROUP block to produce DBCS-specific trace entries in the SYSPRINT and TNDBCSE data sets.

## Telnet configuration data set customization details

This topic includes details for [“Steps for customizing the TN3270E Telnet server configuration data set” on page 599](#).

### Associating Telnet with one TCP/IP stack

In an INET environment where only a single TCP/IP stack can be running, Telnet client connections are automatically associated with the active stack, and you do not need to explicitly associate the Telnet server to the stack.

In a common INET (CINET) environment, Telnet is associated with all stacks that are running. When multiple stacks are supporting a single Telnet server, Netstat displays might not display all Telnet connections. The only connections that are displayed are connections that are supported by the stack from which the command is issued. If another stack is started while Telnet is active, the current LISTEN

for the port is cancelled and is reissued automatically to include the new stack. If you explicitly associate Telnet to one TCP/IP stack, all Telnet clients must connect through that stack.

If you want to explicitly associate Telnet with one stack for control purposes or for functionality support, use the TCPIPJOBNAME statement in the TELNETGLOBALS block when you start Telnet. If you use the TCPIPJOBNAME statement, you must continue to use it on all future profile updates to set affinity to the same stack.

The Telnet SNMP subagent requires that you explicitly associate Telnet with a single TCP/IP stack. Telnet SNMP subagent activation requires that you register the stack name with the agent. If you do not specify the TCPIPJOBNAME statement, then Telnet blocks the subagent activation request. The Telnet SNMP subagent can register with only one agent, and each agent can support only one Telnet subagent. If you are going to use the Telnet SNMP subagent, plan for one agent per Telnet subagent. If multiple Telnet SNMP subagents initialize to the same agent, the agent forwards all data requests to the first subagent that connected, and all other initialization attempts are queued. If the first subagent ends, then the next subagent in the queue receives all data requests.

## Shared LU name groups for Telnet servers

SNA architecture requires every LU in a VTAM network to have a unique name. Multiple Telnet servers create added administrative effort to ensure that LU names are unique among the servers. However, if your environment uses multiple Telnet servers running on a single system or in a sysplex, then you can designate one Telnet server to be the LU name server (LUNS). The LUNS manages LU name assignments from LU groups among the group of Telnet servers, each known as an LU name requester (LUNR).

Shared LU groups are defined at each LUNR and sent to the LUNS. Shared LU group definitions can be the same or different at each LUNR. The LUNS allocates an LU name to a particular LUNR only if that LUNR defined the LU in a shared LU group. The LUNS manages LU names by ensuring that only one LUNR at a time is using a particular LU name. You can use load balancing to distribute Telnet client connections across several LUNR Telnet servers that have identical shared LU name configurations.

A single Telnet server can support both shared and unshared LU groups. Existing unshared LU group definitions continue to be managed at the local Telnet level.

You can configure a Telnet server to be only a LUNS, or a Telnet server can be a LUNS and also function as a regular Telnet server. Running Telnet as only a LUNS in its own address space has the following advantages:

- Telnet port server functions will not compete with the LUNS for resources within the address space.
- You can separate Telnet roles, which makes problem diagnosis easier.
- You can stop and restart the Telnet LUNS without stopping the Telnet ports, and you can stop and restart the Telnet port servers without stopping the Telnet LUNS.
- You can set the Telnet LUNS priority to a different priority than that of Telnet port servers.

Telnet uses XCF local group services to define the set of Telnet servers that participate in a shared LU name management group. You specify the level of participation of a particular Telnet server with shared LU name management by specifying or omitting the XCFGROUP block. For configuration details, see [“Steps for defining a LUNS and a LUNR” on page 612](#).

- Classic Telnet server

If you do not specify the XCFGROUP block for a server or you specify NOJOIN in the XCFGROUP block, the server does not join the XCFGROUP and cannot participate in shared LU name management.

- The server does not join an XCF group
- The server is not included in the Telnet XCF,GROUP display
- Shared LU group Objects cannot be defined on the server

This is the default behavior of a Telnet server.

- XCF Telnet server

If you do specify the XCFGROUP block for a server and you specify JOIN in the XCFGROUP block, the server joins the Telnet XCF group and is able to participate in shared LU name management.
