- The server is included in the Telnet XCF, GROUP display that can be issued for any XCF Telnet server that is in the same sysplex group
- The health of the Telnet server is monitored by XCF
- The server supports shared LU group Objects
- The server can be an LU name requester (LUNR)

The LUNR is in standby state; it becomes active when shared LU group Objects are found while processing a profile. If you issue a VARY OBEYFILE command and there is no active profile that has shared LU group Objects, then the LUNR reverts to standby state.

- XCF LUNS Telnet server

If you specify the XCFGROUP block for a server and include the appropriate statements, you can configure the server to have LUNS capability.

- The server has all the characteristics of an XCF Telnet server
- The server is an LU name server (LUNS)

After you have configured the level of participation, you can use the VARY OBEYFILE command to move the Telnet server to a higher level; however, you cannot use the VARY OBEYFILE command to move the server to a lower level.

There can be only one active LUNS in a sysplex; that LUNS manages requests for shared LU names so that the names are used by only one Telnet server at a time. The remaining Telnet servers are LU name requesters (LUNRs) that request LU names from the LUNS. The LUNR Telnet server connects to an administration listener socket that is created by the LUNS Telnet server. This TCP connection transmits all LU name requests and responses; this connection is not used for status signalling between the XCF Telnet servers. XCF services including XCF user state field updates, XCF status monitoring, and XCF group events are used to communicate LUNS and LUNR state changes and health.

You can configure a LUNS as a primary or a backup LUNS. When the Telnet server is started, a primary LUNS checks to determine whether there is already an active LUNS in the XCF group. If there is not, that primary LUNS attempts to become the active LUNS. If there is already an active LUNS, the primary LUNS becomes a standby LUNS. If several Telnet servers that are designated as a primary LUNS are started concurrently, then the race winner becomes the active LUNS and the others become standby. A backup LUNS always becomes a standby LUNS.

When an active LUNS fails, the following sequence of events automatically occurs:

1. All the LU name servers that are in standby mode examine the list of LU name servers that are in standby mode.
2. The standby LUNS that has the highest configured rank, regardless of whether that LUNS was started as a primary or backup LUNS, automatically becomes the active LUNS.

If several standby LU name servers have the same rank, then all those servers attempt to take over. The race winner becomes the new active LUNS and the others return to standby.

You can initiate manual takeover of a Telnet LUNS at any time. You can direct an operator command to any LUNS that is in standby or joined mode and tell it to start and become the active LUNS. The current LUNS will change to standby mode.

You can define all the Telnet servers in a sysplex that participate in shared LU name management to join the same XCF group. However, if your environment has one or more of the following characteristics, then you should partition the sysplex into Telnet subplexes:

- All Telnet servers in a Telnet XCF group must have IP connectivity to each other. If your sysplex is partitioned into TCP/IP subplexes that do not have connected routes to each other, then you should partition the sysplex into Telnet subplexes along the same TCP/IP boundaries.

- All Telnet servers in a Telnet XCF group should run on VTAMs in the same network. If your sysplex is partitioned into VTAM subplexes and the VTAMs are in different networks, then you should partition the sysplex into Telnet subplexes along the same VTAM network boundaries.
- If you use several Telnet ports, each with a large set of shared LU names that do not overlap, and you load balance these ports across several Telnet servers, you might want to partition the sysplex into Telnet subplexes along the Telnet port boundaries. Subplexes reduce the shared LU name management workload on the LUNS and provide operational independence of the LUNS. All Telnet servers that are DVIPA targets of the same distributed port should be members of the same Telnet subplex.

A static VIPA is the best type of IP address to use for the LUNS administrative listener socket. Dynamic VIPA can work for the LUNS administrative listener, but there are cases in which dynamic VIPA can cause confusion.

- If VIPADEFINE moves the IP address away from the LUNS, LUNRs already connected to the LUNS will continue to be able to send requests and receive replies. However, a new LUNR attempting to connect will be directed to the new TCP/IP stack, and the LUNS will not be there.
- VIPARANGE will work if you can guarantee that each LUNS is supported by a different TCP/IP stack, and that the LUNS is the application that creates the IP address. If not, and the creating application ends, the LUNS socket will be closed. A standby LUNS on the same stack would be a problem. The standby LUNS sets up its listener before the original LUNS finishes cleanup. When the original LUNS finishes, the new LUNS listener socket will be closed.

For information about the XCFGROUP block, see [z/OS Communications Server: IP Configuration Reference](#). For information about Telnet LUNS display, XCF display, and [LUNS VARY commands](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

### ***Steps for defining a LUNS and a LUNR***

If your environment uses multiple Telnet servers running on a single system or in a sysplex, you can designate one Telnet server to be the LU name server (LUNS). The LUNS ensures that LU names are unique among your Telnet servers, managing LU name assignments.

### **Before you begin**

Determine which LU names are going to be shared and determine the setup of the LU groups. If you are running the Telnet server on multiple systems, ensure that all systems can function in a sysplex. The systems must have at least an XCF group connection. You do not need a coupling facility.

### **Procedure**

Perform the following steps to configure an LU name server (LUNS) or an LU name requester (LUNR):

1. On the XCFGROUP statement block on the TELNETGLOBALS statement block, define the level of participation in the Telnet XCF group and in shared LU name management.
  - Specify the NOJOIN parameter (or do not include the XCFGROUP block) if this Telnet server should not join the Telnet XCF group. If you specify NOJOIN (or omit the XCFGROUP block), the server is not included in the XCF,GROUP display and does not allow the definition of shared LU group objects.
  - Specify the JOIN parameter if this Telnet server should join the Telnet XCF group. JOIN is the default if you code XCFGROUP. If you specify JOIN or it is in effect by default, the server is included in the XCF,GROUP display that is issued by any other XCF Telnet server; the server has LUNR capability and supports shared LU group objects. With additional XCFGROUP statements, the server can have LUNS capability.
2. Determine whether you need to partition your Telnet server sysplex into Telnet subplexes.
  - If you are not partitioning your sysplex into subplexes, do not code the SUBPLEX parameter on the XCFGROUP statement. All Telnet servers in the sysplex that participate in shared LU name management join the default Telnet XCF group EZZTLUNS.
  - If you are partitioning your sysplex, configure the SUBPLEX parameter with a suffix that is 1 - 4 characters in length. The specified suffix is right-aligned and overlays the end of the string EZZTLUNS

to form a unique subplex string. For example, if the suffix value is 23, Telnet joins XCF group EZZTLU23.

3. Determine the frequency with which you want to monitor the health of the Telnet LUNS and LUNR.  
Use the XCFMONITOR parameter to set the frequency. At the specified time interval, Telnet checks the health of the LUNS, LUNR, and XCF Telnet tasks, and checks the health of the connection between the LUNS and LUNR. If any of these tasks or the connection appear to be unresponsive, message EZZ6099I is issued and the X indicator is set under the PDMON column in the XCFGROUP display. No action is taken by Telnet to correct the issue. A short time value can lead to false indications in a busy system. A long time value might not provide feedback quickly enough so that you can take appropriate action. The default value is a good compromise between these two possibilities.
4. To configure a LUNR, perform the following steps:
  - a) Configure the following parameters on the XCFGROUP statement:
    - CONNECTTIMEOUT: You can use this parameter for a LUNR only. Specify the length of time that a LUNR attempts to establish a connection to the LUNS before quiescing its LUNR capabilities. If the CONNECTTIMEOUT time elapses and the LUNR has not been able to connect with the LUNS, then the LUNR drops all connections that are waiting in negotiation for an LU name and quiesces all ports that have shared groups. Dropping connections that are in negotiation state enables the client to try again to connect to Telnet. Quiescing the port alerts a distributor that it should send requests to other working Telnet LUNRs. When the client connection is dropped and the client reconnects to the distributor, the connection is directed to a working LUNR. When the LUNS-LUNR connection is established, the port is automatically resumed and new client connections are again routed to this LUNR. Setting the CONNECTTIMEOUT time to 0 causes client connections to remain in LU name negotiation until LUNS-LUNR communication is established.
    - RECOVERYTIMEOUT: You can use this parameter for a LUNR only. Specify the length of time that the LUNR attempts to establish a connection when the LUNS is in RECOVER state before dropping active client connections that have shared LU names assigned to them. A new LUNS in RECOVER state cannot become active until it has received updates from all LUNRs that have shared LUs that are in use. If a LUNR cannot communicate with the LUNS during recovery time and the LUNR has shared LUs assigned, then the LUNS cannot become active and none of the LUNRs are able to receive LU name assignments. If the LUNR drops all active client connections with shared LUs, then the LUNS is alerted through XCF that the LUNR no longer owns shared LUs, and the LUNS can then become active.
  - b) Define the shared LU groups for the LUNR.  
Use the SLUGROUP and SPRTGROUP statements to define the shared LUs.
5. To configure a LUNS, specify LUNS on the XCFGROUP statement and configure the following parameters on the LUNS statement:
  - *ipaddr port*: Specify the IP address and port on which the LUNS will listen for its administrative connection to communicate with LUNRs.
  - PRIMARY or BACKUP: Specify whether this Telnet server is a primary LUNS or a backup LUNS.
  - RANK *nnn*: Specify the start rank of this LUNS, relative to others, when this LUNS is in standby mode and the active LUNS fails.

## Results

You have configured your Telnet servers correctly when you can issue a D TCPIP,*tnproc*,XCF,GROUP command and see the appropriate LUNS or LUNR status for each server. You should be able to connect a client to the LUNR and at the LUNS you should be able to issue a D TCPIP,*tnproc*,LUNS,OBJ command to verify that an LU was allocated from the LUNS.

## Qualified ports

In some cases all clients need to use the same port number, but the Telnet parameters need to be differentiated by destination IP address or destination linkname. The destination IP address can be either an IPv4 or IPv6 IP address.

For example, two TN3270E Telnet servers are going to be merged into one server. Currently, server 1 is bound to IP address 1.1.1.1 and is running with a set of definitions for port 23. Server 2 is bound to IP address 2.2.2.2 and is running with a different set of definitions for port 23. Before the servers are merged into one, users connect to either 1.1.1.1,port 23 or 2.2.2.2,port 23, depending on which Telnet services the users want. The sample definition statements are:

```
Server 1

TelnetParms
 Port 23
 Inactive 600 ; Drop after 10 minutes of no activity
EndTelnetParms

BeginVTAM
 Port 23
 DefaultLus TCPABC01..TCPABC49 EndDefaultLus
 DefaultAppl TSO
EndVTAM

Server 2

TelnetParms
 Port 23
 Inactive 0 ; Never drop
EndTelnetParms

BeginVTAM
 Port 23
 DefaultLus TCPABC50..TCPABC99 EndDefaultLus
 DefaultAppl CICS
EndVTAM
```

After the servers are merged, both home addresses are supported by a single server. One way to keep the Telnet definitions separate is to change the port number in one of the definition sets. For instance, the port 23 definitions associated with the old server 2 could be changed to be port 2023. The end result is one TN3270E Telnet server with port 23 and port 2023, where port 23 has the definitions used in the old server 1 and port 2023 has the definitions used in the old server 2. The definitions are still separate. However, all the users who were connecting to 2.2.2.2 port 23 now have to change their clients to port 2023. The sample definition statements are changed as follows:

```
Merged Server

TelnetParms
 Port 23
 Inactive 600 ; Drop after 10 minutes of no activity
EndTelnetParms

BeginVTAM
 Port 23
 DefaultLus TCPABC01..TCPABC49 EndDefaultLus
 DefaultAppl TSO
EndVTAM

TelnetParms
 Port 2023
 Inactive 0 ; Never drop
EndTelnetParms

BeginVTAM
 Port 2023
 DefaultLus TCPABC50..TCPABC99 EndDefaultLus
 DefaultAppl CICS
EndVTAM
```

With port qualification, the system administrator can qualify the port number with the destination IP address or linkname to keep the Telnet services separate. In this case, the destination IP address is used. The qualified port allows the users of either old stack to connect without making any changes to their client. The sample definition statements would be changed to:

```
Merged Server

TelnetParms
 Port 23,1.1.1.1
```

```

 Inactive 600 ; Drop after 10 minutes of no activity
EndTelnetParms

BeginVTAM
 Port 23,1.1.1.1
 DefaultLus TCPABC01..TCPABC49 EndDefaultLus
 DefaultAppl TSO
EndVTAM

TelnetParms
 Port 23,2.2.2.2
 Inactive 0 ; Never drop
EndTelnetParms

BeginVTAM
 Port 23,2.2.2.2
 DefaultLus TCPABC50..TCPABC99 EndDefaultLus
 DefaultAppl CICS
EndVTAM

```

You cannot QUIESCE, RESUME, or STOP a qualified portion of a port. If the port has several qualified port profiles, the VARY TCPIP,*tnproc*,QUIESCE, the VARY TCPIP,*tnproc*,RESUME, and the VARY TCPIP,*tnproc*,STOP commands affect all qualified port profiles associated with the port being quiesced, resumed, or stopped. In the example above, V TCPIP,*tnproc*,T,STOP,PORT=23 will stop port 23,1.1.1.1 and port 23,2.2.2.2. It is not possible to stop port 23,1.1.1.1 or port 23,2.2.2.2 individually. All display commands that allow port specification allow you to specify a qualified port. If just the port number is specified, only the unqualified port, if it exists, is displayed. The qualified port profiles are not displayed. DBCSTRANSFORM can be active on only one port, but can be active on one, some, or all of the qualified profiles of that port.

## Multiple ports

Telnet supports up to 255 ports on one server. A unique TELNETPARMS block must be created for each port or qualified port. Telnet allows the use of the same BEGINVTAM block for all ports, some ports, or a unique BEGINVTAM block for each port. Both TELNETPARMS and BEGINVTAM blocks are required for each port started or modified by a VARY TCPIP,*tnproc*,OBEYFILE command. There are several reasons that more than one Telnet port or qualified port might be needed. The most common reasons are to simplify the setup of clients on the workstation and the logon process, and to differentiate client security needs.

Assigning a single application to a port simplifies the setup of clients on the workstation and the logon process. Workstation clients can be labeled with the associated application name and then be set up to connect to the appropriate port or qualified port. With a client per application on the workstation, the user can select the needed client, connect, and be immediately in session with the application defined on the DEFAULTAPPL statement in BEGINVTAM. This implementation requires a unique BEGINVTAM block for each port due to the unique DEFAULTAPPL statements. The example below shows how to set up TSO, IMS, and CICS on ports 23, 2023, and 4023, respectively. The same LU names are used in each BEGINVTAM block. Telnet maintains a master LU "in-use" registry across all ports so that the same LU name will not be used by two different ports.

```

TELNETPARMS
 PORT 23
ENDTELNETPARMS
TELNETPARMS
 PORT 2023
ENDTELNETPARMS
TELNETPARMS
 PORT 4023
ENDTELNETPARMS

BEGINVTAM
 PORT 23
 DEFAULTLUS TCPABC01..TCPABC99 ENDDEFAULTLUS
 DEFAULTAPPL TSO
ENDVTAM
BEGINVTAM
 PORT 2023
 DEFAULTLUS TCPABC01..TCPABC99 ENDDEFAULTLUS
 DEFAULTAPPL IMS
ENDVTAM

```

```

BEGINVTAM
 PORT 4023
 DEFAULTTLUS TCPABC01..TCPABC99 ENDDFAULTLUS
 DEFAULTAPPL CICS
ENDVTAM

```

Assigning different security levels to different ports is an easy way to differentiate client security needs. External connections might require SSL security, while internal connections do not. Other than that difference, all other aspects of the Telnet profile can be the same. For example, external clients can connect to port 23 of a firewall that converts the request to the Telnet secure port 992. Internal clients would connect directly to the Telnet basic port 23. The statements below show how two ports allow implementation of different security levels. Note the same BEGINVTAM block is used for both ports, which can significantly reduce profile maintenance complexity. The PORT statement in BEGINVTAM links the BEGINVTAM block to the multiple TELNETPARMS blocks defined.

```

TELNETPARMS
 PORT 23
ENDTELNETPARMS
TELNETPARMS
 TTLSPORT 992
ENDTELNETPARMS
BEGINVTAM
 PORT 23 992
 DEFAULTTLUS TCPABC01..TCPABC99 ENDDFAULTLUS
 ALLOWAPPL *
ENDVTAM

```

If a profile that contains a new port number is processed, it is treated as an additional port, and the VARY TCPIP,*tnproc*,OBEYFILE command request will succeed if all parameters for the new port are correctly specified. Existing, non-referenced ports remain active and unchanged. You can use the VARY TCPIP,*tnproc*,TELNET,STOP command to stop a port.

## Connection mode choices

Telnet supports several connection types. The negotiation process is hierarchical in the order listed below:

- TN3270 Enhanced (TN3270E)
- TN3270
- Linemode
  - Standard
  - Binary
  - Transform

TN3270E is the default connection mode for Telnet. If the client refuses TN3270E mode, Telnet tries TN3270 mode. If the client refuses TN3270 mode, Telnet tries Linemode. Telnet does not support Network Virtual Terminal (NVT) mode, except to allow the negotiation of TN3270E, TN3270, or linemode connections.

**Note:** The Type of Service (ToS) byte, also known as the Differentiated Services field, is not managed directly by Telnet. If you want to use Differentiated Services for Telnet, use the Quality of Service (QoS) support discussed in [Chapter 15, “Quality of service,”](#) on page 857.

TN3270E and TN3270 are very similar. If the TN3270E functions are not needed, the user does not notice any difference between TN3270E and TN3270 connections. In some cases, older clients do not properly refuse the server request for a TN3270E connection, and the connection is dropped. In these unusual cases, use the NOTN3270E parameter to disable the TN3270E function for those clients. Similarly, use the NOSNAEXT parameter for any client that does not properly negotiate the extension functions (Contention Resolution and SNA Sense). TN3270E/NOTN3270E and SNAEXT/NOSNAEXT parameters can be coded at all three parameter block levels for different levels of granularity.

TN3270E and TN3270 clients can receive a Telnet solicitor screen to submit an application name, User ID, and password or password phrase to Telnet. The cursor is positioned on the application line unless

the OLDSOLICITOR parameter is specified which causes the cursor to be positioned on the user line. See [“Using the Telnet solicitor or USS logon screen” on page 667](#) for detailed information.

The ATTN key function is supported over TN3270, TN3270E, and Transform Linemode connections. It is not supported over Standard or Binary Linemode. Default LOGMODEs for TN3270E connections are SNA, and default LOGMODEs for TN3270 and Transform connections are non-SNA. Telnet processes the ATTN key differently for SNA and non-SNA LOGMODEs. In addition, Telnet can be configured to handle double ATTNs sent by some clients by specifying SINGLEATTN. See [“Device types and logmode considerations” on page 666](#) for more information.

For TN3270E, LU assignment is done during connection negotiation. For TN3270, LU assignment is done at application selection time. To delay LU assignment until application selection time for TN3270E, specify the SIMCLIENTLU parameter. See [“LU mapping by application name” on page 653](#) and [“LU mapping selection rules” on page 654](#) for details.

You might experience unexpected results if you start a Telnet session from within an application that is already connected using Telnet. For example, if you start a new Telnet session from within a TSO session that was established on a TN3270E connection, the keyboard will unlock when it seems it should not. This happens when an unlock keyboard intended for only the original, first session is sent from Telnet. The second session should remain locked but does not. An unlock keyboard intended for only the first session has the affect of unlocking the keyboard for both the first and second session because both are represented by the same client.

Some host applications send 3270 read commands (for example, X'F2' read buffer) to the client during the course of a session. Telnet sends an unlock keyboard sequence (that is, X'F1C2') before the read command is sent to the client. This is the default behavior or can be specified by coding UNLOCKKEYBOARD BEFOREREAD. In some cases, a problem can arise if the keyboard is unlocked prior to the read command being forwarded to the client. The unlock keyboard sequence allows transmission of buffered keyboard data to the host application. The buffered keyboard data is not expected in response to a read command. The UNLOCKKEYBOARD AFTERREAD parameter can be used to send the unlock keyboard sequence after the read command rather than before. In most cases, the default value will suffice and there is no need to code or change the setting of this parameter. Certain applications, however, will issue error messages when buffered keyboard data is unexpectedly received from the client. In these cases, UNLOCKKEYBOARD AFTERREAD can be coded to resolve the application error.

Some applications expect the user to initiate session data traffic. If a USSMSG10 screen or solicitor screen was used to initiate the session, the keyboard is locked. A BIND flows to the client on a TN3270E connection alerting the client to unlock the keyboard. A non-TN3270E connection does not support sending a BIND to the client. Therefore, when a BIND is received from the application, Telnet sends an unlock keyboard to the client on a non-TN3270E connection to ensure the user can initiate data traffic if necessary. This behavior is the default or can be specified by coding UNLOCKKEYBOARD TN3270BIND. In some cases, the unlock keyboard might not be correctly interpreted by an older client. If this is the case, UNLOCKKEYBOARD NOTTN3270BIND can be coded to stop Telnet from sending an unlock keyboard when a BIND is received.

The two unlock keyboard functions must be specified on a single UNLOCKKEYBOARD statement. If only one is specified, it is assumed the other is the default value. The UNLOCKKEYBOARD parameter can be coded at all three parameter block levels for different levels of granularity.

### ***TN3270 Enhanced***

TN3270 Enhanced (TN3270E) connections support full-screen 3270 emulation that is sometimes referred to as TN3270 Extended. Do not confuse TN3270E function with the IBM 327x device types that end in -E (for example, 3278-2-E). In these cases, the *E* indicates that the terminal supports Extended field attributes such as color and highlighting and is not related to Telnet functions.

Telnet is often used as the primary method of connection between client workstations and the SNA mainframe environment. To make this form of remote connection as seamless as possible, Telnet terminal emulation simulates actual SNA terminals as closely as possible. To accomplish this, RFC1647 and RFC2355 (both known as TN3270E) add the ability to specify device names at connection time, add

support for printer devices, and add additional SNA functions. An Internet draft, RFC 2355 Extensions, adds Contention Resolution and SNA Sense code support.

### **Device name specification**

Telnet assigns LUs based on the LU mapping statements supplied. Clients are assigned a device name (Telnet LU name) based on those statements. However, a TN3270E client can optionally specify that a particular device name be assigned, or it can specify that a device name from a pool of LUs be assigned. If the specified device name is allowed for this client based on the LU mapping statements and the LU is available, Telnet assigns the specified device name. If the specified device pool is allowed for this client based on the LU mapping statements and an LU within the pool is available, Telnet assigns a device name from the specified pool. Otherwise, the request is rejected with an appropriate reason code, and the connection is dropped. See [“Mapping Objects to Client Identifiers”](#) on page 629 for additional LU mapping information.

### **328x printer support**

Many Telnet clients emulate 328x class printers (device type IBM-3287-1). Most support both SNA Character Stream (SCS) as an LU1 and 3270 data stream as an LU3. The support of each is negotiated at connection time. When connected in TN3270E mode, Telnet supports these emulators in a manner similar to terminal LUs. Telnet can be configured to initiate a session at connection time or to open an ACB to let the application initiate the session. The bind initiating each session is sent to the client, and the bind informs the emulator which data stream to expect. The VTAM application perceives the Telnet LU to be an actual 3287-class printer and sends the SCS or 3270 data to the Telnet LU. Telnet passes the data on to the client, which prints the data. Telnet printer support allows you to use a single product, Telnet, to control both SNA terminals and SNA printers.

Some Telnet client printer emulators can request to be associated with a terminal device name by specifying the terminal device name during connection negotiation. Using printer association, users can connect their Telnet terminals to an application and then have Telnet assign an associated printer device name based on the terminal name. To associate printers with terminals, Telnet must have a printer device pool of LUs defined and a terminal device pool of LUs defined with each having the same number of device names. For more information, see [“Associated printer function”](#) on page 650.

### **Additional negotiated TN3270E support**

Responses and SysReq functions are supported by most clients that support TN3270E connections. Contention Resolution and SNA Sense support are newer and less prevalent.

- **Responses** - The client or host VTAM application can request that it receive definite, exception, or no response. Client responses to application requests provide more accurate response information for application-based monitoring tools compared to TN3270 connections. When the client negotiates responses and the SNA application sends data with a definite response, the Telnet Server disables the DELAYACKs function at times. For TN3270 connections, Telnet must intercept response requests from the host and respond on behalf of the client, incorrectly reducing measured response time. Telnet monitoring will provide accurate response time information for either TN3270E or TN3270 connections.
- **SysReq function** - The user can request that a current session be dropped by entering LOGOFF (in upper, lower, or mixed case) after pressing the SysReq key. If LUSESSIONPEND is not mapped to the client, the connection will be dropped. Otherwise, a USSMSG10 screen is sent to the client. If, instead of entering LOGOFF, the SysReq key is pressed a second time and if the application supports LUSTAT 082B (presentation screen is lost), the previous screen is resent to the client emulator.
- **Contention Resolution** - Improves communication between the client and host VTAM application about which owns the send state. Contention Resolution includes the following items:
  - **Keyboard Restore Indicator (KRI)** - Whenever the host VTAM application sends End Bracket (EB), Telnet sends a KRI to the client. This directly notifies the client that the keyboard can be unlocked. Without the KRI indicator, Telnet would have to make sure a WCC with the unlock keyboard flag set is sent to the client. The KRI flag is set regardless of whether the keyboard restore flag in the WCC byte is set.
  - **Start Data Indicator (SDI)** - When the host VTAM application sends change direction or end bracket, Telnet sends the SDI to the client. This allows the client to know exactly when data can be sent to Telnet.

- BID - A BID sent from the host VTAM application is forwarded to the client instead of being intercepted and handled by Telnet. This allows the client to manage the BID process itself.
- Signal Indicator - A signal that is received from the host VTAM application is forwarded to the client. When the client responds to the signal, Telnet sends a change direction indicator to the host VTAM application.
- SNA Sense Support - Allows the client to include SNA sense codes in a response message. The client retains the option of letting Telnet map the errors to an appropriate sense code by not turning on the SNA-Sense-Code indicator in the response message.

## **TN3270**

TN3270 connections support full-screen 3270 emulation. TN3270 connections do not support:

- Device name or pool name specification
- Printers
- Client involvement with responses, SysReq, Start Data Indicator, BID, Signal or SNA Sense data.

RFC1646 defines device name specification and printer support for TN3270 connections. However, this RFC is not supported on the TN3270 Telnet server. If either of these requests is received on a TN3270 connection, the server will drop the connection.

## ***Linemode***

In some cases, the client or the application does not support full-screen presentation, or the user needs to work in a linemode environment. For these reasons, most emulators support linemode. Linemode supports a *go-ahead* function to simulate a half-duplex format. With go-ahead negotiated, the partner cannot send data until it receives a go-ahead from the current sender of data. In most cases, sessions are naturally half-duplex and the go-ahead adds unneeded transmissions. Therefore, the Telnet default is to Suppress Go Ahead (SGA). If go-ahead is needed to maintain a half-duplex format, use the NOSGA parameter. SGA or NOSGA can be coded at all three parameter block levels for different levels of granularity.

Telnet supports the following types of Linemode connections:

- Standard
- Binary
- Transform

*Standard Linemode* is assumed if neither DBCS transform nor BINARY linemode parameters are specified, or if the device type is not supported by transform. Standard Linemode is the only connection mode that requires translation by Telnet. Telnet provides multicultural support for standard Linemode connections. ASCII and EBCDIC code pages are the basis for translation. Telnet uses the ICONV services available in the C runtime library. For custom code page information, see the ICONV services in *z/OS XL C/C++ Programming Guide*. When ASCII and EBCDIC code pages are specified, a conversion descriptor will be given to Telnet. Telnet creates ASCII-EBCDIC and EBCDIC-ASCII translation tables based on the conversion descriptor. The CODEPAGE parameter is used to specify the code page names. For example:

```
CODEPAGE ISO8859-1 IBM1047
```

The possible results from CODEPAGE processing are:

- If a conversion descriptor is not returned, CODEPAGE is not coded, or there is an error in the syntax, a default code page of ISO8859-1 will be used for ASCII, and the language environment code page taken from locale information will be used as the EBCDIC code page.
- If a conversion descriptor is not returned again, a default code page of IBM-1047 will be used for EBCDIC.

- If a conversion descriptor is not returned again, predefined translation tables within Telnet will be used. These tables are similar, but not exactly the same as the tables which would have been generated if ISO8859-1 and IBM-1047 had worked. Some of the differences are noted below:

| EBCDIC  |        | ASCII     |                          |
|---------|--------|-----------|--------------------------|
| x'0D25' | -----> | x'0D0085' | using ISO8859-1/IBM-1047 |
| x'0D25' | -----> | x'0D0A'   | using internal tables    |
| x'15'   | <----  | x'0A'     | using ISO8859-1/IBM-1047 |
| x'25'   | <----  | x'0A'     | using internal tables    |

No message is issued to the console if the first conversion succeeds. If there is any conversion failure a message is issued. If one of the later conversions succeeds, a message is issued indicating success.

If your Linemode connection does not perform correctly, the default translation tables may be causing the problem. Try the internal Telnet translation tables by specifying TNSTD for both ASCII and EBCDIC choices. For example:

```
CodePage TNSTD TNSTD
```

The internal code pages must be used together. If only one of the two internal tables is specified, then the other internal table will also be used.

CODEPAGE can be coded at all three parameter block levels for different levels of granularity.

*Binary Linemode* is set using the BINARYLINEMODE parameter. It indicates that Telnet should not do translation. The ASCII data from the client should be passed as-is to the VTAM application. BINARYLINEMODE or NOBINARYLINEMODE can be coded at all three parameter block levels for different levels of granularity.

*Transform Linemode* is set using the DBCSTRANSFORM parameter. When coded, all data that passes through Telnet will be transformed from DBCS or SBCS ASCII full screen to 3270 full screen for all supported device types. If the device type is not supported, Standard or Binary Linemode is used. DBCSTRANSFORM can be coded in TELNETPARMS or PARMSGROUP for different levels of granularity. It cannot be coded in TELNETGLOBALS. A unique logmode for transform can be set using TELNETDEVICE with a device type of TRANSFORM. Any logmode used must not support extended graphics.

**Note:** Transform can be used by only one port when multiple ports are active on one TCP/IP stack. DBCSTRANSFORM supports a maximum of 250 concurrent connections.

DBCSTRANSFORM can be used for either the VT100 single-byte character set (SBCS) or VT282 double-byte character set (DBCS) transform mode. When DBCSTRANSFORM is specified and the TCP/IP procedure JCL has been modified as shown below, ASCII-based terminal emulators (VT100 or VT282) will appear as full-screen 3270 terminals. Telnet receives ASCII data from the client and transforms it into SBCS or DBCS EBCDIC data, depending on the terminal type. Telnet adds appropriate SNA control bytes to give the appearance that the data is coming from a 3270 terminal. Telnet receives EBCDIC data from the host application and transforms the SNA control bytes and data into appropriate ASCII control bytes and data. The data is sent to the ASCII-based terminal where it is displayed in 3270 full-screen emulation. DBCSTRANSFORM requires additional special Data Definition (DD) statements in the TCP/IP procedure.

You must add the following three DD statements to the TCP/IP procedure JCL to support Transform:

```
//TNDBCSCN DD DSN=TCPIP.SEZAINST(TNDBCSCN),DISP=SHR
//TNDBCXSL DD DSN=TCPIP.SEZAXLD2,DISP=SHR
//TNDBCSEB DD SYSOUT=*
```

- The TNDBCSCN DD statement must point to the configuration data set for 3270 DBCS transform mode. This configuration data set specifies the default DBCS conversion mode that will take effect at initialization time. Specify the CODEKIND and CHARMODE parameters according to the required DBCS code page. If CODEKIND and CHARMODE are not specified, or if the TNDBCSCN DD statement is not added, by default, CODEKIND is SJISKANJI and CHARMODE is ALPHABET. A sample can be found in SEZAINST(TNDBCSCN).
- The TNDBCXSL DD statement must point to the data set containing binary translation table code files for 3270 DBCS transform mode. The installation data set, SEZAXLD2, contains the default

binary translation table code files. The binary translation table code files for 3270 Transform can be customized by using the CONVXLAT command. See [z/OS Communications Server: IP Configuration Reference](#) for more information about customizing translation table code files. If the TNDBCSSL DD statement is not added, the following message will appear and an abend will occur:

```
IEC130I PASCAL01 DD STATEMENT MISSING
```

- The TNDBCSSL DD statement defines where Transform-specific error messages are recorded. This DD statement can specify an output data set or SYSOUT=\*. If the TNDBCSSL DD statement is not added, transform initialization will fail.

Specifying the DBCSTRACE parameter sends detailed trace output from 3270 Transform to the location specified in the SYSPRINT output DD statement. Additional detailed trace output is also sent to TNDBCSSL. Both data sets will contain detailed trace data. DBCSTRACE or NODBCSTRACE can be coded in TELNETPARMS or PARMSGROUP for different levels of granularity. They cannot be coded in TELNETGLOBALS.

## Connection security

This topic describes data overrun security, Transport Layer Security (TLS), and Network Access Control.

### *Data overrun security*

Use the MAXRECEIVE, MAXREQSESS, MAXRUCHAIN, MAXTCPSNDQ, and MAXVTAMSENDQ parameters to protect against data overrun. These parameters can be coded at all three parameter block levels for different levels of granularity.

#### *MAXRECEIVE*

This parameter limits the number of bytes received from a client without an End Of Record (EOR) being received. If the data received exceeds the limit, the connection is dropped. This parameter protects against a client stuck in a send-data loop. In general, large file transfers will not be affected because the sending client typically divides the file into smaller records that are sent. The receiving application rebuilds the file as the smaller records are received.

#### *MAXREQSESS*

This parameter limits the number of session requests received by Telnet in a 10-second period. For this parameter, a BIND received by Telnet defines a session request. If the number of BINDs received in a 10-second period exceeds the limit, an error is reported. This parameter protects against session logon loops that are possibly created by an automatic CLSDST-PASS to an inactive session. This parameter cannot protect against logon loops caused by an inactive default application and a client using auto-reconnect.

#### *MAXRUCHAIN*

This parameter limits the number of chained RUs that can be received over a session from a host application without a corresponding end chain RU. If the number of RUs exceeds the limit, the session is dropped. This parameter protects against using up large amounts of storage to hold data that is destined for a client in session with the host application.

#### *MAXTCPSNDQ*

This parameter limits the number of bytes that are queued to be sent to a Telnet client. If the queue size exceeds the limit, the connection is dropped. This parameter protects against using up large amounts of storage to hold data that is destined for an unresponsive Telnet client.

#### *MAXVTAMSENDQ*

This parameter limits the number of data segments (RPLs) queued to be sent to VTAM. If the queue size exceeds the limit, the connection is dropped. This parameter protects against using up large amounts of storage to hold data destined for a host application that is not receiving data.

### *Auto-reconnect loop*

Without MSG07 coded a client connection error causes Telnet to drop the connection. The error may be an inactive DEFAULTAPPL or an LU assignment error. If the client has AUTO-RECONNECT specified, a continuous loop of attempts occurs. The best protection against this is to code the MSG07 parameter which keeps the client from being disconnected. However, other applications can be chosen from the error screen returned to the user. To block users from other applications, use the DEFONLY parameter.

## **Transport Layer Security**

**Note:** References to RACF® apply to any SAF-compliant security product that contains the required support.

The TN3270E Telnet server (Telnet) provides the ability to secure Telnet connections with Transport Layer Security (TLS) or the Secure Sockets Layer(SSL) protocol using Application Transparent Transport Layer Security (AT-TLS) in TCP/IP. A port using AT-TLS security configuration is referred to as a TTLSPORT port. A basic port is one that does not use the TLS protocol. Connections are either secure or basic. The flows between Telnet and VTAM are unchanged.

The expired Internet Engineering Task Force (IETF) *TLS-based Telnet security* draft is supported in Telnet. This draft allows a Telnet negotiation to determine whether the client wants or supports TLS protocol prior to beginning the secure handshake. The default action that Telnet takes for a secure port is to first attempt a TLS handshake. If the client does not start the handshake within the specified handshake timeout time, an attempt is made to negotiate TLS as defined by the expired TLS-based Telnet security draft. If the client responds that it wants a secure connection, the handshake is started; if the client rejects the TLS negotiation request, the connection is closed. In this way, installations can support both types of secure clients without knowing which protocol the client is using. The default action can be changed by specifying the CONNTYPE statement described later in this topic. You can also use the CONNTYPE statement to support secure and basic connections on the same port.

Telnet server authentication and client authentication are described in [Appendix B, “TLS/SSL security,”](#) on page 1359. The Telnet server supports level 1, level 2 and level 3 client authentication. Client authentication is done with the ClientAuthType parameter of the TTLSEnvironmentAdvancedParms statement in AT-TLS policy. Level 2 and level 3 client authentication use RACF services to translate the client certificate to an associated user ID. That user ID can also be used as a client identifier.

## **Telnet Transport Layer Security setup**

The TTLSPORT statement in the TELNETPARMS block is required to define a port as a secure port that is using AT-TLS to secure the connections.

The CONNTYPE statement is an optional statement on secure ports that provides more control over how connections initiate the TLS handshake, whether or not the connection is secure, and whether the connection is available for use. Valid CONNTYPE statement options are as follows:

- **SECURE**

Indicates that the TLS handshake is used to start the connection. If the client does not start the handshake within the time specified by the handshake timeout time, an attempt is made to perform a negotiated TLS handshake (as defined by the expired IETF TLS-based Telnet security draft). If the client rejects TLS, the connection is closed.

- **NEGTCURE**

Indicates that the client supports the expired IETF TLS-based Telnet security draft. A Telnet negotiation with the client determines whether the client is willing to enter into a secure connection. If the client agrees, a TLS handshake is started and secure protocols are used for all subsequent communication. If the client rejects TLS, the connection is closed. You should consider using this option only if you know that the Telnet secure clients connecting into the port are all using the protocol defined by the expired TLS-based Telnet security draft. With this option, the TLS handshake is not attempted until a positive response to the Telnet DO\_StartTLS IAC is received. This avoids the timeout delay that can occur when a TLS handshake is immediately started (as occurs with the CONNTYPE SECURE option), but the client is expecting the protocol used by the expired TLS-based Telnet security draft. Use the SECURE option

instead of the NEGOTSECURE option in case some clients in your network do not support the expired TLS-based Telnet security draft.

- BASIC

Indicates that a basic connection is established.

- ANY

Indicates that the connection can be either secure or basic. Telnet first tries a standard TLS handshake. If the handshake times out, a negotiated TLS connection (see the CONNTYPE NEGOTSECURE option description) is attempted:

- If the client is willing to enter into a secure connection, secure protocols are used for all subsequent communication.
- If the client is not willing to enter into a secure connection, a basic connection is established.

- NONE

Indicates that no connection is allowed and the connection will be closed. If this option is specified in the TELNETPARMS block, a PARMSMAP statement must cover every allowable connection, and the related PARMSGROUP statement must specify the connection type on the CONNTYPE statement.

If the CONNTYPE statement is not specified, by default, secure ports are CONNTYPE SECURE and basic ports are CONNTYPE BASIC.

## Using one port for both basic and secure connections

You can use the CONNTYPE statement to modify connection types on a single port. Allowing a port to support both basic and secure connections assumes that either of the following statements are true:

- The installation allows the client to determine the connection type.
- A subset of the connections that should use a particular connection security type can be identified by Client Identifier.

In the first case, specify CONNTYPE ANY. If the port was defined as a secure port but the client wants a basic connection, there is a slight delay before connection negotiation begins. This is because when CONNTYPE ANY is coded, Telnet first attempts a TLS handshake to ensure that the client is not requesting TLS support. It is only after the handshake times out and negotiated security is rejected that the basic connection negotiation begins.

In the second case, the TELNETPARMS block should specify the default connection security type (see the CONNTYPE statement). For connections with different connection security requirements:

- Identify the clients by Client Identifier.
- Create a group using the PARMSGROUP statement with the alternate CONNTYPE definitions.
- Map the group created with the PARMSGROUP statement to the clients using the PARMSMAP statement.

## Configuring Telnet security using AT-TLS

The TTLSPORT statement in the TELNETPARMS block indicates that the port uses AT-TLS to manage System SSL. All TTLSPORT ports must be defined by specifying a TELNETPARMS block for each port.

Other than the CONNTYPE statement, all security configuration is done in AT-TLS policy. For details about AT-TLS setup, see [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#). For [Policy Agent and policy applications setup](#) and [AT-TLS policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#). A sample list of tasks to perform for AT-TLS policy includes:

1. Be sure that the TCP/IP stack profile includes the TCPCONFIG statement with the TTLS parameter.
2. Permit Policy Agent and any other required administrative application to the RACF resource EZB.INITSTACK.sysname.tcpname in the SERVAUTH class.

3. Define the pagent environment file on the STDENV DD statement in Policy Agent JCL. For example:

```
//STDENV DD PATH='/etc/pagent/pagent.env',PATHOPTS=(ORDONLY)
```

4. In the pagent environment file, point to a configuration file. For example:

```
PAGENT_CONFIG_FILE=// 'SYS1.TCPPARMS(PAGENT)'
```

5. In the configuration file, set up policy files for each TCP/IP stack image. For example:

```
TcpImage TCP1 /etc/pagent/TCP1.policy FLUSH
TcpImage TCP2 /etc/pagent/TCP2.policy FLUSH
```

6. In the TcpImage file, point to the TTLS configuration file. For example:

```
TTLSConfig /etc/pagent/pagttls1.ttls
```

7. In the TTLS configuration file, code the TTLSRule, TTLSGroupAction, TTLSEnvironment, and TTLSConnectionAction statements. Be sure to set the ApplicationControlled parameter to the value On in the TTLSEnvironmentAdvancedParms statement. For example:

```
TTLSRule tn_serv1
{
 LocalPortRange 23
 Direction Inbound
 Jobname TCP1
 TTLSGroupActionRef tn_grp_act
 TTLSEnvironmentActionRef tn_env_act
}

TTLSGroupAction tn_grp_act
{
 TTLSEnabled On
 Trace 7
 GroupUserInstance 1
}

TTLSEnvironmentAction tn_env_act
{
 HandshakeRole Server
 TTLSKeyringParms
 {
 Keyring TN3270E/TNsafkeyring
 }
 TTLSEnvironmentAdvancedParms
 {
 ApplicationControlled On
 }
 EnvironmentUserInstance 1
}
```

8. Verify that the policy is correctly entered by using the z/OS UNIX **pasearch** command to query information from the z/OS UNIX Policy Agent. Issue the **pasearch -t** command from the z/OS UNIX System Services shell. If you have multiple TCP/IP stacks that are active, issue the **pasearch -t -p procname** command to query a specific TCP/IP stack. The **pasearch** command is a Policy API (PAPI) application. If you have never run a PAPI application, you might receive a message indicating that the papi.dll file was not found. For more information about [PAPI](#) and running PAPI applications, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

## Telnet profile example

This example defines three ports with the following characteristics:

- Port 23 allows only basic connections.
- Ports 992 and 1023 are enabled for secure connections defined by AT-TLS policy.
- Port 992 allows only secure connections. No client authentication is requested.
- Port 1023 allows both basic and secure connections. The installation wants the following characteristics for port 1023:

- The system administrator is at IP address 10.1.3.3 and wants the capability to choose to connect with secure or basic connections.
- Buildings A and B are local and do not need connection security. The clients in these buildings have identifiable subnetworks (10.1.1.0/24 and 10.1.2.0/24, respectively). The installation wants these clients to use basic connections to avoid the encryption overhead.
- TLS security with client authentication is required for all other connections.

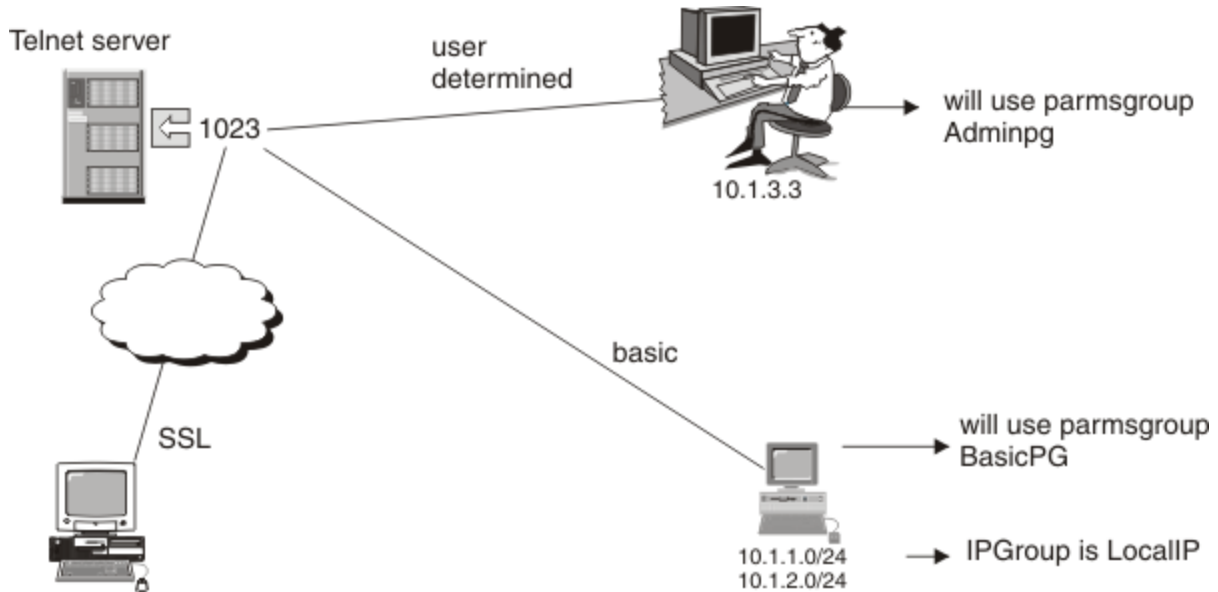

Figure 93. Port 1023 connection characteristics

**Note:** Definitions that are applicable to TLS connection security are the only definitions shown; additional parameters might be needed. Assume that all connections go through TCP/IP stack with job name TCP1.

TCP/IP configuration statements:

```

:
: TCPCONFIG TTLS
:

```

Telnet profile statements:

```

TELNETPARMS ; basic port does not support secure connections
Port 23
ENDTELNETPARMS

TELNETPARMS ; port that allows only secure connections
TTLSPT 992 ; no client authentication requested
ENDTELNETPARMS

TELNETPARMS ; port that allows secure and BASIC connections.
TTLSPT 1023 ; note: BEGINVTAM block has PARMSGROUP that may override
CONNTYPE SECURE ; this CONNTYPE setting. If not, SECURE will be default.
ENDTELNETPARMS

BEGINVTAM
Port 1023
...
IPGROUP LocalIP ; Mapping statements
255.255.255.0:10.1.1.0 ; Subnets for buildings A and B
255.255.255.0:10.1.2.0
ENDIPGROUP
PARMSGROUP BasicPG ; override default ConnType
CONNTYPE BASIC ; support basic connections if mapped to this group
ENDPARMSGROUP
PARMSGROUP AdminPG ; override default ConnType
CONNTYPE ANY ; allow any type of connections if mapped to this group

```

```

ENDPARMSGROUP
PARMSMAP AdminPG 10.1.3.3 ; this ip address can use secure or basic connections
PARMSMAP BasicPG localIP ; hosts defined in IPGROUP localIP will use basic
 ; connections as defined in PARMSGROUP BasicPG
ENDVTAM

BEGINVTAM
Port 992 23
...
; Mapping statements
; no PARMSGROUP defined for these ports
; TELNETPARMS definitions used for all connections
ENDVTAM

```

AT-TLS policy statements:

```

TTLSRule tn992_serv
{
 LocalPortRange 992
 Direction Inbound
 Jobname TN3270A
 TTLSGroupActionRef tn_grp_act
 TTLSEnvironmentActionRef tn992_env_act
}

TTLSRule tn1023_serv
{
 LocalPortRange 1023
 Direction Inbound
 Jobname TN3270A
 TTLSGroupActionRef tn_grp_act
 TTLSEnvironmentActionRef tn1023_env_act
}

TTLSGroupAction tn_grp_act
{
 TTLSEnabled On
 Trace 7
 GroupUserInstance 1
}

TTLSEnvironmentAction tn992_env_act
{
 HandshakeRole Server
 TTLSKeyringParmsRef tn_keyring
 TTLSEnvironmentAdvancedParms
 {
 ApplicationControlled On
 }
 EnvironmentUserInstance 1
}

TTLSEnvironmentAction tn1023_env_act
{
 HandshakeRole ServerWithClientAuth
 TTLSKeyringParmsRef tn_keyring
 TTLSEnvironmentAdvancedParms
 {
 ClientAuthType Required
 ApplicationControlled On
 }
 EnvironmentUserInstance 1
}

TTLSKeyringParms tn_keyring
{
 Keyring TN3270E/TNsafkeyring
}

```

## Network Access Control

Network Access Control (NAC) limits user access to certain IP security zones defined by the NETACCESS statement. A security product, such as RACF, is used to check the permission of user IDs to send data to or receive data from these security zones. The NAC user ID is based on the Telnet address space user ID information.

The NACUSERID parameter provides more control over Network Access Control checking for Telnet. This parameter is used to associate Telnet ports with a specified user ID that is defined to the security server. The user ID specified on the NACUSERID parameter must be a valid user ID defined to the security server. If not, the Telnet port will fail initialization. NACUSERID can be coded in TELNETGLOBALS to affect all ports or TELNETPARMS to affect a single port. NACUSERID cannot be coded in PARMSGROUP. Specify NONACUSERID to disable a higher level specification. For example, a TN3270E Telnet server with an address space user ID of user1 can specify in TELNETGLOBALS the statement NACUSERID user2. If one port should instead be controlled by user1, the TELNETPARMS statement for that port should be NONACUSERID to disable the user2 specification in TELNETGLOBALS.

When Telnet is modified with a VARY TCPIP,*tnproc*,OBEYFILE command, the NACUSERIDs are reverified for the Telnet ports defined in the data set referenced by the command. If a Telnet port has NACUSERID *NAC\_name\_1*, you cannot use the VARY TCPIP,*tnproc*,OBEYFILE command to change that port's NACUSERID to *NAC\_name\_2*. The port must first be stopped, and then started with the new *NAC\_name\_2* value using the VARY TCPIP,*tnproc*,OBEYFILE command.

The NETACCESS statement in the TCP/IP profile is used to configure portions of your IP network into named security zones. Each defined security zone must have a SERVAUTH profile for the resource named EZB.NETACCESS.*sysname.tcpname.zonename*. The user ID associated with the Telnet port must have READ access to the security zone that maps its bind address (0.0.0.0/32 for INADDR\_ANY or ::/128 for the IPv6 unspecified address, in6addr\_any, unless overridden by the PORT statement in the TCP/IP profile) and to every security zone that maps client IP addresses that Telnet is to accept connections from on this port.

For more information, see [“Network access control” on page 162](#).

## Connection persistence

Several timers are available in Telnet to control how long connections stay up. The list includes:

- INACTIVE - How long a terminal connection can be idle with no SNA data traffic before the connection is dropped.
- PRTINACTIVE - How long a printer connection can be idle with no SNA data traffic before the connection is dropped.
- PROFILEINACTIVE - How long a Telnet connection can be active with no active SNA session, while it is associated with a Telnet profile that is not the current profile.
- KEEPINACTIVE - How long a KEEPOPEN connection can be idle with no SNA session before the connection is dropped. When a KEEPOPEN connection is in session with a SNA application the INACTIVE timer is used instead of the KEEPINACTIVE timer.
- SCANINTERVAL - How often Telnet runs the list of connections looking for potentially lost connections. Because of the methodology, it also determines how long Telnet will wait for a TIMEMARK response before assuming the connection is lost.
- TIMEMARK - How long a connection is active without receiving any data before Telnet sends a TIMEMARK command which acts as an "are you there".

To facilitate these timers, Telnet records the time at which data is received from the client, received from VTAM, or sent to VTAM. Data received from the client is used by SCANINTERVAL/TIMEMARK to measure idle time on the connection. Data received from or sent to VTAM is used by the INACTIVE family of timers to measure idle time without SNA data traffic.

### ***The INACTIVE family of timers***

INACTIVE, PRTINACTIVE, PROFILEINACTIVE, and KEEPINACTIVE all share one timer associated with a port profile to reduce system overhead. The timer with the smallest value defined in TELNETGLOBALS, TELNETPARMS, or PARMSGROUP for that port profile is used to define how often the connections are checked.

For example, assume KEEPINACTIVE is defined as 1800, PROFILEINACTIVE is 1800 by default, INACTIVE is defined as 3000, and PRTINACTIVE is defined as 5400 in a profile. The Telnet timer will run every 1800 seconds. Therefore, every time the timer expires, Telnet will check each KEEPOPEN

connection not in session to see if there has been a SNA session created in the prior 1800 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-K. For PROFILEINACTIVE, Telnet checks each connection associated with a profile that is not current to determine whether a SNA session existed in the previous 1800 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-PF. Telnet will also check each terminal connection to see if there has been any SNA data traffic in the prior 3000 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-S. Telnet also will check each printer connection to see if there has been any SNA data traffic in the prior 5400 seconds. If not, the connection is dropped with DEBUG SUMMARY message CONN DROP reason INACT-P.

Setting KEEPOPEN to the smallest time was done as an example. Any of the four timers could be the smallest. Also, because all inactivity checks are done by one timer, a connection check could occur just before the connection would be considered timed out. The connection will remain active until the next check is made.

Using the example above, if a terminal connection has had no SNA activity in the past 2999 seconds when a check is made, the connection is not dropped. Another check is done 1800 seconds later and the connection is dropped, but the connection will have remained active for 4799 seconds instead of the specified 3000 seconds.

### ***SCANINTERVAL and TIMEMARK***

SCANINTERVAL and TIMEMARK are used together to determine if a connection has been lost. These parameters can be specified in TELNETGLOBALS, TELNETPARMS, and PARMSGROUP. The smallest SCANINTERVAL value is used to define how often the connections are checked. If the SCANINTERVAL value is greater than the TIMEMARK value, the SCANINTERVAL value is reset to the TIMEMARK value. Whenever data is received from the client, Telnet records the time. Telnet checks all connections at regular intervals defined by the SCANINTERVAL value. Each connection is checked to see if any data has been received from the client in the past TIMEMARK period of time. If not, a TIMEMARK command is sent to the client which acts as an "are you there" and Telnet remembers a TIMEMARK was sent to this client. During the next check at SCANINTERVAL time later, each connection is again checked to see if any data has been received from the client. If not, and a TIMEMARK was sent on the previous check, the connection is dropped with DEBUG SUMMARY message CONN DROP reason TIMEMARK.

For example, assume the values for SCANINTERVAL and TIMEMARK are 1800 and 10800, respectively. That means every 30 minutes all connections are checked to see if any data has been received in the last 3 hours. If not, a TIMEMARK is sent to the client. 30 minutes later Telnet checks the connections again. If the client responded to the TIMEMARK or sent in actual data of some type Telnet leaves the connection active. If nothing has been received Telnet drops the connection.

A SCANINTERVAL check could occur just before the last data received is old enough to trigger sending a TIMEMARK. The connection remains active until the next SCANINTERVAL is made. Then a TIMEMARK is sent, and at the next SCANINTERVAL the connection is dropped.

Using the example above, SCANINTERVAL checks a connection that received data 2 hours, 59 minutes ago. No TIMEMARK is sent. The next SCANINTERVAL runs 30 minutes later. Now the data received time is greater than 3 hours and a TIMEMARK is sent. At the next SCANINTERVAL, the connection is dropped. The connection's last activity was 3 hours 59 minutes ago.

**Tip:** Use Scaninterval and Timemark to find abandoned connections that do not require quick reset. Scaninterval and Timemark are intended to eventually clean up abandoned connections. They should not be used as an immediate reset function. If immediate reset of lost connections is needed, use the CheckClientConn parameter.

### ***Setting the timers***

Caution must be used in setting these timers. Setting the INACTIVE family of timers or SCANINTERVAL timer too low could cause excessive CPU usage. Setting the TIMEMARK value too low could also cause excessive flooding of the network with TIMEMARK commands or high storage usage. For example, these timers should take into account extended breaks such as lunch. If TIMEMARK is smaller than the lunch

break time, the network may be flooded with TIMEMARK commands around the lunch hour. Be aware of the default values and be sure to set appropriate values for the situation.

## **MSG07 and LUSESSIONPEND**

MSG07 and LUSESSIONPEND are Telnet parameter statements that define what Telnet should do in case of a session setup error and after normal logoff when the client is emulating a terminal. These parameters do not affect a printer connection.

- Connection negotiation error - If any problems occur during negotiation nothing can be done to keep the connection. If appropriate, Telnet will send the client an error code to help inform the client why the connection was dropped and issue a CONN DROP DEBUG message at the console.
- Session setup error - If a problem occurs during session setup such as an application name that is not valid, session request failure, or a BIND error, Telnet will drop the connection and issue a CONN DROP DEBUG message. The user cannot get to any application other than the default. No error messages are sent to the user and auto-reconnect loops are possible. For these reasons it is recommended that MSG07 always be used. If the MSG07 parameter is coded, the connection will not be dropped and an error message will be sent to the user. MSG07 function applies to any connection mode whether or not USS tables are mapped to the client. If a USS table is used, the user can press the CLEAR key to return to the USSMSG10 screen. If the LUMAP-DEFAPPL or PRTMAP-DEFAPPL statement is coded and the default application is not available, an error screen will be sent to the client whether or not MSG07 is coded.
- Normal Session Logoff - When the user logs off a session using a normal logoff, Telnet drops the connection. If the user typically logs on to another application after logging off the first application, it might be more efficient to present the user with another solicitor (or USSMSG10) screen or for Telnet to initiate a new session with the default application after logoff. This can be accomplished by coding the LUSESSIONPEND parameter. Code LUSESSIONPEND to go through the initial database lookup again after session logoff. Later results will be identical to the first lookup. If a default application for the client exists, Telnet will immediately initiate another session request; otherwise, a USSMSG10 screen or solicitor screen is sent to the user. When LUSESSIONPEND is coded, the connection remains active but terminal LU ACBs are closed.
- SYSREQ LOGOFF - When the user logs off of a session using a SYSREQ LOGOFF sequence (TN3270E connection supported) and LUSESSIONPEND is coded, Telnet does not drop the connection. Instead, the user is presented with a solicitor (or USSMSG10) screen. If DEFAULTAPPL is in effect, Telnet again requests a session with the default application.
- USS LOGOFF - When the user issues a LOGOFF command from the USSMSG10 screen, the connection is dropped whether or not the LUSESSIONPEND parameter is coded.

## **Mapping Objects to Client Identifiers**

Telnet provides flexibility for mapping Objects to clients based on Client Identifiers. This topic provides definitions, rules, and examples of many mapping methods. Examples start with simple concepts, then progress to more complicated concepts showing interaction between mapping statements. All mapping statements are specified in the BEGINVTAM block. See [z/OS Communications Server: IP Configuration Reference](#) for statement rules not discussed here.

The general relationship of mapping statements is:

*MAP OBJECTS* to clients based on *CLIENT IDENTIFIER*

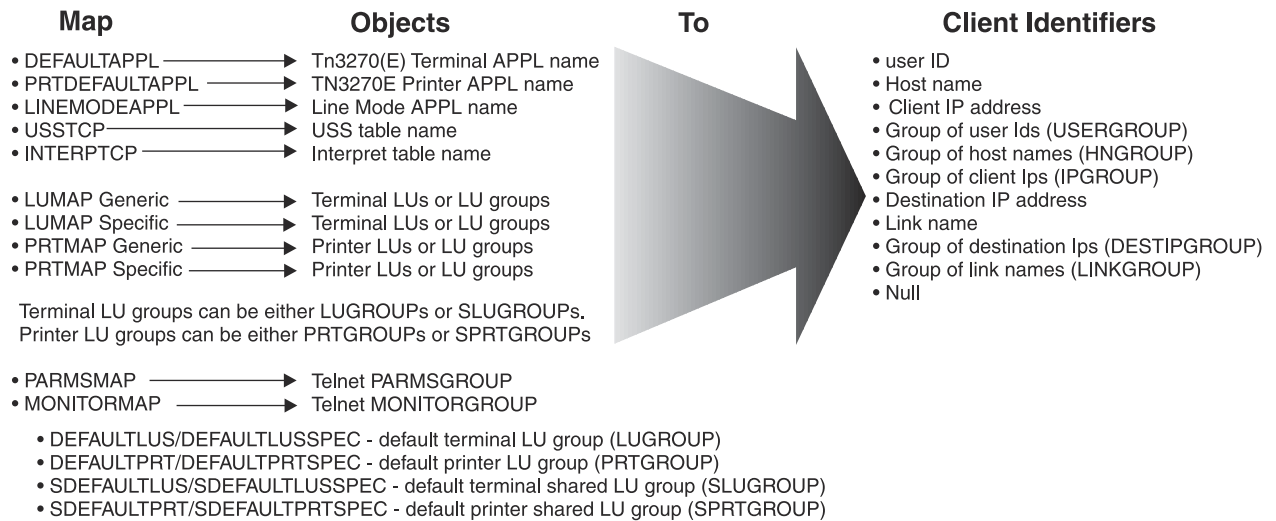

Figure 94. Mapping model

Telnet tries to assign all 11 Objects to a client based on the mapping statements when the connection is accepted. The search for Objects continues until all Objects are found or until all mapping statements are checked.

## Objects

When a client connection request is made, Telnet must assign an LU name to represent the client. Optionally, a USS table, default application, unique parameters defined in the PARMSGROUP statement, or network monitoring can be assigned to the connection. See “Mapping Objects to Client Identifiers” on page 629 for details about how these objects are mapped to clients. The complete list of objects follows:

- TN3270 or TN3270E terminal application name – The DEFAULTAPPL mapping statement maps the TN3270 or TN3270E terminal application Object to a terminal client. When a TN3270 or TN3270E connection is negotiated, Telnet immediately initiates a session request to the VTAM application.
- TN3270E printer application name – The PRTDEFAULTAPPL mapping statement maps the TN3270E printer application Object to a printer client. When a TN3270E printer connection is negotiated, Telnet immediately initiates a session request to the VTAM application.
- Line Mode application name – The LINEMODEAPPL mapping statement maps the linemode application Object to a client. When a linemode connection is negotiated, Telnet will immediately initiate a session request to the VTAM application.
- USS table name – The USSTCP mapping statement maps the USS table Object to a client. When a TN3270 or a TN3270E connection is negotiated, Telnet will send a USSMSG10 screen to the client. A special case condition exists when an application name and a USS table are both mapped to the client by the exact same Client Identifier. In this case, Telnet will immediately initiate a session request to the VTAM application and use the USS table for error messages.
- Interpret table name – The INTERPTCP mapping statement maps the Interpret table Object to a client. When a TN3270 or a TN3270E connection is negotiated, Telnet uses the Interpret table to modify USS commands. The client must have a USS table mapped to it for the Interpret table to be used.
- Terminal LU, local LU group (LUGROUP), or shared LU group (SLUGROUP) (Generic) - The Generic LUMAP mapping statement maps a single LU, LUGROUP, or SLUGROUP Object to a client.
  - For single LU mappings, Telnet assigns the LU name to the connection if the LU is available.
  - For LUGROUP mappings, Telnet assigns an available LU from the group to the connection.
  - For SLUGROUP mappings, Telnet requests that the LUNS allocate an available LU from the group and then assigns it to the connection.

An LU is required to represent the client when a VTAM session is initiated. DEFAULTLUS is a default local terminal LUGROUP Object mapped Generically to the NULL Client Identifier. SDEFAULTLUS is a default shared terminal SLUGROUP Object mapped Generically to the NULL Client Identifier.

- Terminal LU, LUGROUP, or SLUGROUP (Specific) - The Specific LUMAP mapping statement maps a single LU, LUGROUP, or SLUGROUP Object to a client.

Unlike the Generic mapping in which Telnet assigns the LU, the Specific mapping requires the client to specify the LU name that it wants. Telnet verifies that the LU is mapped and available. The specified LU name can be either a mapped single LU, an LU within a mapped LUGROUP or SLUGROUP, or the group name of the mapped LUGROUP or SLUGROUP.

- If the client specifies an LU name within a SLUGROUP, Telnet requests the LUNS to verify that the LU is available and allocate the LU to this Telnet.
- If the client specifies an LUGROUP name, Telnet assigns an available LU from within the group.
- If the client specifies an SLUGROUP name, Telnet requests the LUNS to allocate an available LU from the group and then assigns the LU.

DEFAULTLUSSPEC is a default local terminal LUGROUP Object mapped Specifically to the NULL Client Identifier. SDEFAULTLUSSPEC is a default shared terminal SLUGROUP Object mapped Specifically to the NULL Client Identifier.

- Printer LU, local printer group (PRTGROUP), or shared printer group (SPRTGROUP) (Generic) - The Generic PRTMAP mapping statement maps a single LU, PRTGROUP, or SPRTGROUP Object to a client.
  - For single LU mappings, Telnet assigns the LU name to the connection if the LU is available.
  - For PRTGROUP mappings, Telnet assigns an available LU from the group to the connection.
  - For SPRTGROUP mappings, Telnet requests the LUNS to allocate an available LU from the group and then assigns it to the connection.

An LU is required to represent the client when a VTAM session is initiated. DEFAULTPRT is a default local printer PRTGROUP Object mapped Generically to the NULL Client Identifier. SDEFAULTPRT is a default shared printer SPRTGROUP Object mapped Generically to the NULL Client Identifier.

- Printer LU, PRTGROUP, or SPRTGROUP (Specific) - The Specific PRTMAP mapping statement maps a single LU, PRTGROUP, or SPRTGROUP Object to a client.

Unlike the Generic mapping in which Telnet assigns the LU, the Specific mapping requires the client to specify the LU name that it wants. Telnet verifies that the LU is mapped and available. The specified LU name can be either a mapped single LU, an LU within a mapped PRTGROUP or SPRTGROUP, or the group name of the mapped PRTGROUP or SPRTGROUP.

- If the client specifies an LU name within a SPRTGROUP, Telnet requests that the LUNS verify that the LU is available and allocate the LU to this Telnet.
- If the client specifies a PRTGROUP name, Telnet assigns an available LU from within the group.
- If the client specifies a SPRTGROUP name, Telnet requests that the LUNS allocate an available LU from the group and then assigns the LU.

DEFAULTPRTSPEC is a default local printer PRTGROUP Object mapped Specifically to the NULL Client Identifier. SDEFAULTPRTSPEC is a default shared printer SPRTGROUP Object mapped Specifically to the NULL Client Identifier.

- Telnet PARMSGROUP – The PARMSMAP mapping statement maps the PARMSGROUP Object to a client. The parameters in the group override parameter values specified in either TELNETGLOBALS or TELNETPARMS.
- Telnet MONITORGROUP – The MONITORMAP mapping statement maps the MONITORGROUP Object to a client. The parameters in the group define what monitoring measurements will be done for a mapped client. For details, see [“Connection monitoring mapping statement”](#) on page 672.

**Rule:** All LUGROUPs and all PRTGROUPs, whether local or shared, that are used on a given profile must have unique names.

The two following statements are not Objects but can affect application and LU Object usage:

- ALLOWAPPL – This statement allows client access to applications and optionally maps or confirms the mapping of an LU name to the client based on the application name chosen. DEFAULTAPPL application names are presumed allowed and do not require the ALLOWAPPL statement for Telnet acceptance.

However, ALLOWAPPL may be used by default applications for LU assignment and other advanced functions.

- **RESTRICTAPPL** – This statement restricts Telnet acceptance of application names to only users that specify an acceptable User ID and password. It also optionally maps or confirms the mapping of an LU name to the client based on the application name and User ID chosen.

## Client Identifiers

One client can be represented by many different Client Identifiers. For example, Telnet might assign an LU based on client host name, assign an application based on a client IP address, and assign a USS table based on connection link or interface name. See [“Mapping Objects to Client Identifiers”](#) on page 629 for details about how these Client Identifiers are used to map Objects. In some cases, two different Client Identifiers that represent the same client are used on mapping statements to map the same type of Object. In these cases, Telnet must determine which Client Identifier to use when assigning the Object. See [“Client Identifier selection rules”](#) on page 634 for more details. The complete list of Client Identifiers and mapping examples follow:

- **User ID or USERGROUP name** - AT-TLS parameter ClientAuthType SAFCheck requires the client to send a client certificate to authenticate itself to the server. That certificate must be associated with a valid z/OS user ID in the security product such as RACF. The resulting User ID is associated with the connection. Objects can be mapped to the connection based on an exact User ID, or Objects can be mapped to a USERGROUP name containing exact User IDs and wildcarded User IDs. For example, mobile employees need to be assigned a unique set of LU names and the manager must always be assigned LU name LUMOBL01. These employees are not within a secure network and always use client authenticated secure connections. Their certificates are translated to User IDs by Telnet.

```
USERGROUP USGMOBL1
 MOBL0002 MOBL0003
 MOBL1%%C
ENDUSERGROUP
LUGROUP LUGMOBL1
 LUMOBL02..LUMOBL20
ENDLUGROUP
LUMAP LUMOBL01 USERID,MOBL0001 ; mgr mapping
LUMAP LUGMOBL1 USERGRP,USGMOBL1 ; employee mapping
```

**Rule:** The specification of the Client Identifier type USERID is required on the mapping statement. If you do not specify this type, Telnet assumes that the name is a link or interface name.

**Tip:** The specification of the Client Identifier type USERGRP is optional. The following statement is equivalent to the last LUMAP statement in the previous example:

```
LUMAP LUGMOBL1 USGMOBL1
```

- **Host name or HNGROUP name** - If the network dynamically assigns IP addresses, the same client will not have the same IP address from one connection to the next. With static host names, Objects can be mapped to clients based on their host name, or Objects can be mapped to HNGROUP names containing exact host names and wildcarded host names. For example, LUADMNM is mapped to exact host name ADMIN.DEPT1.GROUP1.COM, and application INVENTORY is mapped to HNGROUP name HNGINV.

```
HNGROUP HNGINV
 INV1.DEPT1.GROUP1.COM
 *.DEPT3.GROUP1.COM
 **.GROUP3.COM
ENDHNGROUP
LUMAP LUADMNM HOSTNAME,ADMIN.DEPT1.GROUP1.COM
DEFAULTAPPL INVENTORY HNGRP,HNGINV
```

**Tip:** The specification of the Client Identifier types HOSTNAME and HNGRP is optional. The following two mapping statements are equivalent to the last two statements in the previous example:

```
LUMAP LUADMNM ADMIN.DEPT1.GROUP1.COM
DEFAULTAPPL INVENTORY HNGINV
```

- Client (source) IP address or IPGROUP name - Client IP address is the most common method used to map Objects to the client. In a static network, Objects can be mapped to clients based on the exact IP address, or Objects can be mapped to IPGROUP names containing exact IP addresses and subnets. For example, LUADMN is mapped to exact IP address 1.1.1.1, and application PAYROLL is mapped to IPGROUP name IPGPAY.

```
IPGROUP IPGPAY
 1.1.2.2 1.1.2.3 ;IPv4 addresses
 255.255.0.0:2.2.0.0 ;IPv4 subnet
 2001:0DB8:9:11:15:4 ;IPv6 address
 6C11:10::0/96 ;IPv6 subnet
 6.1.3.4..6.1.3.8 ;IPv4 range
 2AB0::12:5:1321..2AB0::12:5:1410 ;IPv6 range
ENDIPGROUP
LUMAP LUADMN IPADDR,1.1.1.1
DEFAULTAPPL PAYROLL IPGRP,IPGPAY
```

### Tips:

- The specification of the Client Identifier types IPADDR and IPGRP is optional. The following two mapping statements are equivalent to the last two statements in the previous example:

```
LUMAP LUADMN 1.1.1.1
DEFAULTAPPL PAYROLL IPGPAY
```

- The IP/subnet combinations of 0.0.0.0:0.0.0.0 (IPv4 only) and 0::0/0 (IPv4 and IPv6) are special cases that include all connections. This might be useful if you want to have a default mapping with a higher priority than the NULL client identifier.
- The client IP address can be either an IPv4 or IPv6 IP address. IP address ranges can also be specified and are treated as if individual IP addresses were coded. An IPv4 range can vary in the last octet only. An IPv6 range can vary in the last two hexadecimal bytes only.
- Destination IP address or DESTIPGROUP name - A destination IP address is the host address that is the destination for a Telnet connection. Linkname can be used as a Client Identifier to map Objects to destination IP addresses when the linkname is static and defined in the profile. However, if the destination IP address is a dynamic Virtual IP Address (VIPA), the linkname is not known before the VIPA is created. In this case, destination IP address is the ideal solution. In other cases, specifying the destination IP address in the Telnet profile may be more clear than specifying the linkname. For example, two TCP/IP stacks are backups for each other. Telnet connections to stack 1 (VIPA 5.5.5.1) use logon manager application APPL1 by default, and connections to stack 2 (VIPA 51CB:C3E4::9:4) use logon manager application APPL2 by default. If one of the stacks becomes unavailable, the other will take over and dynamically add the failing stack's VIPA. The dynamic linkname created is not easily predicted. Use the following statements in the profile of each stack to ensure users connecting to 5.5.5.1 always get APPL1 and users connecting to 51CB:C3E4::9:4 always get APPL2 regardless of which stack is used.

```
DEFAULTAPPL APPL1 DESTIP,5.5.5.1
DEFAULTAPPL APPL2 DESTIP,51CB:C3E4::9:4
```

**Rule:** The specification of the Client Identifier type DESTIP is required on the mapping statement. If you do not specify this type, Telnet assumes that the IP addresses are client (source) IP addresses.

**Tip:** When the destination IP address is the IP address of a dynamic XCF address, multiple linkname values can be associated with the IP address. Telnet will use the first linkname associated with the IP address in the home list. If a dynamic XCF destination is used as a Client Identifier, it is recommended that DESTIP be used instead of linkname. Results can vary using linkname.

- Linkname or LINKGROUP name - A linkname is defined by the TCP/IP LINK or INTERFACE statement. The linkname defines a host IP address that is a destination address for clients connecting to Telnet. Linkname can be useful in cases where Object assignment is dependent on the client destination IP address instead of the client source IP address. Several linknames can be defined and the same LU mapping or other Object mapping might be wanted for several linknames. In this case, a LINKGROUP can be defined and used on a single mapping statement. For example, based on the statements below, a client connecting to LINK1 IP address will be assigned an LU from the LUGROUP name LUGLNKS and

will establish a session with TPX1. A client connecting to LINK2 IP address will be assigned an LU from the LUGROUP name LUGLNKS and will establish a session with TPX2. Because LINK1 and LINK2 are not group names, host names, or IP addresses, they are assumed to be linknames. The Client Identifier type, LINKNAME, can be used for clarity but is not required.

```
LINKGROUP LNKGRP1
 LINK1 LINK2
ENDLINKGROUP
LUMAP LUGLNKS LINKGRP, LNKGRP1
DEFAULTAPPL TPX1 LINKNAME, LINK1
DEFAULTAPPL TPX2 LINKNAME, LINK2
```

### Tips:

- The specification of the Client Identifier types LINKNAME and LINKGRP is optional. The following three mapping statements are equivalent to the last three statements in the previous example:

```
LUMAP LUGLNKS LNKGRP1
DEFAULTAPPL TPX1 LINK1
DEFAULTAPPL TPX2 LINK2
```

- When the destination IP address is the IP address of a dynamic XCF address, multiple linkname values can be associated with the IP address. Telnet will use the first linkname associated with the IP address in the home list. If a dynamic XCF destination is used as a Client Identifier, it is recommended that DESTIP be used instead of linkname. Results can vary using linkname.
- NULL (no Client Identifier) - The NULL Client Identifier type indicates that no Client Identifier was specified. The NULL Client Identifier is valid on the DEFAULTAPPL, LINEMODEAPPL, USSTCP, and INTERPTCP mapping statements. It is the implied Client Identifier for the DEFAULTLUS, DEFAULTLUSSPEC, DEFAULTPRT, and DEFAULTPRTSPEC Objects. ParmsGroup and MonitorGroup are the only Objects that cannot be mapped to the NULL Client Identifier. The NULL Client Identifier mapped Objects are the last Objects checked when assigning Objects to a client. For example, assume a client does not match any Client Identifier in the profile for DEFAULTAPPL or USSTCP. You can put the user into session with a security application, named SecAppl, that can verify the user is authorized to use the company's system. The Client Identifier field is blank.

```
DEFAULTAPPL SECAPPL
```

## Client Identifier selection rules

When Client Identifiers are used together, conflicts might occur. For example, host name NAME1.HOST1.COM may also be IP address 1.2.3.4. If the following DEFAULTAPPL statements exist, only one of the applications can be chosen.

```
DEFAULTAPPL TSO NAME1.HOST1.COM
DEFAULTAPPL CICS 1.2.3.4
```

If USSTCP and DEFAULTAPPL have the same Client Identifier, DEFAULTAPPL will be used. For detailed information, see [“Resolving DEFAULTAPPL and USS table conflicts” on page 645](#).

Telnet uses a very specific Client Identifier hierarchy when assigning Objects, as shown in [“The mapping rule search order” on page 634](#)

## The mapping rule search order

- Exact client identifier:
  - 1) User ID, 2) hostname, 3) IP address
- Exact client identifier in a group definition:
  - 4) User group, 5) hostname group, 6) IP address group
- Wildcard match for client identifier in a group definition:
  - 7) User group, 8) hostname group, 9) IP address group

- Exact destination:
  - 10) destination IP address, 11) link or interface name
- Exact destination in a group definition:
  - 12) destination IP address group, 13) link or interface name group
- Wild card match for destination in a group definition:
  - 14) destination IP address group, 15) link or interface name group
- Null client ID
  - 16) DEFAULTAPPL, LINEMODEAPPL, USSTCP, INTERPTCP, DEFAULTLUS, DEFAULTLUSSPEC, DEFAULTPRT, DEFAULTPRTSPEC

### Examples

- Exact client identifier:

```
1) LUMAP LU1 USERID,USER1
2) LUMAP LU2 NAME1.HOST1.COM
3) LUMAP LU3 1.2.3.4
```

Client Identifier type USERID is required. If not specified, USER1 is assumed to be a link or interface name.

- Exact client identifier in a group definition:

```
LUGROUP LUGRP1 LU100..LU199 ENDLUGROUP
LUGROUP LUGRP2 LU200..LU299 ENDLUGROUP
LUGROUP LUGRP3 LU300..LU399 ENDLUGROUP
```

```
USERGROUP USRGRP1
USER1 USER2 USER3
ENDUSERGROUP
```

```
HNGROUP HNGRP1
NAME2.HOST1.COM NAME2.HOST3.COM
ENDHNGROUP
```

```
IPGROUP IPGRP1
1.2.3.5 1.2.3.6
1.3.4.7..1.3.4.E
ENDIPGROUP
```

```
4) LUMAP LUGRP1 USRGRP1
5) LUMAP LUGRP2 HNGRP1
6) LUMAP LUGRP3 IPGRP1
```

- Wild card match for client identifier in a group definition:

```
USERGROUP USRGRP2
USER%% TCPU*
ENDUSERGROUP
```

```
HNGROUP HNGRP2
*.HOST2.COM **.HOST3.COM
ENDHNGROUP
```

```
IPGROUP IPGRP2
255.255.0.0:2.3.0.0
2001:0DB8:3:274C::0/80
ENDIPGROUP
```

```
7) LUMAP LUGRP1 USRGRP2
8) LUMAP LUGRP2 HNGRP2
9) LUMAP LUGRP3 IPGRP2
```

- Exact destination:

```
10) DEFAULTAPPL TSO DESTIP,1.2.3.4
11) USSTCP USSTAB1 LINK1
```

Client Identifier type DESTIP is required. If not specified, destination IP address 1.2.3.4 is assumed to be a client IP address.

- Exact destination in a group definition:

```
DESTIPGROUP DSTIPGRP1
 1.2.3.5 1.2.3.6
 79DA:10:3.4.9.5
 613D:10::9241..613D:10::C510
ENDESTIPGROUP
```

```
LINKGROUP LINKGRP1
 LINK1 LINK2 LINK3
ENDLINKGROUP
```

```
12) LUMAP LUGRP1 DSTIPGRP1
13) LUMAP LUGRP2 LNKGRP1
```

- Wild card match for destination in a group definition:

```
DESTIPGROUP DSTIPGRP2
 255.255.0.0:1.4.0.0
ENDESTIPGROUP
```

```
LINKGROUP LINKGRP2
 LINK* %LINK
ENDLINKGROUP
```

```
14) LUMAP LUGRP1 DSTIPGRP2
15) LUMAP LUGRP2 LNKGRP2
```

- Null client ID

```
16) DEFAULTAPPL TSO
 LINEMODEAPPL CICS
 USSTCP USSTAB1
 INTERPTCP INTTAB1
 DEFAULTTLUS LU01..LU99
 ENDEFAULTLUS
```

NULL is a single Client Identifier. The order of the examples has no significance. If DEFAULTAPPL and USSTCP mapping statements both have the NULL Client Identifier, the DEFAULTAPPL will be used regardless of order. For more information, see [“Resolving DEFAULTAPPL and USS table conflicts” on page 645](#).

## Object assignment examples

A client can be known by several different Client Identifiers. These Client Identifiers are used to assign as many Objects as possible to the connection based on the profile mapping statements. Telnet starts with the highest priority Client Identifier of the client and assigns all Objects mapped by that Client Identifier. If all 11 Objects are not assigned, Telnet uses the next highest priority Client Identifier (for prioritization details, see [“Client Identifier selection rules” on page 634](#)) and assigns all Objects mapped by that Client Identifier. This Object assignment process continues by using lower and lower priority Client Identifiers until all 11 Object types are found or until all of the matching Client Identifier mappings have been checked. If an Object is mapped by multiple Client Identifiers, only the Object mapped by the highest Client Identifier is used. It is unlikely all Objects are assigned to connections because not all Objects are always mapped. For example, many profiles do not contain PRTDEFAULTAPPL or INTERPTCP mapping statements. In this case, the printer default appl and Interpret table Objects will not be assigned.

Figure 95 on page 638 is a graphical representation of the following Telnet mapping statements. The numbered mapping statements correspond to the numbered buttons in the figure. The mappings that specify USERGROUP USGRP1 generate buttons 4 through 8 for exact user ID in a group and buttons 12 through 16 for wildcard user ID in a group.

|                       |          |                     |                 |
|-----------------------|----------|---------------------|-----------------|
| LUGROUP               | LUGRP1   | LU01..LU10..FFNN    | ENDLUGROUP      |
| LUGROUP               | LUGRP2   | LU11..LU99..FFNN    | ENDLUGROUP      |

| (11) PARMSMAP         | PGSCAN   | HNGRP1              |                 |
| (17) INTERPTCP        | INTTAB1  | LINK1               |                 |
| (18) MONITORMAP       | MONGRP1  | LINK1               |                 |
| (19) DEFAULTAPPL      | TPX1     |                     |                 |
| (20) USSTCP           | USSTAB1  |                     |                 |

The **CLIENT**, known by **CLIENT IDENTIFIERS**, is assigned **OBJECTS**

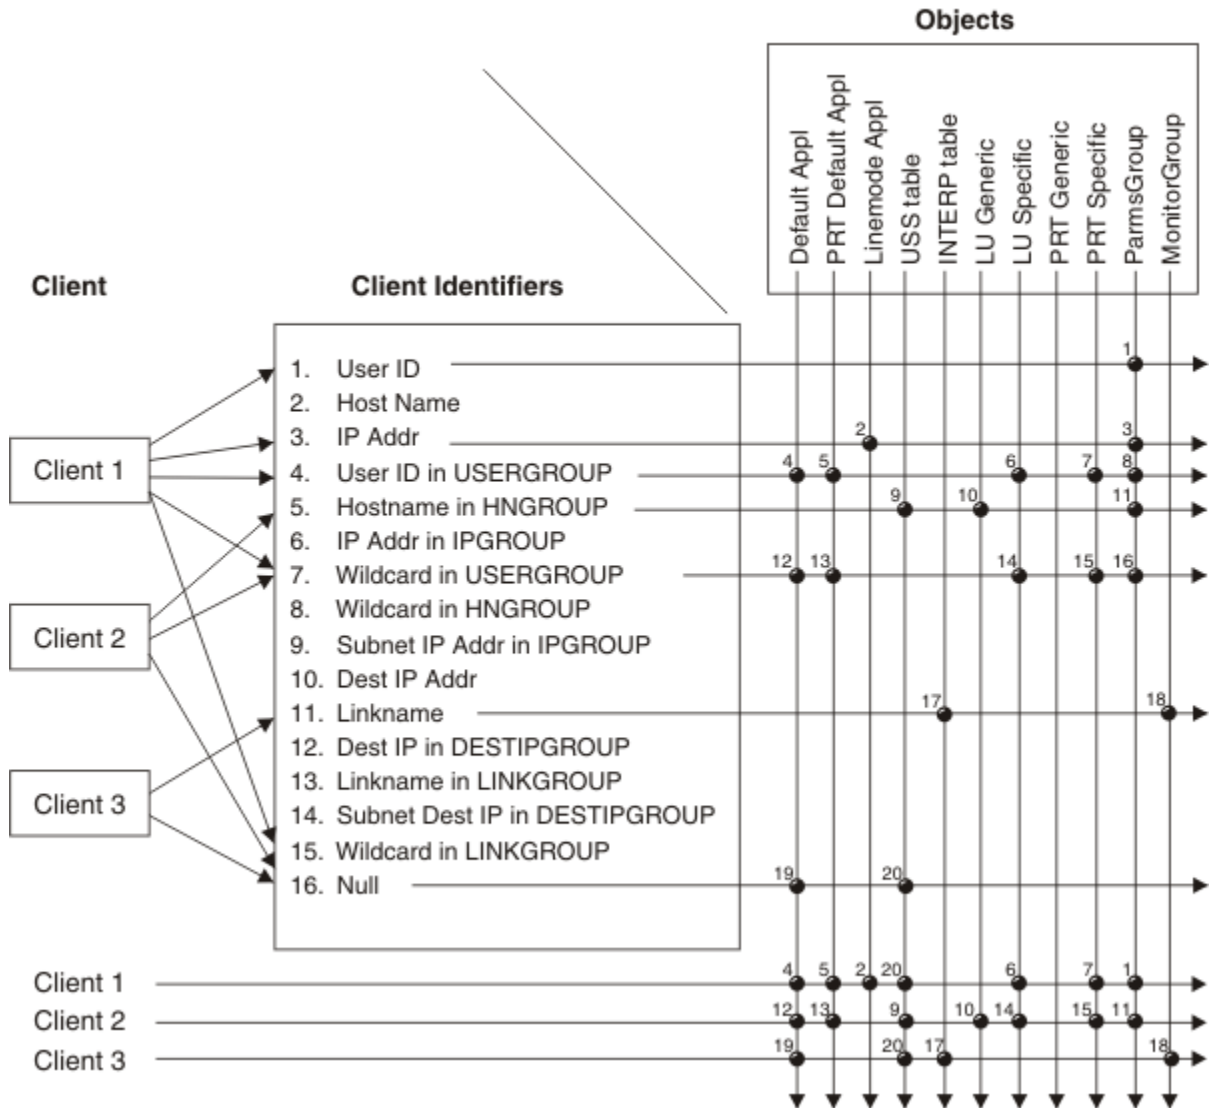

Figure 95. Search method

#### Client mappings

This example uses the following assumptions:

- Client 1 connects from IP address 9.9.9.9 using client authentication and is assigned PAYUSR1. The client does not have a host name ending in GROUP3.COM and does not have a link name LINK1.
- Client 2 connects from IP address 9.1.1.1 using client authentication and is assigned PAYUSR5. The client has the host name USER5.GROUP3.COM and does not have a link name LINK1.
- Client 3 connects from IP address 9.2.2.2 without client authentication and has the host name USER3.GROUP1.COM. The client connects to link name LINK1.

Based on [Figure 95 on page 638](#), the clients are assigned objects as shown in [Table 29 on page 639](#).

## LU name mapping statements

Every connection must be represented by an LU name before a session can be initiated. The time of LU assignment depends on the connection type. In general, for TN3270E clients, the LU name is assigned early during connection negotiation before an application name is known. For all other types of clients, the LU name is assigned immediately after application name selection. For details and exceptions to this rule, see [“Advanced LU name mapping topics” on page 647](#). Mapping statements define which LU name is assigned to the connection.

### DEFAULTLUS

The simplest way to assign LUs is to create a default LU group that Telnet can use for all terminal connections. DEFAULTLUS is a combination statement that defines the LUs in a default group and maps the group to the NULL Client Identifier. If the client's Client Identifiers do not match any LU mapping statements, the client is identified by the NULL Client Identifier and will be assigned LUs from the default group.

For example, use the following statement to create an LU group with a numeric range of LUG1001 to LUG1100. When Telnet assigns an LU to a terminal connection, it will assign the next available LU from that group of 100 LUs.

```
DEFAULTLUS LUG1001..LUG1100..FFFFN ENDEFAULTLUS
```

By default, Telnet uses a sequential selection method to assign LUs from the LU group. No LU name will be reused until all the names in the group have been used. Specifying NOSEQUENTIALU changes the selection process to always start at the beginning and find the first name available. If the range is large and a large number of LUs are already assigned, NOSEQUENTIALU might degrade LU lookup performance.

## **DEFAULTPRT**

The DEFAULTPRT statement is used to create a default LU pool that Telnet will use for all printer connections. For example, use the following statement to create an LU group with a numeric range of PRTG1001 to PRTG1100. When Telnet assigns an LU to a printer connection, it will assign the next available LU from that group.

```
DEFAULTPRT PRTG1001..PRTG1100..FFFFN ENDEFAULTPRT
```

## **LUMAP, PRTMAP, LUGROUP, PRTGROUP**

The LUMAP and PRTMAP statements allow you to map LUs to connections based on the Client Identifier for terminal emulators and printer emulators, respectively. For example, use the following statements to map LU name LUT001 to any terminal client identified by the client IP address 1.1.1.1 and map LU name PRT001 to any printer client identified by client IP address 2.2.2.2.

```
LUMAP LUT001 1.1.1.1
PRTMAP PRT001 2.2.2.2
```

A local or shared LU group can be used when it is not necessary to have an exact LU name to Client Identifier match. For example, use the following statements to create a terminal LU group and a printer LU group, and map both groups to the Client Identifier IPGPAY. When a terminal client connects, Telnet will assign an LU from LUGRP1. When a printer client connects, Telnet will assign an LU from PRTGRP1.

```
LUGROUP LUGRP1 LUT101..LUT400..FFFFN ENDLUGROUP
PRTGROUP PRTGRP1 PRT101..PRT400..FFFFN ENDPRTGROUP

IPGROUP IPGPAY 255.255.0.0:9.8.0.0 ENDIPGROUP

LUMAP LUGRP1 IPGPAY
PRTMAP PRTGRP1 IPGPAY
```

If these same LUs can be mapped by more than one Telnet, put them into shared LU groups instead by adding an S to the object type as follows:

```
SLUGROUP LUGRP1 LUT101..LUT400..FFFFN ENDSLUGROUP
SPRTGROUP PRTGRP1 PRT101..PRT400..FFFFN ENDSPRTGROUP
```

After all 300 LUs are assigned, the next client connection request will fail. In this way, the LUGROUP Object can limit the number of clients connected at one time.

If a client connection is known by a Client Identifier that has an LU group mapping, only that mapping will be used to assign an LU name. The DEFAULTLUS group will not be used. It is used only in the case when no other LU mapping exists.

## **LU range specification**

Telnet LU range rules allow for almost any type of LU range needed. Ranges can be alphabetic (A), numeric (N), alphanumeric (B), hexadecimal (X), or a complete wildcard (?), which includes alphanumeric and the three national characters (@, #, \$). The range type can be different for each character position. Within the LU range, any character position can be fixed (F). To conform with VTAM LU naming convention,

the first character must be alphabetic or a national character. If the first character is a range, only the alphabetic range can be used.

An LU range is created by specifying a starting LU name, an ending LU name, and the range rules to be used. For example, the following statement creates a range from TCPM1000 to TCPM1100.

```
TCPM1000..TCPM1100..FFFFNNN
```

The three components are:

- Starting LU name (TCPM1000)
- Ending LU name (TCPM1100)
- Range rules (FFFFNNN)

All three components must be the same length, the Starting LU name overall must be lower than the Ending LU name, and each character position value must be appropriate for the specified range rule.

**Tip:** In the above example, the character 1 following the character M is defined as fixed because it cannot change. The range rule cannot specify N even though it seems to be part of the number range.

The ascending order of characters is 0-9, A-Z, @, #, \$.

If the range rule is omitted, Telnet assumes the following style, where LowerRange and UpperRange must be all numeric or all alphabetic:

```
LuBase+LowerRange..LuBase+UpperRange
```

Numeric values are lower than alphabetic values to facilitate the use of hexadecimal ranges. The range rules are:

| Range        | Rule | Characters     |
|--------------|------|----------------|
| Numeric      | N    | 0-9            |
| Alphabetic   | A    | A-Z            |
| AlphaNumeric | B    | 0-9,A-Z        |
| Hexadecimal  | X    | 0-9,A-F        |
| Wildcard     | ?    | 0-9,A-Z,@,#,\$ |

The maximum number of LUs per range is 4294967295 and the maximum number of LUs per group is 4294967295.

The creation of LU name values from the range specification begins at the Starting LU and increments the rightmost variable position first, moving to the left as each variable position reaches its range maximum. The process is like an odometer, except that each position can have different basing instead of all positions being base 10. For example, the following statement has 223 LU name entries.

```
LU555..LU777..FFNNN
```

The breakdown of the range is:

```
LU555->LU559, 5
LU560->LU569, LU570->LU579, LU580->LU589, LU590->LU599, 40
LU600->LU699, 100
LU700->LU769, LU770->LU777 78
=====
Total -----> 223
```

The LU names increment just as the numbers on an odometer would. A less intuitive case involves an alphabetic range of 1407 LU name entries.

```
LUCCC..LUEEE..FFAAA
```

The breakdown of the range is:

```
LUCCC->LUCCZ, 24
LUCDA->LUCDZ, LUCEA->LUCEZ, LUCFA->LUCFZ, ... LUCZA->LUCZZ, 598
```

|                            |      |
|----------------------------|------|
| LUAAA->LUZZZ,              | 676  |
| LUAAA->LUEDZ, LUEEA->LUEEE | 109  |
|                            | ==== |
| Total ----->               | 1407 |

It is important to realize that these ranges do not break down in the following patterns:

```
LUCCC->LUCCE, LUCDC->LUCDE, LUCEC->LUCEE, ...
LU555->LU557, LU565->LU567, LU575->LU577, ...
```

It is an incorrect assumption that the LU name after LUCCE would be LUCDC. The correct LU name after LUCCE is LUCCF. The LU names increment to LUCCZ and the next name is LUCDA. When the rightmost position reaches the range maximum, the position to its left is incremented by one, and the rightmost position starts at the range beginning, not the character specified in the Starting LU name.

All range types are handled the same way. The position is incremented to its maximum value and then wraps to the beginning range value, not the specified Starting LU name value. By the same logic, the position is incremented to the ending range value and not the Ending LU name value.

All LU names increment the same way. A more complicated example mixes fixed and variable character positions with several different range types. The LU range has 39744 LUs.

```
LUAD1800..LUGD98FZ..FFAFNFXB
```

Calculating the number of LUs is easier if the fixed positions are removed. For purposes of calculating the number of LUs, the range is specified as follows:

```
A100..G9FZ..ANXB
```

This breaks down as follows:

|                                                                   |       |
|-------------------------------------------------------------------|-------|
| A100->A10Z, D110->D11Z, ... A190->A19Z, A1A0->A1AZ ... A1F0->A1FZ | 576   |
| A200->A2FZ, A300->A3FZ, ... A900->A9FZ                            | 4608  |
| B000->B9FZ, C000->C9FZ, ... F000->F9FZ                            | 28800 |
| G000->G9FZ                                                        | 5760  |
|                                                                   | ====  |
| Total ----->                                                      | 39744 |

## SEQUENTIALLU

Telnet, by default, uses a sequential method to choose LUs from a group.

```
LUGROUP LUGRP1
 LU001..LU120..FFNNN
 LU201..LU250..FFNNN
 LU240..LU280..FFNNN
 LU010..LU050..FFFNN
ENDLUGROUP
```

From the previous example, the first LU assigned is LU001, second is LU002, and so on. If five clients repeatedly connect and disconnect, they will be assigned new LUs farther into the range each time:

- When the end of the first range is reached, selection goes to the beginning of the second range.
- At the end of the second range, selection goes to the beginning of the third range.
- At the end of the third range, selection goes to the beginning of the fourth range.
- At the end of the fourth range, selection goes to the beginning of the first range again.

Telnet does not enforce an overall ascension in LU name selection. The selection process begins at the first name of the first range and progresses to the last name of the last range. In the example, after LU250 is assigned from range 2, LU240 from range 3 is attempted next. After LU280, LU010 is attempted. After LU050, the process starts over and LU001 is attempted.

The SEQUENTIALLU function can be turned off by coding NOSEQUENTIALLU. In this case, the five LUs that are repeatedly connecting and disconnecting would never use any LU names other than LU001, LU002, LU003, LU004, and LU005. NOSEQUENTIALLU might degrade LU lookup performance when a

large range is specified and only LUs at the end of the range are available. Every connection has to relearn that most of the LUs are already in use. SEQUENTIALLU allows Telnet to start its search near the last chosen LU where LUs are more likely to be available. SEQUENTIALLU and NOSEQUENTIALLU parameters can be coded at all three parameter block levels for different levels of granularity.

If several clients are connecting at the same time, the order of LU assignment might not be in exactly the same order as the connection IDs due to process timing between connection ID assignment and LU name assignment.

If single LU names are in a group with LU ranges, the single LU names are selected before any LU range names are selected, regardless of their order. In the example below, LUAAA, LUBBB, LUCCC, and LUDDD are all processed before any of the range LU names.

| Profile LUGROUP     | LUGROUP as used by Telnet |
|---------------------|---------------------------|
| LUGROUP LUGRP2      | LUGROUP LUGRP2            |
| LUAAA               | LUAAA                     |
| LU001..LU120..FFNN  | LUDDD                     |
| LU201..LU250..FFFNN | LUBBB                     |
| LUDDD               | LUCCC                     |
| LUBBB               | LU001..LU120..FFNN        |
| LU240..LU280..FFFNN | LU201..LU250..FFFNN       |
| LU010..LU050..FFFNN | LU240..LU280..FFFNN       |
| LUCCC               | LU010..LU050..FFFNN       |
| ENDLUGROUP          | ENDLUGROUP                |

## Application mapping statements

When a client connects, Telnet either immediately initiates a session request to an MVS host VTAM application or solicits the user for an application name.

### DEFAULTAPPL

The DEFAULTAPPL mapping statement is used to assign an application name to the connection and immediately initiate a session with that application, and not solicit the user for an application name. The DEFAULTAPPL statement applies only to terminal emulators connecting in TN3270, TN3270E, or DBCSTRANSFORM mode. For example, use the following statement to map the default application PAYROLL to any TN3270 or TN3270E terminal client identified by the IPGROUP IPGPAY. When a TN3270 or TN3270E client connects, Telnet will immediately initiate a session to the PAYROLL application.

```
DEFAULTAPPL PAYROLL IPGPAY
```

### PRTDEFAULTAPPL and LINEMODEAPPL

The PRTDEFAULTAPPL mapping statement is used to assign an application to a printer emulator client connecting in TN3270E mode. The LINEMODEAPPL mapping statement is used to assign an application to a client connecting in standard or binary LINE mode. For example, use the following statements to map the default application PAYPRINT to any TN3270E printer client identified by the IPGROUP IPGPAY and to map the default application TSO to any linemode client identified by the linkname LINK1. When the printer client connects, Telnet will immediately initiate a session to the PAYPRINT application. When a linemode client connects, Telnet will immediately initiate a session to the TSO application.

```
PRTDEFAULTAPPL PAYPRINT IPGPAY
LINEMODEAPPL TSO LINK1
```

The DEFAULTAPPL, PRTDEFAULTAPPL, and LINEMODEAPPL statements imply a basic ALLOWAPPL statement for the application name if no ALLOWAPPL or RESTRICTAPPL is explicitly coded.

### USSTCP

If the user needs the ability to choose an application, you can create custom solicitor screens using unformatted system services (USS) message tables. These tables are mapped to clients using the USSTCP mapping statement. For example, use the following statement to map a USS table, USSTAB1, to any

TN3270 or TN3270E client identified by any link name that starts with LINK. When a TN3270 or TN3270E client connects, Telnet will immediately send a custom logon screen (USSMSG10) from the USS table.

```
LINKGROUP LNKGRP1 LINK* ENDLINKGROUP
USSTCP USSTAB1 LINKGRP1
```

Assembled USS tables used by VTAM can also be used by Telnet.

## **INTERPTCP**

In some cases, the application name must be generated based on the name provided by the user or the name might be dependent on the LU name representing the client. The INTERPRET table can provide this function. Telnet uses the input from the USSMSG10 screen as input to the INTERPRET table translation list or uses the USSMSG10 input and the LU name as input to one of the INTERPRET table user-written exits. Because USS logon data is required input to the INTERPRET process, any client with an INTERPRET table mapping must also have a USS table mapping. For example, use the following statement to map an INTERPRET table, INTTAB1, to any TN3270 or TN3270E client identified by the linkname LINK1. When a TN3270 or TN3270E client connects to LINK1, Telnet will immediately send a custom logon screen (USSMSG10) from the USS table. The user responds with a USS logon command. LINK1 client input is then processed through the INTTAB1 INTERPRET table to derive an application name. Telnet uses the derived name to initiate a session.

```
LINKGROUP LNKGRP1
LINK*
ENDLINKGROUP
USSTCP USSTAB1 LNKGRP1
INTERPTCP INTTAB1 LINK1
```

Assembled interpret tables used by VTAM can also be used by Telnet.

If neither a default application nor a USS table is mapped to the connection, the Telnet solicitor screen is sent to the user. For a detailed discussion of the Telnet solicitor, USS table, and INTERPRET table, see [“Using the Telnet solicitor or USS logon screen” on page 667](#).

## **Resolving DEFAULTAPPL and USS table conflicts**

If both a default application and a USS table are mapped to the same Client Identifier, Telnet will use the default application to immediately initiate a session. If each is mapped by a different Client Identifier, the Object mapped by the higher priority Client Identifier is used. In all cases, any error messages are sent using the USS table messages. For example, if CICS and USSTAB1 are both mapped to destination IP address 1.1.1.1, Telnet will initiate a session with CICS and use the USS messages for any session setup errors.

If CICS is mapped to USERID USER1 and USSTAB1 is mapped to client IP address 5.5.5.5, Telnet will initiate a session with CICS and use the USS messages for any session setup errors.

If CICS is mapped to linkname LINK1 and USSTAB1 is mapped to hostname TEST1.IBM.COM, Telnet sends a USSMSG10 logon screen to the user. The USS messages will be used for any session setup errors. The default application mapping of CICS will never be used.

## **ALLOWAPPL**

Telnet will not initiate a session for a solicited application name unless the name is allowed. The ALLOWAPPL statement is used to configure Telnet to allow the initiation request. For example, CICS01 and CICS02 are allowable names.

```
ALLOWAPPL CICS01
ALLOWAPPL CICS02
```

The ALLOWAPPL name can have a wildcard value by using an asterisk (\*). For example, if there are no other CICS regions, these lines can be reduced to the following line:

```
ALLOWAPPL CICS*
```

All application names can be allowed by coding the following line:

```
ALLOWAPPL *
```

Default application names do not need to be explicitly allowed. However, if the default application issues a CLSDST-PASS to another application name for the session, the second application must be in the ALLOWAPPL list. For example, TSO is the default application for the NULL Client Identifier. TSO typically passes the session to TSO00001, TSO00002, and so on. The following default application mapping will initiate a session with TSO, but when TSO issues a CLSDST-PASS the new bind to Telnet will have TSO00001 as the application name.

```
DEFAULTAPPL TSO
```

Telnet will fail this session request because TSO00001 is not allowed. Add an ALLOWAPPL statement to allow the TSO\* names as follows:

```
DEFAULTAPPL TSO
ALLOWAPPL TSO*
```

## ***RESTRICTAPPL***

In addition to the ALLOWAPPL statement, Telnet provides more restrictive access to applications. The RESTRICTAPPL statement requires the user to enter a valid user ID and password before the application name is used to initiate a session. Specify the PASSWORDPHRASE parameter statement in Telnet configuration to expand the password length limit on the solicitor screen. You can use either a password or a password phrase with this option.

The user ID specified can be any valid user ID and does not need to be related to the user ID specified for the application. If you code the CERTAUTH option on the RESTRICTAPPL statement, the user does not need to supply a user ID if a client certificate is received and a user ID is derived from the client certificate. In this case, if the user ID derived from the client certificate matches a user ID on the RESTRICTAPPL statement, Telnet immediately initiates a session and does not request a password or password phrase from the user.

For example, use the following statement to allow users USER1, USER2, USER3, USER4, and USER5 access to the PAYROLL application. At the solicitor screen, the user enters USER1, their password or password phrase, and the PAYROLL application name. Telnet verifies that USER1 and the password or password phrase are valid and then immediately initiates a session with PAYROLL.

```
RESTRICTAPPL PAYROLL
 USER USER1
 USER USER2
 USER USER3
 USER USER4
 USER USER5
```

Like ALLOWAPPL, the application name can have a wildcard value by using an asterisk (\*). The USER value can also have a wildcard value by using an asterisk. The user ID and password or password phrase combination is used by Telnet to verify the password or password phrase given for that user ID. In no way is the user ID and password or password phrase used by the application. No matter how the application name request arrived at the server (from DEFAULTAPPL or USSMSG10), Telnet uses the solicitor screen to prompt for the user ID and password or password phrase. After the user ID is validated and a password or password phrase is obtained, Telnet submits the user ID and password or password phrase pair for authorization to a security program such as RACF. The user ID and password or password phrase check authorizes the client to connect to the application through Telnet. The application itself might also ask for a user ID and password or password phrase pair that can be completely different than the pair entered at the Telnet solicitor screen. The user ID and password or password phrase pair that is entered at the Telnet solicitor screen is not passed to the host application. The user ID and password or password phrase pair is solicited only after the user enters an application name on the solicitor (or USSMSG10) screen. If a second application is reached through the original application using CLSDST-PASS, the second

application is verified and Telnet will solicit a new user ID and password or password phrase pair if necessary.

When searching for a match with the input application name, Telnet will find the most specific match whether it is on the ALLOWAPPL or RESTRICTAPPL statement. If each statement has the same name specified, the RESTRICTAPPL entry is used. For example, TSO has its own user ID and password or password phrase requirement and probably does not need the additional Telnet security check. However, the Telnet security check may be needed for all other applications. This example can be supported with the following statements.

```
RESTRICTAPPL *
USER *
ALLOWAPPL TSO*
```

## Connection parameters mapping statement

Connection parameters are typically defined once at the port level. Sometimes it is useful to have different connection parameters depending on the Client Identifier. The PARMSGROUP and PARMSMAP statements allow connection parameters to be mapped at the Client Identifier level. This level of granularity applies to almost all parameters. See [z/OS Communications Server: IP Configuration Reference](#) for a list of Telnet parameters allowed in the PARMSGROUP block.

Assume the PAYROLL department is assigned the highest level of security and connections are being monitored with summary debug messages, general users are assigned negotiable security, and inventory employees are experiencing intermittent problems with Telnet connections that require detailed debug messages for resolution. The following statements assign the security and debug levels to the areas needed and do not affect other areas. See [“Transport Layer Security” on page 622](#) for security information and [“Telnet diagnostic tools” on page 604](#) for debug information.

```
HNGROUP HNGINV
** .GROUP3 .COM
ENDHNGROUP
IPGROUP IPGPAY
255.255.0.0:2.2.0.0
ENDIPGROUP
IPGROUP IPGGEN
255.0.0.0:2.0.0.0
ENDIPGROUP
PARMSGROUP PRMGDBG
DEBUG DETAIL
ENDPARMSGROUP
PARMSGROUP PRMGSEC1
CONNTYPE SECURE
DEBUG SUMMARY
ENDPARMSGROUP
PARMSGROUP PRMGSEC2
CONNTYPE NEGOT
ENDPARMSGROUP
PARMSMAP PRMGDBG HNGINV
PARMSMAP PRMGSEC1 IPGPAY
PARMSMAP PRMGSEC2 IPGGEN
```

## Advanced LU name mapping topics

Beyond the basic LU mapping statements, there are several functions available to the advanced user. This topic includes the following subtopics:

- Generic and Specific connection requests
- Mapping groups to Client Identifiers
- LU name assignment user exit
- Associated printer function
- Map default application and ParmsGroup by LU group
- Multiple LUMAP statements for one Client Identifier
- Keep LU for the Client Identifier

- LU group capacity warning
- LU mapping by application name
- LU mapping selection rules
- LU mapping with multilevel security active

### ***Generic and Specific connection requests***

There are three types of Telnet connection requests that dictate how Telnet chooses a name to represent the client. They are Generic requests, Specific requests, and associated printer requests. For details about associated printer requests, see [“Associated printer function” on page 650](#). Most connection requests are Generic requests.

For Generic requests, Telnet has complete control over LU name assignment using the Generic mapping statements as a reference. All linemode and TN3270 connections use only Generic requests, and TN3270E terminal and printer emulators use Generic requests as their default request type. Specific mapping statements are ignored by Generic requests.

For Specific requests, the TN3270E client specifies the LU name to be used. Telnet validates the name using the Specific mapping statements as a reference. Requesting a Specific LU name allows a client to be assigned the same LU every time. This is important if the host application is LU name dependent, and the client does not have a constant Client Identifier to use for mapping an LU name. It is also important to block Telnet from assigning these LUs to Generic requests. That is why Specific mapping statements are ignored by Generic requests. If a Specific mapping does not find an LU match, Generic mapping statements are checked. Telnet confirms or denies the request during negotiation. If the LU mapping algorithms reject the client choice, Telnet sends a device type reject to the client. Most clients then notify the end user that the requested LU name is not valid or is already in use.

#### ***Default LU groups***

DEFAULTLUS and DEFAULTPRT are default local LU groups for Generic requests from terminal and printer emulators. SDEFAULTLUS and SDEFAULTPRT are default shared LU groups for Generic requests from terminal and printer emulators. DEFAULTLUSSPEC and DEFAULTPRTSPEC are default local LU groups for Specific requests from terminal and printer emulators. SDEFAULTLUSSPEC and SDEFAULTPRTSPEC are default shared LU groups for Specific requests from terminal and printer emulators. DEFAULTLUS and DEFAULTPRT are explained in [“LU name mapping statements” on page 640](#). Like the Generic pools, the Specific pools are checked only if there is no other LU mapping statement match. For example, use the following statements to create a terminal LU group with a numeric range of LUS1001 to LUS1100 and a printer LU group with a numeric range of PRTS1001 to PRTS1100. When Telnet receives a Specific connection request from a terminal, it will verify that the requested LU name is within the range specified.

```
DEFAULTLUSSPEC LUS1001..LUS1100..FFFFNNN ENDEFAULTLUSSPEC
DEFAULTPRTSPEC PRTS1001..PRTS1100..FFFFNNN ENDEFAULTPRTSPEC
```

The sequential selection rules do not apply to Specific requests.

### ***Mapping groups to Client Identifiers***

The LUMAP and PRTMAP statements allow LUs to be mapped based on a Client Identifier. The LU group can be mapped Generically or Specifically. The default mapping is Generic. The keyword SPECIFIC must be coded to define a Specific mapping.

For example, use the following statements to create two LU groups. Map one group Generically to the IP group IPGPAY and map the other group Specifically to the same Client Identifier. When a Generic connection request is received, Telnet will assign the next available LU from LU group LUGRPGEN. When a Specific connection request is received, Telnet will verify the requested LU name is included in the LU group LUGRPSPC. If it is, Telnet will assign the LU name to the connection.

```
LUGROUP LUGRPGEN LUG101..LUG400..FFFXXX ENDLUGROUP
LUGROUP LUGRPSPC LUS001..LUS100..FFFXXX ENDLUGROUP

IPGROUP IPGPAY 255.255.0.0:9.8.0.0 ENDIPGROUP
```

|       |          |        |          |
|-------|----------|--------|----------|
| LUMAP | LUGRPGEN | IPGPAY |          |
| LUMAP | LUGRPSPC | IPGPAY | SPECIFIC |

Generic request connections can be assigned LUs only from Generically mapped LU groups. If no Generic mapping exists, the DEFAULTLUS group is checked. No Specific group is checked. This safeguards the Specific LU names from being used by Generic requests.

For Specific requests, Telnet first checks to see if the LU is in a Specifically mapped LU group. If the LU name is not found, the Generically mapped groups are searched. If neither LU group type contains the requested LU name, the connection request is rejected. The DEFAULTLUSSPEC group is not checked in this case because LU group mappings exist. If no LU group mappings exist, only the DEFAULTLUSSPEC group is checked. If the LU name is not found, the connection request is rejected. The Generic DEFAULTLUS group is not checked.

In addition to requesting an exact LU name, the client can request an LU group name. Telnet first searches within the mapped groups, assuming the name is an exact LU name. If that search fails, Telnet then checks the requested name against mapped Specific LU group names and then checks the name against mapped Generic LU group names. If the group name is found, the next available LU in the group is assigned using sequential LU selection unless it has been turned off.

The LU group itself is not defined as Generic or Specific. Rather, the LU group is *mapped* Generically or Specifically. It is possible to map the same LU group both Generically and Specifically. IBM recommends that you do not map the same group Generically and Specifically unless you are an advanced user.

## ***LU name assignment user exit***

Most LU assignment requirements can be satisfied using the Telnet LU group and LU mapping statements. However, there are cases when the LU assignment requirements are so specific that Telnet cannot satisfy them. In these cases, the LU name assignment user exit might be the solution. The LU name exit is defined like an LUGROUP and is mapped the same way LUGROUPs are mapped. The LUGROUP is defined as an exit by specifying *EXIT* immediately after the LUGROUP name. For LUGROUPs, Telnet selects an LU from the group, verifies its availability, and assigns the LU to the connection. For LU name exits, Telnet calls the user-written assembler program passing a parameter list that contains client and other information. The program creates the LU name, places it in the parameter list, and returns control to Telnet. Telnet will then verify the LU name's availability and assign the LU to the connection. An LU name exit cannot be dynamically updated. After it is loaded, it remains unchanged until Telnet is recycled. To make a change without recycling Telnet, the exit name must be changed. The new name can then be added on a mapping statement. For a detailed description of the parameter list and coding requirements for the Telnet LU exit, see [z/OS Communications Server: IP Configuration Reference](#).

Version 2 of the LU exit allows the exit to override Telnet profile assigned USS (3270 or SCS format) and interpret tables. The values assigned by the Telnet profile or blanks are passed into the exit. The exit can override any of the three values and Telnet will use the new values. For details on [Telnet LU exit setup](#), see [z/OS Communications Server: IP Configuration Reference](#).

In addition to client information, the parameter list includes any LU names or ranges that were coded in the LUGROUP, and the requested application name if known. Telnet does not use the LU list. The LUs specified can be used as seed values if the LU name exit wants to use them. The LUGROUP can be defined without any LUs specified. However, if the exit is used with multilevel security, at least one LU must be specified so the LUGROUP can be assigned a security label. For details, see [“LU mapping with multilevel security active” on page 657](#).

The LU name exit is called when the LU is assigned, when the LU is released, when the LU is deactivated, and when the LU is activated. A different function code is used for each type of call. If you do not need a certain function, like tracking deactivated LUs, the LU name exit can be written to ignore the function code. Telnet allows only one connection at a time to use the LU name exit, which serializes its use in case any local tables are maintained in the exit.

As an example, assume LU names are to be assigned based on client port number and application requested. The SIMCLIENTLU parameter is used to postpone TN3270E LU assignment until the application name is known. The parameter list includes the client port number and the requested

application name. In this case, no seed LU names are needed. The LU name exit will create LU names based on the port number and application name in the parameter list.

```
LUGROUP LUEXIT1,EXIT
ENDLUGROUP
```

In another example, assume that the clients specify LUGROUP names that match the default applications on the LUMAP statement. The LU names are to be created based on the last two numbers of the IP address and a prefix that identifies the application. For example, TSO, IMS, and CICS are three current applications, and the prefix for each is TS, IM, and CI, respectively. The connection from IP address 9.1.240.111 specifies LUGROUP LUGTSO and is assigned the name TS240111. The connection from IP address 9.1.240.212 specifies LUGROUP LUGIMS and is assigned the name IM240212. The connection from IP address 9.1.89.7 specifies LUGROUP LUGTSO and is assigned the name TS089007. Three LU name exits are required (LUGTSO, LUGIMS, LUGCICS), but they are all functionally equivalent. The LU name specified in the LUGROUP statement is passed to the LU name exit as part of the parameter list, and that name is used by the exit as the prefix. The client IP address is also in the parameter list. To force Telnet to call each exit, the LU name exit must return a nonzero return code when the LU name sent by the client does not match the LUGROUP name. The LU name exit combines the prefix with the last portions of the IP address to create an LU name. The following statements can be used to support this scenario.

```
IPGROUP IPGRP1 0.0.0.0:0.0.0.0 ENDIPGROUP ; Matches all connections

LUGROUP LUGTSO,EXIT TS ENDLUGROUP
LUGROUP LUGIMS,EXIT IM ENDLUGROUP
LUGROUP LUGCICS,EXIT CI ENDLUGROUP

LUMAP LUGTSO IPGRP1 DEFAPPL TSO
LUMAP LUGIMS IPGRP1 DEFAPPL IMS
LUMAP LUGCICS IPGRP1 DEFAPPL CICS
```

Capacity checks cannot be performed because Telnet has no way of knowing how many total LUs are available in the LU name exit.

### ***Associated printer function***

The associated printer function allows a printer emulator to specify an active LU terminal name during connection negotiation. Telnet understands this special request and knows to assign a printer LU name that is associated with the requested terminal LU name. You establish the association by linking a pool of terminal LUs (LUGROUP or SLUGROUP) with a pool of printer LUs (PRTGROUP or SPRTGROUP). The groups are linked with the LUMAP statement. The printer LU group name is linked to the terminal LU group name by adding the PRTGROUP name on the LUMAP statement.

The two LU groups must have the same number of LUs defined so the LUs can be paired. The groups must have the same number of single LU names, the same number of LU ranges, and the same number of LU names in each range. If the groups do not have the same number of LUs defined, error messages will be produced during profile processing.

After the groups are linked, Telnet assigns the *n*th printer LU to a printer connection that requests association with the *n*th terminal LU. For example, a CICS table might specify that if terminal LU1 is requesting printer function, the output should be routed to printer PRT1. Within CICS, LU1 and PRT1 are associated with each other. Use the following statements to set up printer association.

```
LUGROUP LUGCICS LU1..LU9 ENDLUGROUP
PRTGROUP PRTCICS PRT1..PRT9 ENDPRTGROUP
IPGROUP IPGRP9 255.0.0.0:9.0.0.0 ENDIPGROUP
LUMAP LUGCICS IPGRP9 GENERIC PRTCICS
```

To use shared groups, change the first two lines to indicate that the groups are shared:

```
SLUGROUP LUGCICS LU1..LU9 ENDSLUGROUP
SPRTGROUP PRTCICS PRT1..PRT9 ENDSPRTGROUP
```

**Rule:** If you are using sysplex distributor to distribute connections across Telnet servers with associated printers, regardless of whether the LUs are in local groups or shared groups, you must use timed client affinity to ensure that the clients connect to the same Telnet server.

If the terminal connection matches a DEFAULTAPPL or LUMAP-DEFAPPL mapping statement, Telnet immediately initiates a session request for the specified application. If the printer connection matches a PRTDEFAULTAPPL mapping statement, Telnet immediately initiates a session request for the specified application. Building on the previous example, use the following statements to set CICS as the default application for both the terminal and printer connections:

```
LUMAP LUGCICS IPGRP9 GENERIC DEFAPPL CICS PRTCICS
PRTDEFAULTAPPL CICS
```

Neither the LU group nor the printer group can be an LU exit group. If either is an LU exit, the mapping statement will be rejected.

#### *Drop the printer connection when dropping the terminal connection*

In many cases, the associated printer connection should be dropped when the terminal connection is dropped. If you code the DROPASSOCPRINTER parameter, Telnet will monitor the terminal connection. When the terminal connection is dropped, Telnet will initiate the closing and dropping of the printer connection. The DROPASSOCPRINTER and NODROPASSOCPRINTER parameters can be coded at all three parameter block levels for different levels of granularity.

### **Map default application and ParmsGroup by LU group**

The DEFAPPL option on the LUMAP statement allows a host VTAM application to be mapped with an LU name or LUGROUP name instead of using DEFAULTAPPL. The LUMAP-DEFAPPL combination is treated just like DEFAULTAPPL when a Client Identifier matches the LUMAP statement. The LUMAP-DEFAPPL combination also supports the LOGAPPL, FIRSTONLY, and DEFONLY parameters that are used by DEFAULTAPPL, PRTDEFAULTAPPL, and LINEMODEAPPL. The LUMAP-DEFAPPL combination is a powerful statement when used with multiple LUMAP statements for the same Client Identifier. If the LUMAP-DEFAPPL or PRTMAP-DEFAPPL statement is coded and the default application is not available, an error screen will be sent to the client whether or not MSG07 is coded.

The PMAP option on the LUMAP statement allows assignment of connection parameters based on LU or LU group name. When the LU is assigned, the parameter values specified in the PMAP PARMSGROUP will override the parameter value specified in TELNETGLOBALS, TELNETPARMS, or PARMSGROUP mapped to this connection's Client Identifier. For example, any client in subnet 9.0.0.0 that specifies the LU group LUGTSO will immediately have a session initiated to TSO with the LOGAPPL function, and the TIMEMARK time will be set for two hours instead of the default three hours.

```
IPGROUP IPGRP9 255.0.0.0:9.0.0.0 ENDIPGROUP
LUGROUP LUGTSO TCPTS001..TCPTS099..FFFFFFN ENDLUGROUP
PARMSGROUP PGRPT2 TIMEMARK 7200 ENDPARMSGROUP
LUMAP LUGTSO IPGRP9 DEFAPPL TSO LOGAPPL PMAP PGRPT2
```

An LUMAP-DEFAPPL defined default application name is always used if specified, regardless of USSTCP mappings. LUMAP-DEFAPPL has a higher priority than any DEFAULTAPPL or USSTCP. The connection parameters assigned using LUMAP-PMAP will override any other setting of the parameters. However, not all parameters have a meaningful use by the time the LU is assigned. For example, NOTN3270E controls whether or not Telnet should negotiate for TN3270E. That negotiation is done before LU assignments. For information on which parameters can be properly applied with LUMAP-PMAP, see the parameter table in [z/OS Communications Server: IP Configuration Reference](#).

The PRTMAP statement supports PRTMAP-DEFAPPL and PRTMAP-PMAP in the same manner as LUMAP-DEFAPPL and LUMAP-PMAP.

### **Multiple LUMAP statements**

Another feature of Specific LU name requests is that the client can specify an LUGROUP name, and Telnet will assign an available LU from that pool. This capability is useful when different applications require

different LU naming schemes, but each user client does not need to use an exact LU name for each emulator. For example, an administrator can create three pools, one for each of three applications. Only three client emulators need to be set up. One for TSO which requests LU name LUTSO, one for CICS which requests LUCICS, and one for IMS which requests LUIMS. Assume the general users are in subnet 3.0.0.0. Any client connecting with a Client Identifier of IPGGEN can be set up to issue a Specific request for LU pool LUTSO, LUCICS, or LUIMS, and will be assigned an LU from the appropriate pool.

After an LU is assigned, the DEFAPPL option will cause Telnet to immediately issue a session request for the appropriate application. If LOGAPPL is coded and the application is not active, VTAM will continue session initiation after the application is active.

In most cases, DEFAPPL on multiple Generic LUMAPs is not useful. LUs are assigned in order starting with the first LUMAP statement. One case that may be useful is if an application has a user limit but can be cloned. Assume the INVENTORY application can support only 20 users but can be cloned. Multiple LUMAPs with DEFAPPL will direct the first 20 HNGINV clients to INVENTORY, the next 20 HNGINV clients to INVENTR2, and the next 20 HNGINV clients to INVENTR3.

```
IPGROUP IPGGEN
 255.0.0.0:3.0.0.0
ENDIPGROUP
LUGROUP LUTSO TS000001..TS000999 ENDLUGROUP
LUGROUP LUCICS CICS0001..CICS0999 ENDLUGROUP
LUGROUP LUIMS IMS000001..IMS00999 ENDLUGROUP
HNGROUP HNGINV
 *.INVDEPT.COM
ENDHNGROUP
LUGROUP LUGINV1 LUINV01..LUINV20 ENDLUGROUP
LUGROUP LUGINV2 LUINV21..LUINV40 ENDLUGROUP
LUGROUP LUGINV3 LUINV41..LUINV60 ENDLUGROUP
LUMAP LUTSO IPGGEN SPECIFIC DEFAPPL TSO LOGAPPL FIRSTONLY
LUMAP LUCICS IPGGEN SPECIFIC DEFAPPL CICS LOGAPPL
LUMAP LUIMS IPGGEN SPECIFIC DEFAPPL IMS LOGAPPL
LUMAP LUGINV1 HNGINV DEFAPPL INVENTORY LOGAPPL DEFONLY
LUMAP LUGINV2 HNGINV DEFAPPL INVENTR2 LOGAPPL DEFONLY
LUMAP LUGINV3 HNGINV DEFAPPL INVENTR3 LOGAPPL DEFONLY
```

Pool name specification is a powerful mapping method because multiple LUMAP statements with different Objects can be used for a single Client Identifier.

### ***Keep LU for the Client Identifier***

An LU name can be kept (or reserved) for a period of time so no other client is assigned that name. Only the same Client Identifier reconnecting to Telnet within the specified time can be assigned that LU name. After the specified time, the LU name is again available for any connection. This function is useful when the application does not clean up session information quickly and a released LU is quickly reassigned to another user by Telnet. The application thinks the new session is a continuation of the previous session but it is not. With KEEPLU, the LU will not be reassigned to a different Client Identifier for a period of time, long enough for the application to clean up its session information. The LU name is kept based on the highest Client Identifier by which the connection is known. It is either a User ID derived from a client certificate, a Hostname, or an IP address, respectively.

### ***LU group capacity warning***

An LU group capacity threshold can be specified on the LUGROUP, PRTGROUP, and default LU group statements. If specified, Telnet will check the number of LUs used in the group when an LU is assigned from the group. A message is issued when the group's in-use LU count is at or above the specified percentage of the total. After the message is issued, no other message is issued until the in-use count has dropped below the threshold by 10% of the total. For example, an LU group has 200 LUs with a capacity threshold of 80%. When the 160th LU is assigned, EZZ6007I is issued. Ten percent of the total in the group is 20. Therefore, after the number of in-use LUs has dropped to 140 or lower, another warning message will be issued when the in-use count rises to 160 again. If multiple LU groups have the same LU name, the only LU group checked is the group from which the LU is assigned to the client. The other LU

groups might go over their capacity limits, but notification will not be issued until an LU is taken from the group. Below are examples for setting the capacity warning.

```
LUGROUP LUGRP1,80% TCPLU000..TCPLUF9F..FFFFFXNX
PRTGROUP PRTGRP1,60% TCPRT000..TCPRTFFF..FFFFFXXX
DEFAULTLUS ,75% LU0000000..LU999999..FFNNNNNN
DEFAULTPRTSPEC ,90% PRTDEFS1..PRTDEFS9
```

Capacity checking cannot be done for LU groups that are defined as LU name exits. During VARY TCPIP,*tnproc*,OBEYFILE command processing, all LU groups are checked for in-use LU counts and a capacity warning message is issued if needed.

**Tip:** Be sure to leave a blank space between the default LU group statement and the capacity ( ,*nnn*%). Do not leave a blank space between a group name and the capacity.

## LU mapping by application name

In some cases, only certain LU names are eligible to be in session with the host application. Or only certain LU names are eligible to represent user IDs. The LU and LUG parameters on the ALLOWAPPL and RESTRICTAPPL statements provide this checking function and allow some LU name mapping based on application name. The LUG parameter can represent either an LUGROUP, a PRTGROUP, or a group that is a mixture of terminal and printer LUs so that both terminal and printer emulators can access the application. If single LUs are specified, they are assumed to be terminal LUs.

For example, assume the only LUs eligible to use the inventory set of applications are the LUs in the inventory LU pools. A new LUGROUP pool named LUGINVT contains LUs from LUGINV1, LUGINV2, and LUGINV3. The ALLOWAPPL statement requires that any session request to the inventory applications have an LU name defined in LUGINVT. The LUG parameter must be used carefully. When specified, Telnet must match the LU using both the common mapping algorithms and the mapping by application. For RESTRICTAPPL, assume security authorization is required to get to the PAYROLL application, and each of the PAYxx user IDs must map to a certain LU.

```
LUGROUP LUGINV1 LUINV01..LUINV20 ENDLUGROUP
LUGROUP LUGINV2 LUINV21..LUINV40 ENDLUGROUP
LUGROUP LUGINV3 LUINV41..LUINV60 ENDLUGROUP
LUGROUP LUGINVT LUINV01..LUINV60 ENDLUGROUP
ALLOWAPPL INVENTR* LUG LUGINVT
RESTRICTAPPL PAYROLL
 USER PAY01 LU LUPAY01
 USER PAY02 LU LUPAY02
 (user pay03 through pay20 not listed)
```

The LU group specified on the LUG parameter cannot be an LU exit. If it is, the ALLOWAPPL statement is rejected. Multiple LUs can be assigned individually using the LU keyword or a single LU group can be assigned using the LUG parameter. LU and LUG cannot be mixed on a single statement and only one LUG entry per statement is permitted. LU assignment based on application is a convenient way to limit the access to applications. However, this increases mapping complexity significantly when LU mapping statements and connection types are part of the overall mapping equation. Non-TN3270E connections or TN3270E connections with NOTN3270E or SIMCLIENTLU specified do not keep the LU name assigned to the connection after a session is dropped. For these connection types, the user can establish a session with different application names even if different LU names are mapped to the application names with the ALLOWAPPL or RESTRICTAPPL-USER statement. However, LU mapping that is based on application name does not work well with TN3270E connections because the LU is assigned during connection negotiation before the correct application name is known. In all CLSDST-PASS cases, the LU name cannot change when switching from the first application to the second because the LU's ACB is not closed during the switch. If the LU mapping by application name requires an LU name switch, the new session attempt will be failed by Telnet.

TN3270 connections do not assign an LU to represent the client until an application name is chosen. Therefore, the LU and LUG parameters can be used as sole LU mapping statements for TN3270 connections. For example, assume no other mapping statements exist (LUMAP or DEFAULTLUS), and either no TN3270E connections will be used or SIMCLIENTLU has been specified. The following

ALLOWAPPL statements will map LUs to the appropriate application based on the application name chosen. The following RESTRICTAPPL statement will assign a single LU or LU pool to each user.

```
ALLOWAPPL TS0* LUG LUGTS0
ALLOWAPPL CICS LUG LUGCICS
ALLOWAPPL IMS LUG LUGIMS
RESTRICTAPPL APP*
 USER USER1* LUG LUG10
 USER USER01 LU LU01
 USER USER02 LU LU02
```

Both of these assignment methods were very popular before TN3270E connections were introduced. TN3270E connections will likely achieve poor mapping results. An LU must be assigned during connection negotiation before the application name is known which will likely result in an LU mismatch later. TN3270E connections require that an LU mapping statement exist because an LU must be assigned to the connection during negotiations before an application name is known. Consider the following example:

```
DEFAULTLUS
 LU1 LU2 LU3 LU4
ENDDEFAULTLUS
RESTRICTAPPL APPL1
 USER USER3 LU LU3
ALLOWAPPL APPL2 LU LU4
```

Assume two TN3270 connections are started.

- Two solicitor screens appear.
- Specify APPL1, USER3, and a password. Telnet selects LU3 based on both the DEFAULTLUS and the RESTRICTAPPL statements.
- Specify APPL2. Telnet selects LU4 based on both the DEFAULTLUS and the ALLOWAPPL statements.

Assume two TN3270E connections are started.

- Two solicitor screens appear. Telnet assigns LU1 and LU2.
- Specify APPL1, USER3, and a password. Telnet fails the connection because of an LU mismatch.
- Specify APPL2. Telnet fails the connection because of an LU mismatch.

If LU name mapping by application name or user ID is wanted with TN3270E clients, the following three solutions are available:

- If the same application or user ID is always used at the same client, individual LUMAP statements can be used to map the correct LU name to each client. Then every connection request will result in the correct LU assignment for that client. The assumptions are that the client keeps the same Client Identifier and only one client exists per Client Identifier.
- Map the NOTN3270E parameter to clients to disable all TN3270E function in Telnet so those connections will be TN3270, not TN3270E. The drawback is that all TN3270E function is disabled. This includes printer function, Generic/Specific function, and SNA function to the client. The TN3270E and NOTN3270E parameters can be coded at all three parameter block levels for different levels of granularity.
- Mapping the SIMCLIENTLU parameter is a less severe solution. This function will send a dummy LU name of EZBSIMLU to all TN3270E clients issuing Generic connection requests to satisfy the negotiation but will not assign a Telnet LU until an application name is chosen. This alternative preserves printer function, Specific requests, and SNA function to the client. The drawback is the name sent to the client is not the name Telnet ultimately uses to represent the client. Printer association will not work for these TN3270E Generic connections and any emulator programming that depends on the LU name will be using the dummy LU name. The SIMCLIENTLU and NOSIMCLIENTLU parameters can be coded at all three parameter block levels for different levels of granularity.

### ***LU mapping selection rules***

LU mapping selection can become complicated because of the many variations of mapping statements, TN3270E versus TN3270 connections, Generic versus Specific connection requests, printer association,

and LU mappings based on application name. LU mapping is very different between TN3270E and TN3270 and will be discussed separately. But first, some general Mapping Rules for both TN3270E and TN3270 follow:

- If multiple LUMAP statements exist for a Client Identifier all Specific LUMAPs are searched (TN3270E only) and then all Generic LUMAPs are searched in the order they are listed in the profile.
- If the application is known during the LU lookup and the ALLOWAPPL or RESTRICTAPPL-USER statement has LUs listed, then the found LU must be in both the mapped LU group and in the application LU group.
- When an LU match is found, the search stops.
- Telnet performs database lookup for Objects based on the Client Identifier. TN3270E connections require an Early Lookup so Telnet can give the client an LU name during connection negotiation. In all cases a Complete Lookup is done when the application name is known. Telnet performs an Early Lookup and a Complete Lookup for TN3270E connections. Telnet performs only a Complete Lookup for TN3270 and Linemode connections.

### *TN3270E LU mapping*

TN3270E connections require an Early Lookup during connection negotiation. Telnet will use as much information as is available to assign an LU to the client. However, the eventual application is not known at this time unless an LUMAP-DEFAPPL or DEFAULTAPPL statement defines the application name. After connection negotiations are complete, Telnet will either send a logon solicitor (or USSMSG10) screen to the client or will perform a Complete Lookup using the application name obtained from the LUMAP-DEFAPPL or DEFAULTAPPL statement. If Complete Lookup is successful, Telnet will begin session initiation. If a solicitor (or USSMSG10) screen is sent to the client, an application name must be entered, at which time Telnet will perform a Complete Lookup. If LU mapping is being done based on application name, a conflict might occur between the application LU mapping and the LU already assigned to the connection. For TN3270E, after an LU name is assigned during connection negotiation it can never change until the connection is dropped. The SIMCLIENTLU statement allows Telnet to assign LUs for TN3270E connections as though they were TN3270 connections. See [“TN3270 LU mapping”](#) on page 656 for mapping Generic TN3270E connection requests with SIMCLIENTLU. A request for a Specific LU from the Telnet Client will be treated as if SIMCLIENTLU were not specified. The exact lookup process for TN3270E (non-SIMCLIENTLU) is described below.

Early Lookup: An LU must be found during Early Lookup. LUMAP-DEFAPPL and DEFAULTAPPL statements are considered but not necessarily used. Possible lookup results are:

- An LU is found.
- An LU is not found, the connection is dropped.

Perform TN3270E Early Lookup in the following order. The process stops when LU lookup is successful. Printer connections use the same process, substituting PRTMAP and PRTDEFAULTAPPL.

- Check for LUMAP matches considering application lookup results and possible application-based LU mappings.
  1. For each Specific LUMAP used for Specific connection requests: If the Specific LUMAP has DEFAPPL, or DEFAULTAPPL was specified and the application lookup return code is either OK or USER\_REQUIRED, then perform LU lookup.
  2. For each Generic LUMAP used for Specific or Generic connection requests: If the Generic LUMAP has DEFAPPL, or DEFAULTAPPL was specified and the application lookup return code is either OK or USER\_REQUIRED, then perform LU lookup.
- Check for LUMAP matches without considering application lookup results.
  1. For each Specific LUMAP used for Specific connection requests: Ignore DEFAPPL and DEFAULTAPPL and perform LU lookup.
  2. For each Generic LUMAP used for Specific and Generic connection requests: Ignore DEFAPPL and DEFAULTAPPL and perform LU lookup.

- If LUMAP statements were not checked (different from checked but no match), use the appropriate Default LU pool considering application lookup results and possible application-based LU mappings. In this case the only relevant application is the DEFAULTAPPL, if specified. If the application lookup return code is either OK or USER\_REQUIRED, then perform LU lookup.
- If LUMAP statements were not checked, try the appropriate Default LU pool without considering application lookup results. Perform LU lookup.

Complete Lookup: An application name is required for Complete Lookup. The application name is obtained from one of three sources in the order specified.

1. Input from the USER or VTAM (via CLSDST with OPTCD=PASS)
2. DEFAPPL parameter on the LUMAP statement
3. DEFAULTAPPL statement

Use the application name and the previously found LU to perform Complete Lookup. Possible lookup results are:

- The application is not valid.
- The application is valid (return code OK or USER\_REQUIRED) for the existing LU.
- The application-based LU map does not match the already chosen LU.

#### *TN3270 LU mapping*

TN3270 connections perform Complete Lookup only after all information is known. LU lookup is not done during connection negotiation. Telnet will either send a solicitor (or USSMSG10) screen to the client or will perform Complete Lookup using the application name known through the LUMAP-DEFAPPL or DEFAULTAPPL statement. If Complete Lookup is successful, Telnet will begin session initiation. If not successful, the solicitor (or USSMSG07) screen is sent to the client without an LU being assigned to the connection or the connection is dropped. The LU is not assigned until the application name is valid. If the application name is a RESTRICTAPPL, the LU is not assigned until a user ID is specified. Application-based LU mappings have a very good chance of success due to the late LU mapping aspect of TN3270 connections. When SIMCLIENTLU is coded, Generic TN3270E connections have this same characteristic.

Complete Lookup: An application name is required for Complete Lookup. The application name is obtained from one of three sources in the order specified.

1. Input from the USER or VTAM (CLSDST with OPTCD=PASS)
2. DEFAPPL parameter on the LUMAP statement
3. DEFAULTAPPL statement

Use the application name to perform Complete Lookup. Possible lookup results are:

- The application is not valid.
- The application is valid but an LU is not found.
- The application is valid (return code OK) and an LU is found.
- The application LU map does not match the Client Identifier LU map.

If the application is not valid, no LU is assigned to the connection and an error message is sent to the client. If the application is valid, continue the LU lookup in the following order.

- Check for LUMAP matches considering application-based LU lookup results. Only Generic LUMAPs are searched. If the application lookup return code is OK, then perform LU lookup.
- If no LUMAP statements were used, check for application-based LU mappings. If the application lookup return code is OK and LUs are defined on the application statement, perform LU lookup.
- If no LUMAP or application-based LU mapping statements were used, use the DEFAULTLUS pool considering application lookup results. If the application lookup return code is OK, then perform LU lookup.

## ***LU mapping with multilevel security active***

Telnet can be in a multilevel secure environment that uses security labels. For more information about preparing for IP networking in a multilevel secure environment, see Chapter 4, “Preparing for IP networking in a multilevel secure environment,” on page 213 and [z/OS Planning for Multilevel Security and the Common Criteria](#). To ensure correct security label comparisons, Network Access Control (NAC) must also be active for Telnet. For more information about NAC, see [“Network Access Control”](#) on page 626.

If multilevel security is active, Telnet ensures the security label of the selected LU is compatible with the security label of the client.

- Telnet retrieves the security label of the client when the connection is accepted.
- Telnet assigns a security label to all LUGROUPs based on the first LU name in the group. The first single LU name in the group is used. If no single LU names exist, the first LU name within the first LU range is used.
  - If multilevel security is active, an LUGROUP EXIT is required to have at least one LU name in the group. The LU name is used to obtain a security label for the group. The name is passed to the exit in the parameter list and can be used or ignored by the exit.
  - A single LU name on a mapping statement is treated as an LUGROUP with one LU name. That LU name is used to obtain the security label for the LUGROUP created by Telnet.

When multilevel security is active, LU lookup uses the following process:

1. The security label of the client is compared with that of the mapped LUGROUP. If the group is compatible, Telnet searches for an available LU in the group. If not compatible, the LUGROUP is skipped.
2. Telnet retrieves the security label of the selected LU and compares it with the security label of the LUGROUP. If the selected LU is not compatible with the LUGROUP, the LU is deactivated and no other LU in the group is tried.
3. If the LUGROUP was not compatible or no LU was available, the steps are repeated for each mapped LUGROUP until an LU is found or all LUGROUPs are checked.

## **Advanced application topics**

In addition to the basic function of facilitating session setup, Telnet supports several advanced functions such as:

- Connection information passed on the CINIT control vector 64 (CV64)
- Session initiation management (LOGAPPL, QINIT, FIRSTONLY, and DEFONLY)
- Check client connection and connection/session takeover
- Queueing sessions
- Disconnect on session error
- Bypass RESTRICTAPPL with CERTAUTH
- Allow printer sessions with RESTRICTAPPL
- Keeping the ACB open
- Express Logon Feature

### ***Connection information passed on the CINIT control vector 64***

During session establishment, a VTAM session initiation record called a CINIT is created and sent to the primary application. Attached to the CINIT is a control vector 64 (CV64) that is created by Telnet to provide additional information about the Telnet connection. The CV64 control vector contains four sub-vectors. The CV64 control vector and the four sub-vectors are all defined as key/length vectors.

- CV64 - Start of control vector

- Key/Length (2 bytes)  
X'64mm', where *mm* is (*ii* + 2) + 4 + (*hh* + 2 (if SBV85 present)) + 19 (if SBV86 present)
- SBV81 - Flags and IP address
  - Key/Length (2 bytes)  
X'81ii', where *ii* is 06 for IPv4, 18 for IPv6
  - IP address type (1 byte)
    - 04 - IPv4
    - 06 - IPv6
  - Flags (1 byte)
    - 80 - Reserved for future use
    - 40 - Reserved for future use
    - 20 - On if secure connection
    - 10 - On if secure connection flag is valid
    - 08 - On if takeover of the connection is possible
    - 04 - On if the TCP/IP stack supports IPv6 addresses and the client has an IPv4 address
    - 02 - On if the Telnet server is the z/OS Communications Server TN3270E Telnet server
    - 01 - On if the client is a TN3270E client and supports definite response
  - IP address (4 bytes if IPv4, 16 bytes if IPv6)
- SBV82 - Port number
  - Key/Length (2 bytes)  
X'8202'
  - Port (2 bytes)
- SBV85 - Host name of the client (SBV85 is not always present)
  - Key/Length (2 bytes)  
X'85hh', where *hh* is 1 + DNS name length
  - Flags (1 byte)
    - 80 - On if DNS name is truncated to 128 bytes
  - DNS name (Maximum 128 bytes)
- SBV86 - Zone ID if specified for a client IPv6 address (SBV86 is not always present)
  - Key/Length (2 bytes)  
X'8611'
  - Flags (1 byte)
    - 80 - On if zone is truncated
  - Zone ID (16 bytes)

### ***Session initiation management (LOGAPPL, QINIT, FIRSTONLY, and DEFONLY)***

The LOGAPPL, QINIT, FIRSTONLY, and DEFONLY options can be coded on DEFAULTAPPL, PRTDEFAULTAPPL, LINEMODEAPPL, LUMAP-DEFAPPL, or PRTMAP-DEFAPPL. For the remainder of this topic, DEFAULTAPPL represents all the default application statements.

- LOGAPPL, QINIT

The LOGAPPL or QINIT functions keep the Telnet LU active if a Request Session fails due to the host VTAM application not being active. In addition, VTAM remembers the attempted Request Session and will initiate a session request to the Telnet LU on behalf of the application when the application becomes active. When the Request Session fails, Telnet sends the client a solicitor screen or USSMSG07

screen. The user then has the option of logging on to a different host VTAM application (if DEFONLY is not coded). When this different session is started, VTAM drops the queued Request Session for the original session.

What happens at session logoff depends on whether or not LUSESSIONPEND and FIRSTONLY are coded and whether LOGAPPL or QINIT is coded. If LUSESSIONPEND is coded, the connection remains; otherwise, it is dropped. If FIRSTONLY is coded, Telnet sends a USSMSG10 screen or solicitor screen to the client. If FIRSTONLY is not coded, Telnet will initiate another session with the default application defined by the DEFAULTAPPL statement. LOGAPPL and QINIT have different results when logging off the original application. When LOGAPPL is specified, a USSMSG10 or solicitor screen is sent to the client. When QINIT is specified, Telnet requests a session with the default application.

- **FIRSTONLY, DEFONLY**

Sometimes a default application is used for the initial connection, but after LOGOFF a USSMSG10 or solicitor screen is more appropriate than redriving the default. In this case, code the FIRSTONLY parameter. This indicates the default should be used on the first session only. After a session has been established, any subsequent lookups ignore the default and send the USSMSG10 screen or solicitor screen.

If MSG07, LUMAP-DEFAPPL, or PRTMAP-DEFAPPL is coded and the default application is inactive, an error screen will be sent to the client. The DEFONLY parameter will block a user-entered application choice if it is different than the default. This parameter prevents application choice while giving the user error information.

The following table summarizes several possible session initiation failure scenarios.

- ReqSess OK - A Request Session to the default application succeeded or a Request Session to a second application from the USSMSG07 screen succeeded.
- ReqSess Fail - A Request Session to the default application failed.
- 2nd Appl Fail - A Request Session to a second application from the USSMSG07 screen failed.

| Mapping Statement \ Scenario                       | ReqSess OK | ReqSess Fail |          | 2nd Appl Fail |          |
|----------------------------------------------------|------------|--------------|----------|---------------|----------|
|                                                    |            | MSG07        | No MSG07 | MSG07         | No MSG07 |
| DEFAULTAPPL name                                   | 1          | 2            | 5        | 2             | N/A      |
| DEFAULTAPPL name LOGAPPL<br>DEFAULTAPPL name QINIT | 1          | 3            | 3        | 4             | 4        |

*Figure 96. Session initiation failure scenarios*

FIRSTONLY is not a consideration because the first session has not been established.

1. In session.
2. Send USSMSG07 or solicitor screen to client. Close the ACB.
3. Send USSMSG07 or solicitor screen to client. Keep ACB open, queue original session request in VTAM.
4. Send USSMSG07 or solicitor screen to client. Keep ACB open, keep the original queued session request in VTAM.
5. Drop connection.

The following table summarizes several possible session ending scenarios. The session is ending due to normal LOGOFF or session breakage (possibly caused by loss of the application).

- Original Application - User is in session with the original default application.
- CLSDST from Original Appl - User is in session with a second (or later) application after issuing a CLSDST-PASS from the original application.

| Scenario<br>Mapping Statement                                          | Original Application |       | 2nd Appl or CLSDST from Orig |       |
|------------------------------------------------------------------------|----------------------|-------|------------------------------|-------|
|                                                                        | Logoff               | Break | Logoff                       | Break |
| DEFAULTAPPL name<br>DEFAULTAPPL name QINIT                             | 1                    | 1     | 1                            | 1     |
| DEFAULTAPPL name LOGAPPL                                               | 2                    | 1     | 1                            | 1     |
| DEFAULTAPPL name FIRSTONLY LOGAPPL<br>DEFAULTAPPL name FIRSTONLY QINIT | 2                    | 1     | 2                            | 1     |

Figure 97. Session ending scenarios

In all cases, if LUSESSIONPEND is not coded the connection is dropped.

1. Request a session with the default application.
2. Send USSMSG10 or solicitor screen to client. Close the ACB.

### **Check client connection and connection/session takeover**

A Telnet client can detect the loss of connectivity to Telnet without Telnet being aware of the loss. This condition is typically caused by a temporary problem in the network, such as a router experiencing a failure. In many cases, the network can correct itself and client retransmission can recover the data flow. However, the user often terminates the Telnet TCP connection at the emulator without waiting for the network to recover. In other cases, such as when a single router supports the client, the Telnet TCP connection is eventually terminated by the client TCP/IP stack after a certain number of retransmissions fail. When network connectivity is restored, the user initiates a new connection to Telnet. Even though the user is reconnected, in many cases the original SNA session cannot be associated with the new TCP connection because the session continues to be associated with the original TCP connection.

Assume that the host application is TSO and the user is in session with TSO user ID USER1. The route is lost and the user disconnects. The user then establishes a new Telnet connection without specifying an LU name. Telnet assigns a different LU to represent the client. When the logon to user ID USER1 is attempted, TSO fails the logon attempt because USER1 is still in session with the original Telnet LU. If the user does specify the same LU name when reconnecting, the connection is rejected sooner. Telnet fails the request during Early Lookup, indicating that the LU is already in use. The problem with both situations is that Telnet assumes that the original connection is still active and that the SNA session is still associated with that original connection.

The user can not terminate the original TCP connection and SNA session. The user has two choices:

- Wait for an inactivity timer in Telnet to clean up the original SNA session and close the original TCP connection
- Wait for an inactivity timer in TSO to initiate session termination

In the second case, either Telnet is configured to close the connection at session termination (NOLUSESSIONPEND), or when Telnet attempts to refresh the TCP connection, Telnet detects that the TCP connection is gone and closes its representation of the connection. The end result in all cases is that the original SNA session and the original TCP connection are cleaned up after the specified inactive period of time has elapsed.

The user would like to quickly close the original connection to free the LU and the SNA session. If you specify the CheckClientConn parameter, Telnet checks the connectivity of all pre-existing connections associated with the client identifier of the new connection being established. The check is performed by sending a Timemark to each existing connection. The new connection is delayed early in the connection negotiation until all existing connections have responded or the specified wait time has elapsed. When all connections have responded, setup of the new connection continues. If some connections do not respond, then after the specified time elapses, Telnet closes any connections that did not receive a response. As soon as all of the unresponsive connections are closed, setup of the new connection

continues. The new connection is held until cleanup is performed to ensure that an LU is available and that the previous SNA session is cleaned up before the new connection continues negotiation. The CheckClientConn parameter is useful when multiple emulators exist on a single client and the user can tolerate the session being disconnected.

**Rule:** If you are using sysplex distributor to distribute connections across Telnet servers with CheckClientConn, you must use timed client affinity to ensure that the clients reconnect to the same Telnet server.

**Tip:** Be careful using the CheckClientConn parameter where proxy servers are being used and the Client Identifier is IP address rather than Host name or User ID. Telnet perceives all connections coming from the same IP address as coming from the same client. Depending on the number of connections, Telnet could send a large number of Timemarks every time a new emulator connects. A second parameter is available to limit the number of connections checked for a single client identifier.

Some users require that the same LU be assigned when the new connection takes over the old connection. The takeover function fixes this problem. When takeover is active for a connection, Telnet LU lookup attempts LU takeover upon entry to the lookup function, whenever a single LU name can be associated with a connection. Any number of existing Specific requests from one client identifier can be associated with new Specific requests. A single existing Generic request from one client identifier can be associated with a new Generic request. If there are multiple existing Generic requests, only the first is taken over and the remaining connections continue to hang.

The TKOSPECLU and TKOSPECLURECON statements activate takeover for the connection and require that the user specify the LU name. The statement name is derived from the function of connection takeover (TKO) for a Specific LU (SPECLU) connection request. Because the LU name is specified, LU lookup attempts to take over the original connection to which the LU was assigned. The Specific LU request allows a user to move to any client to take over a connection that is lost and provides some level of security because it requires the user to know the LU name.

The TKOGENLU and TKOGENLURECON statements activate takeover for a connection without the user specifying an LU name. The statement name is derived from the function of connection takeover (TKO) for a Generic LU (GENLU) connection request. During the original connection LU lookup, Telnet saves the LU name by Client Identifier. If another connection request is received from the same Client Identifier, Telnet assumes takeover should be attempted using the original LU name. If multiple connections are made from a single client, all additional connection setups will be delayed by the time it takes to attempt takeover of the first connection. When the takeover attempt fails, Telnet resumes normal Generic LU lookup for that connection. For Generic LU takeover to work, the Client Identifier must remain the same. The Client Identifier can be the client user ID derived from the client security certificate. If no user ID is available, the client hostname is used. If no hostname is available, the client IP address is used.

**Rule:** If you are using sysplex distributor to distribute connections across Telnet servers with TKOGENLU or TKOGENLURECON, you must use timed client affinity to ensure that the clients reconnect to the same Telnet server.

The TKOSPECLU and TKOGENLU statements cause the following events to occur. When the takeover connection request arrives, Telnet LU lookup discovers the LU name is in use and suspends the new request. Telnet sends a TIMEMARK request to the original client, which acts as an "are you there" message. The client is required to respond to the TIMEMARK. If no response is received by Telnet within the time specified on the takeover statement, Telnet drops the original session and connection. The original LU is reserved during the drop process. After the original session and connection are dropped, Telnet resumes processing the new request. This time the LU is not in use, only reserved for takeover purposes, and is assigned to the new takeover session. The user is essentially starting over. The original session has been dropped, allowing the user to immediately log on to the same TSO user ID again.

When sysplex distributor is used to distribute connections across Telnet servers with the TKOSPECLU or TKOSPECLURECON statements, the series of events can be extended to include the LUNS and possibly the previous owning LUNR. When the takeover connection request arrives at a LUNR and Telnet LU lookup discovers that the LU name is shared and is not already allocated to itself, the new request is suspended, and verification and allocation is requested from the LUNS. If the LUNS determines that the LU name has been allocated to another LUNR, the LUNS sends a verification request to the other LUNR. That LUNR sends a TIMEMARK to its original client. If the client responds, the owning LUNR informs the LUNS that

the LU name is still in use. If the client does not respond, the owning LUNR drops the original connection and tells the LUNS to deallocate the LU name. If the LUNS determines that the LU name is not in use, the name is allocated to the requesting LUNR. Depending on the response from the LUNS, the new LUNR then either accepts or rejects the takeover request.

The TKOSPECLURECON or TKOGENLURECON statements can be used to accomplish the same connection drop but avoid the session drop. When the original connection is dropped, the Telnet LU stays in session with the host application. The new connection is established and Telnet sends an LUSTAT to the host application indicating that Presentation Space Integrity was lost (X'082B'). Depending on the application, it will either end the session or resend the previous screen. By resending the previous screen, the user is able save the original session and avoid the SNA session tear-down and restart process. At worst, if the application drops the session upon receipt of the LUSTAT, the user is able to immediately log on again as if TKOSPECLU or TKOGENLU were coded.

In some cases, the original client TCP/IP stack may respond to the Timemark with a RESET. Telnet interprets this RESET as a client disconnect and assumes the user disconnected the session. Telnet then drops the session. To keep the session in this case, add the KeepOnTmReset option to the TKOSPECLURECON or TKOGENLURECON statement. A security risk exists when using this parameter. A user may actually disconnect just before the Timemark arrives due to an unauthorized takeover attempt. Telnet will interpret the disconnect as a response to the Timemark and allow the takeover without loss of the VTAM session.

Part of session initiation includes Telnet issuing a SETLOGON VTAM macro that contains control vectors, including control vector 64 described in [“Connection information passed on the CINIT control vector 64”](#) on page 657.

The control vectors include client information, such as IP address and host name if available. If the connection is capable of being taken over, a flag is set in the control vector. This information is passed to the application's logon exit for use by the application. If the connection is taken over, a second SETLOGON macro is issued. However, the control vector information does not go beyond the VTAM that processed the SETLOGON. The application's logon exit does not run again and is not aware of connection changes.

Some applications require the IP address to remain constant. Because the application cannot be notified of changes, Telnet has the ability to allow takeover by only clients from the same IP address. Specify SAMEIPADDR on the TKOGENLURECON or TKOSPECLURECON statements to ensure takeover is done by a client from the same IP address.

TKOSPECLU, TKOSPECLURECON, TKOGENLU, and TKOGENLURECON can be coded at all three parameter block levels for different levels of granularity. Code NOTKO to turn off all takeover function at any of the three levels.

The new connection must have an equal or higher security level to take over the original connection. The order for connection security is:

1. Basic
2. Secure
3. Secure with ClientAuthType Required
4. Secure with ClientAuthType SAFCHECK

If the original connection used SSL with ClientAuthType SAFCHECK, either takeover method will verify that the new connection is using a client certificate that maps to the same user ID. Telnet verifies this by translating the new certificate to a user ID and comparing the new user ID to the user ID on the original connection.

**Tip:** If you are using TKOSPECLURECON or TKOGENLURECON, you can specify SAMECONNTYPE to force the same connection type between the taker and the target connections. CV64 information is not updated when a session takeover occurs, and if a secure connection takes over a basic connection, the application is not updated with the new connection level because no new CV64 is sent to the application. You can also consider using takeover without reconnect (TKOSPECLU or TKOGENLU).

**Guideline:** If you map multiple certificates to the same user ID, a client presenting any of those certificates will be able to take over the connection. If there is a chance the connection can be taken

over by an unauthorized user, TKOSPECLURECON and TKOGENLURECON should not be used. Neither statement requires the user to reverify user authenticity to the host application.

**Tip:** A time value of zero is permitted. In this case the server will always perform the takeover whether or not the original connection is still active. The zero value is intended for testing purposes rather than production use.

Sometimes a takeover attempt will not complete as expected. This might be due to one of the following factors:

- The profile of the original connection defines how the original connection can be taken over. Be sure that the original connection supports the wanted takeover method.
- The new connection is not of the same connection type as the original session, and SAMECONNTYPE was specified on the TKOSPECLURECON or TKOGENLURECON statement.
- The new connection request must specify the LU name of the connection being taken over if TKOSPECLU or TKOSPECLURECON is specified.
- TKOSPECLURECON and TKOGENLURECON do not preserve a session if the takeover is done from a different port. The ACB of the LU is associated with the original port and must be closed before it can be associated with the new port. The takeover will function as a TKOSPECLU and TKOGENLU takeover.
- TKOSPECLURECON and TKOGENLURECON do not preserve a session if the takeover is done for a shared Telnet LU name managed by a LUNS.
- TKOSPECLURECON and TKOGENLURECON might not preserve a session if the original client connection is ended before the TKOSPECLURECON or TKOGENLURECON timer expires. If the close reason is TIMEMARK or INACTIVE, the session will be preserved under the assumption that the inactivity is due to a lost connection. Any other close reason will cause the takeover to function as a TKOSPECLU or TKOGENLU takeover. This is done to protect users who disconnect their client as a means of logging off their session. These sessions will not be taken over. Instead, the user will have to issue a new logon.

Takeover is also affected by where the new client is and how the old client responds. There are several event scenarios and results will vary.

- Event 1

New client connects from a different IP address or Port.

Original client responds to TIMEMARK.

Result - Takeover will not occur in this case because the original client is still responding. With a Specific LU request, the new client will receive an error indicating the LU is already in use. With a Generic LU request, Telnet assigns the next available LU to the connection.

- Event 2

New client connects from a different IP address or Port.

Original client does not respond to TIMEMARK.

Result - Connection takeover will occur. If TKOSPECLURECON or TKOGENLURECON is mapped to the client, session takeover will occur. A likely scenario in this case is Telnet has lost connectivity to the old connection due to a failed router and the new connection is using a different route, the original machine lost power and has not reestablished connectivity, or the original machine lost power but reestablished connectivity with a different IP address.

- Event 3

New client connects from a different IP address or Port.

Original client stack responds with RESET.

Result - Connection takeover will occur. However, even if TKOSPECLURECON or TKOGENLURECON is coded, session takeover will not occur because Telnet handles the RESET as a client disconnect. A likely scenario in this case is a PC lost power and then regained power. The takeover request is accepted from either a different PC or the same PC using a different port. After the new connection request is accepted, Telnet sends a TIMEMARK to the original client PC stack. The PC stack does not recognize the

IP-port and responds with a RESET. If KeepOnTmReset is specified and the RESET is received by Telnet after the Timemark has been sent, Telnet will keep the session.

- Event 4

New client connects from the same IP address and Port.

Telnet stack rejects the request.

Original client times out and sends a RESET.

Result - The original session and connection are dropped. Takeover does not occur. The new client is able to connect on retry because the original connection and session were cleaned up. A likely scenario in this case is a PC has lost power and then regained power. The same PC is used to attempt takeover. The client is assigned the same port as before the power loss and has the same IP address.

## ***Queueing sessions***

Logon manager applications are very popular. Typically they are set up as a default application which sends a selection screen to the user. After the user specifies the destination application choice, the logon manager typically issues a CLSDST macro with OPTCD=PASS to the destination application. A new session is started with the destination application. The logon manager session is closed with a special UNBIND sent to Telnet indicating that a new session BIND is forthcoming. Telnet receives that special UNBIND and then waits for the next BIND instead of cleaning up as it would when receiving a normal UNBIND. When the user logs off the destination application, Telnet either goes through the initial database lookup process again (which will result in a session with the logon manager) or drops the connection, depending on whether LUSESSIONPEND is coded. Logoff of the original application will cause Telnet to perform normal close function instead of leaving the LU ACB open.

Many logon managers were written to support real terminals, not Telnet, and issue a SIMLOGON OPTCD=Q immediately after issuing the CLSDST-PASS. When SIMLOGON Q is coded, the logon request is added to a VTAM queue. The first application queued is the first application off the VTAM queue. Immediately after user logoff from the destination application, VTAM (on behalf of the logon manager) will request a session with the terminal LU (or Telnet LU representing the client). This works very well for real terminals, but causes timing problems for Telnet when the logon manager is a default application. In this case, Telnet and VTAM both end up requesting a session.

The QSESSION option on ALLOWAPPL or RESTRICTAPPL can be used to correct this timing problem. When coded for the logon manager, Telnet will not do normal close processing when the UNBIND from the destination application arrives. Telnet will leave the LU ACB open and wait for the BIND from the logon manager that is generated because of the Queued SIMLOGON. When the BIND does arrive, Telnet will verify that the application name is the original logon manager and finish session setup.

If QSESSION is specified for an application that does not queue a SIMLOGON, or the SIMLOGON is removed from the queue because the original application was recycled, Telnet will be waiting for a BIND that is never coming. The connection will appear to be hung. To safeguard against this hang condition, a timer can be started when the destination application UNBIND is received. Telnet will wait for the specified period of time for a BIND from the QSESSION application. If the timer expires and there is no session, Telnet will clean up the connection as if the QSESSION parameter had not been specified.

As an example of the QSESSION parameter, assume that APPL1, APPL2, and APPL3 are each defined in VTAM. APPL1 will issue a SIMLOGON-Q after CLSDST-PASS. The following Telnet statements allow connections to access the applications and define which is a QSESSION application.

```
ALLOWAPPL APPL1 QSESSION,3
ALLOWAPPL APPL*
```

The client first logs on to APPL1. APPL1 issues a CLSDST-PASS to APPL2 and a SIMLOGON-Q. Finally, APPL2 issues a CLSDST-PASS to APPL3. When the APPL3 session is ended, VTAM sends an APPL1 BIND to Telnet. If the queued SIMLOGON had been removed, Telnet would have continued cleanup 3 seconds after receiving the UNBIND from APPL3. When the APPL1 session is ended, the ACB is closed and Telnet either goes through the initial database lookup again or closes the connection, depending on whether LUSESSIONPEND is coded.

As a second example, assume that APPL2 also issues a SIMLOGON-Q after it issues a CLSDST-PASS to APPL3. As in the previous example, when the APPL3 session is ended, VTAM sends an APPL1 BIND to Telnet. If the queued SIMLOGON had been removed, Telnet would have continued cleanup 3 seconds after receiving the UNBIND from APPL3. When the APPL1 session is ended, VTAM sends an APPL2 BIND to Telnet. The APPL2 SIMLOGON-Q was queued behind the APPL1 SIMLOGON-Q in VTAM.

### ***Disconnect on session error***

The DISCONNECTABLE option on either the ALLOWAPPL or RESTRICTAPPL statement determines what type of session termination to send to the host VTAM application when Telnet initiates session termination. If DISCONNECTABLE is coded, Telnet issues a TERMSESS UNBIND(OF). Otherwise, Telnet issues a TERMSESS UNCOND. For example, when DISCONNECTABLE is coded for the TSO application, an unexpected connection loss results in an UNBIND(OF) being sent to TSO putting it in a reconnectable state. The DISCONNECTABLE parameter has no effect on a session ended normally by the user logging off the session. The QSESSION parameter can be coded with DISCONNECTABLE on either statement.

### ***Bypass RESTRICTAPPL with CERTAUTH***

CERTAUTH is an option on RESTRICTAPPL used in conjunction with client authenticated secure connections or Express Logon. In both cases the client certificate is used to derive a user ID. If the user chooses an application that is a RESTRICTAPPL, the normal Telnet response is to request a valid user ID and password before allowing access to the application. However, if the user has been authenticated with a client certificate it may not be necessary to require a user ID and password. With the CERTAUTH option on RESTRICTAPPL Telnet will use the derived user ID. If the user ID is valid (listed on the RESTRICTAPPL statement), Telnet will bypass the user solicitation and immediately give access to the application. The derived user ID value depends on the type of connection. If Express Logon is being used, the user ID is derived from the latest Client Certificate/Aplid combination received from the client. If Express Logon is not being used, the user ID is the Client Identifier user ID derived from the Client Certificate from the SSL handshake.

### ***Allow printer sessions with RESTRICTAPPL***

The ALLOWPRINTER option enables printers to establish a session with an application defined as a RESTRICTAPPL. Telnet verifies all session requests before finishing session setup, and if the application name is restricted by the RESTRICTAPPL statement, Telnet requires the user to enter a user ID and password before session initiation begins. The user of a printer emulator has no way to provide a user ID and password, and you might want to allow printer sessions without the user ID and password verification, mimicking the behavior of the ALLOWAPPL statement. The ALLOWPRINTER option on RESTRICTAPPL gives you the flexibility to keep the terminal LU sessions restricted while allowing all printer LU sessions access to the application, without user ID and password. In most cases, printer sessions originate from the application and not the user, keeping security control in the application. However, use this option with care if you have coded PRTDEFAULTAPPL or PRTMAP-DEFAPPL. In this case, it is possible for users to originate a printer session.

### ***Keeping the ACB open***

Some host VTAM applications are set up to inquire whether a secondary LU is active. If the LU is active, the application initiates a session. The LUMAP option, KEEPOPEN, causes the LU to be activated when the LU is assigned to the connection, and to remain active for as long as the LU is assigned to the client by this mapping statement.

LU assignment is different for TN3270E and TN3270 connections. TN3270E connections have an LU assigned during connection negotiation. TN3270 connections do not have an LU assigned until the VTAM application name is known.

When the host VTAM application initiates a session with the secondary LU, the host must issue an INQUIRE to see if the LU is active with an OPEN ACB. This INQUIRE will fail for Telnet LUs because Telnet does not open the ACB until a session request is sent from Telnet to VTAM. When the user gets the solicitor (or USSMSG10) screen, Telnet has not opened the ACB of the LU assigned to a TN3270E connection. TN3270 and LineMode connections do not have LUs assigned yet. If the KEEPOPEN

parameter is coded on the LUMAP statement used by Telnet to assign an LU during Early Lookup for a terminal TN3270E connection, Telnet opens the ACB before sending the solicitor (or USSMSG10) screen. At that time a user can either log on to an application as usual or wait for a host application to INQUIRE about the LU and initiate a session. TN3270 connections will not have an LU assigned until an application name is known. When the name is known, an LU is assigned to the connection, the ACB of the LU is opened, and a session request is issued. If the KEEPOPEN parameter is coded on the LUMAP statement used by Telnet to assign the LU, the LU stays assigned to the connection with the ACB open until the connection is dropped. If profile statements define LUs uniquely to different applications, a second logon to a different application might fail. When KEEPOPEN is mapped to a connection, the MSG07 and LUSESSIONPEND functions are in effect whether or not they were explicitly coded. When a session is ended, the connection remains and the ACB remains open. Only a client disconnect, a Telnet error, or the KEEPINACTIVE/INACTIVE timers will cause a KEEPOPEN connection to be dropped. The KEEPINACTIVE timer is used whenever the Telnet LU is not in session with a VTAM application. Otherwise, the INACTIVE timer is used. See [“Connection persistence” on page 627](#) for information about ending idle KEEPOPEN connections.

### **Express Logon Feature**

The Express Logon Feature (ELF) allows a user to connect to an MVS host VTAM application without explicitly entering a user ID or password. Telnet uses the client certificate to resolve the user ID and RACF generates a Multi-Factor Authentication (MFA) token or a temporary password called a PassTicket. ELF requires a secure connection with level 2 client authentication, a client that supports ELF, and RACF MFA or PassTicket setup.

The ELF function is activated by specifying the EXPRESSLOGONMFA parameter (to use MFA) or the EXPRESSLOGON parameter (to use PassTickets). The function can be deactivated by specifying NOEXPRESSLOGONMFA or NOEXPRESSLOGON. Any of these parameters can be coded in TELNETGLOBALS, TELNETPARMS, or PARMSGROUP. For a detailed discussion of ELF, see [Appendix C, “Express Logon Feature,” on page 1365](#).

### **Device types and logmode considerations**

The VTAM logmode defines many characteristics of the session established between the Telnet LU representing the client and the host VTAM application. For example, the logmode defines response types, presentation style, and the type of LU Telnet is emulating. LU0 (non-SNA) and LU2 (SNA) represent terminal LU types. LU1 (SCS) and LU3 (3270 Data) represent printer LU types.

Telnet matches a VTAM logmode to each client as it connects based on the client device type, unless the user specifies a logmode on the USSMSG10 screen or logmode is configured in the USS table mapped to the connection. See [z/OS Communications Server: IP Configuration Reference](#) for default device type and logmode table information. The default terminal logmodes are non-SNA for TN3270 connections and SNA for TN3270E connections. At session request time, Telnet indicates to VTAM the appropriate logmode based on device type. The host VTAM application usually honors the request and binds the session using the requested logmode. However, depending on VTAM statements, the application can override the requested logmode and bind the session using different characteristics than Telnet requested. For this reason, some screen sizes might not work correctly even though the logmode defined in Telnet is correct. If the KEEPOPEN function is used to allow session initiation by the host application, the wanted logmode must be coded on the DLOGMOD parameter as part of the VTAM application definition statement that defines the Telnet LU. Otherwise, the application will choose its own logmode.

Telnet processes the ATTN KEY request differently for non-SNA and SNA sessions. For non-SNA sessions (BIND FM value 02), Telnet converts the ATTN KEY request to a '6C'x data byte and sends it to the application. For SNA sessions (BIND FM value 03), Telnet converts the ATTN KEY request into a SNA signal and sends it to the application as expedited data. Some clients send both an ATTN KEY function code and a '6C'x data byte to ensure the ATTN is seen by the application. Telnet converts the ATTN KEY function into either a '6C'x data byte or a SNA signal and also forwards the '6C'x data. Some applications give unexpected results or Telnet might appear to not support ATTN when two ATTNs are received. The SINGLEATTN parameter causes Telnet to drop the second ATTN if it immediately follows an ATTN. The SINGLEATTN and NOSINGLEATTN parameters can be coded at all three parameter block levels for different levels of granularity.

To change either the TN3270 or the TN3270E logmode for a device type, use the TELNETDEVICE parameter. Whenever Telnet initiates the session request, Telnet will request that the logmode specified on the TELNETDEVICE statement be used for the session. The application (the primary LU) does have the ability to override the requested logmode and use a completely different logmode. The TELNETDEVICE parameter can be coded in all three parameter block levels for different levels of granularity. Coding TELNETDEVICE in a PARMSGROUP that is mapped on the LUMAP-DEFAPPL-PMAP statement enables the logmode to be LU and application specific.

If the application initiates the session, the TELNETDEVICE logmode has no affect on the session. For example, printer sessions are initiated by the application unless a printer default application is specified. The LUMAP-KEEPOPEN parameter can be used to open a terminal ACB and wait for the primary application to initiate the session.

Transform Linemode connections can have a unique logmode by coding TELNETDEVICE with a device type of TRANSFORM. Any logmode used must not support extended graphics.

The special case logmode NONE can be specified indicating that Telnet should not send any logmode request when initiating the session.

In the examples that follow, the first line causes only the TN3270 logmode to change from the default to SNX32705. The second line causes both the TN3270 and TN3270E logmodes to change from their defaults to SNX32705 and SNX32702. The third line causes only the TN3270E logmode to change from the default to SNX32702.

```
TELNETDEVICE 3278-5-E SNX32705
TELNETDEVICE 3278-5-E SNX32705,SNX32702
TELNETDEVICE 3278-5-E ,SNX32702
```

## Using the Telnet solicitor or USS logon screen

This topic describes the Telnet solicitor screen and Telnet Unformatted System Services (USS) support. You can use the Telnet solicitor screen to obtain all information that is needed to establish a session. However, Telnet is often the primary method of connecting to the SNA mainframe environment; SNA users are accustomed to entering abbreviated logon commands, specifying their own logmode, and entering user data from SNA terminals. The USS table itself can be used to customize information such as logmode before it is sent to VTAM. The logmode specified by the user or the USS table overrides the logmode specified by the TELNETDEVICE statement. For ease of migration, Telnet simulates SNA USS processing very closely. This simulation extends to being able to use the same assembled USS tables that are used by VTAM. VTAM-only character substitutions are ignored by Telnet and Telnet-only character substitutions are ignored by VTAM. Blanks are used in their place. To further extend the simulation of SNA terminals, Telnet also supports all of the INTERPRET table function.

### Using the Telnet solicitor logon screen

Telnet sends a solicitor screen to the user if one of the following conditions is true:

- No DEFAULTAPPL, LINEMODEAPPL, USSTCP, or LUMAP-DEFAPPL mappings match the client's Client Identifier.
- The requested application is a RESTRICTAPPL.

The following example shows the Telnet solicitor screen:

```
Enter Your Userid:
Password: New Password:
Application:
```

Initial cursor placement can be specified. Where initial placement should be depends on client macros used and user preferences. The OLDSOLICITOR parameter is used to implement this choice. The default cursor position is on the 'Application:' field. If OLDSOLICITOR is coded, the cursor is positioned on the 'Enter Your Userid:' field. The OLDSOLICITOR and NOOLDSOLICITOR parameters can be coded at all three parameter block levels for different levels of granularity.

Use the PASSWORDPHRASE parameter to configure Telnet so that the solicitor screen can accept either a password or password phrase. The screen layout changes to accommodate the potentially larger password phrase length. The following example shows the Telnet solicitor screen when the PASSWORDPHRASE parameter is specified:

```
Enter Your Userid:
Password:

New Password:

Application:
```

In addition to satisfying RESTRICTAPPL, there are other times when a user might want to use the user ID and password fields. For example, the solicitor screen might also be used to change a password by entering the user ID, old password, and new password. The application field does not need to be filled in. If insufficient information was provided by the client (for example, a user ID but no password), the Telnet solicitor screen is returned with a message prompting for the required field. A message is also returned if the security program encounters an error when attempting to change the password. Example messages include:

- Password required
- Password is not authorized

### ***Using the Telnet USS and INTERPRET support***

The Telnet USS function provides the user with a USSMSG10 logon screen similar to the logon screen used by native SNA terminals. The Telnet USS function supports sending USSMSGs to the client, receiving and parsing USSCMDs from the client, and using a translation table defined in the USS table.

Telnet supports both 3270-format and SNA character stream (SCS)-format USS tables. The SCS USS table name is optional on the USSTCP mapping statement. If an SCS name is provided, the SCS USS table is used for all TN3270E connections.

The CLEAR key is handled differently by the client depending on whether a 3270-format or SCS-format USS table is used. The CLEAR key has a special function for 3270-format USSMSGs. Pressing the CLEAR key sends the CLEAR key data stream to Telnet. If REFRESHMSG10 is specified or used by default, pressing the CLEAR key refreshes the screen with USSMSG10 for any USSMSG other than USSMSG10. If you press the CLEAR key while at USSMSG10, the screen is cleared and the cursor is placed near the upper left corner (row 1, column 2). If you press the CLEAR key a second time, the screen refreshes with USSMSG10. If NOREFRESHMSG10 is specified, pressing the CLEAR key always clears the screen of any USSMSG and places the cursor in the upper left corner (row 1, column 1). For SCS-format USSMSGs, the CLEAR key does not provide the same special function. For SCS, the client processes the CLEAR key by clearing the screen and placing the cursor at the upper left corner (row 1, column 1) with no data sent to Telnet.

USS data traffic is also handled differently depending on whether a 3270-format or SCS-format USS table is used. If a 3270-format USS table is used with a TN3270E connection that has negotiated BIND-IMAGE, a Telnet-generated Bind/Unbind encapsulates the USS traffic. If the connection is TN3270, BIND-IMAGE is not negotiated, or the SCS-format USS table is used, Telnet does not encapsulate the USS traffic in a Bind/Unbind. If a 3270-format USS table is used, the Telnet data type for all traffic is 3270-DATA. If an SCS-format USS table is used, the Telnet data type for all traffic is SSCP-LU-DATA. Regardless of USS table format, if the SYSREQ function is supported on a TN3270E connection and SYSREQ is received by Telnet, Telnet will accept a LOGOFF command in SSCP-LU-DATA format. If the client sends any command other than LOGOFF, COMMAND UNRECOGNIZED is returned in SSCP-LU-DATA format. If the client sends a second SYSREQ, Telnet reverts back to whatever the session state was prior to receiving the first SYSREQ.

USSCMD parsing also includes checking for INTERPRET table entries that might provide more function than USS tables alone can provide. Sample USS tables are in TCP/IP data sets SEZAINST(EZBTPUST) and SEZAINST(EZBTPSCS). A sample INTERPRET table is in TCP/IP data set SEZAINST(EZBTPINT). The 3270 format USS sample has been assembled, linked, and loaded into the product data set. The tables can be used by coding the USSTCP and INTERPTCP mapping statements in BEGINVTAM. For example, the

statements below will map the sample tables to the client at IP address 1.1.1.1. See [“Mapping Objects to Client Identifiers”](#) on page 629 for mapping details.

|           |                   |         |
|-----------|-------------------|---------|
| USSTCP    | EZBTPUST,EZBTPSCS | 1.1.1.1 |
| INTERPTCP | EZBTPINT          | 1.1.1.1 |

A new table can be created at any time and link-edited. Customized USS and INTERPRET tables can be created to change messages, commands, and translation tables. For example, messages can be changed to have non-English text or to have different syntax. Commands can be changed to accept different syntax or to have different default values. A VARY TCPIP,*tnproc*,OBEYFILE command will cause Telnet to load the new table with the new profile being processed. Any new connection using the new profile will be assigned the new table. Telnet also supports dynamic updating of same-name USS or INTERPRET tables. The VARY TCPIP,*tnproc*,OBEYFILE command adds the new version of the table to the new profile. New connections use the new copy associated with the new profile while old connections continue to use the old copy associated with the old profile.

### *USS table customization*

Customized USS tables are used by both VTAM and Telnet, with any product-specific character substitutions converted to blanks. For example, @@SSCPNM is blank for Telnet and @@PRT is blank for VTAM. Telnet USS processing also supports system symbolic substitution. VTAM does no substitution for system symbolics. The tables must be in a data set that is in the system's linklist or is in the STEPLIB statement of the TCP/IP startup procedure. Any changes to a Telnet USS table should be made with supplementary user-defined USS tables. The IBM-supplied USS table should not be changed as it provides a good example of coding most commands and messages. Telnet loads the first table that is found with the name EZBTPUST and defines it as the default USS table. If this table is not found, there is no default USS table. Whether to include a default USS table depends on the wanted message output. When writing a USS Message, Telnet searches the USS table that is mapped to the client first. If the message does not exist in the mapped table, Telnet searches the default table. If the message does not exist in the default table, Telnet writes USSMSG14. If no default table exists, Telnet generates a USSMSG14. For 3270 format USSMSGs, the user can get back to the USSMSG10 from any message by pressing the CLEAR key. The default table does not affect the USS commands. The command entered must be in the mapped table or it is not recognized. The sample SCS USS table found in SEZAINST(EZBTPSCS) is not assembled and linked, and it is not loaded into Telnet as a default SCS USS table. The table must be assembled, linked, loaded, and mapped in the Telnet profile to be used.

### *Creating a USS table*

The following macro instructions are used to create the USS table. Telnet USS function supports almost all VTAM session-level USS message and command definitions. See [z/OS Communications Server: IP Configuration Reference](#) for macro details.

- USSTAB indicates the beginning of the USS table.
- USSCMD defines commands accepted by Telnet.
- USSPARM defines each operand or positional parameter that can be specified on the USSCMD macro instruction. It also defines default values for the operand or positional parameter. Multiple USSPARM macro instructions can be associated with a USSCMD macro instruction. For each operand or positional parameter code a USSPARM macro instruction.
- USSMSG defines messages sent from Telnet.
- USSEND indicates the end of the USS table.

The following rules are some of the more common rules to consider when you are coding a new USS table. Also, see the samples in SEZAINST(EZBTPUST) and SEZAINST(EZBTPSCS) as a guide. [“Considerations when using mixed-case passwords”](#) on page 670 describes general table rules.

- If a DEFAULTAPPL application is mapped at the same Client Identifier level as a USS table, or an LUMAP-DEFAPPL application is mapped, the USS table is used only to return error messages and optionally after the first session logoff. FIRSTONLY or LOGAPPL options on DEFAULTAPPL will cause Telnet to send a USSMSG10 after the first session logoff. DEFAULTAPPL without the FIRSTONLY or LOGAPPL options will cause Telnet to request a session with the default application after every session logoff.

- Both the 3270 data stream and the SNA character stream (SCS) formats are supported. For more information, see *3270 Data Stream Programmer's Reference* and the table samples.
- If a user-defined table is coded as part of another module, code an assembler EXTRN definition statement for the table name in that module so the table will be known externally and can be accessed by other modules.

Below are message related rules.

- 3270 format USSMSGs must contain the 3270 data stream write control characters (WCCs).
- All character substitutions (@@'s) substitute the same number of characters. Any character substitution that is VTAM-specific will be translated to blanks. If the substituted value is smaller, the field is padded to the right with blanks. The parameter LUNAME or SCAN must be coded on the USSMSG macro instruction for Telnet to perform character substitutions. For a complete list of character substitutions, see *z/OS Communications Server: IP Configuration Reference for Telnet* and *z/OS Communications Server: SNA Resource Definition Reference for VTAM*. Telnet supports multiple USSPARMs with the DATA keyword. This method can be used to pass multiple data parameters to the host application. For example, two DATA USSPARMs allow the user to type 'TSO USER1 PROC001' and have both the user ID and the Procname passed to TSO as data. Telnet also supports the system symbolics substitution, padding to the right when the substituted value is smaller than the symbolic. VTAM USS processing does not support system symbolic substitution.

Below are command related rules.

- LOGON command format  
 PL1 - logon applid(tso) logmode(snx32702) data(user1)  
 BAL - logon applid=tso,logmode=snx32702,data=user1
- Any application defined in a USSCMD macro instruction must also be specified on either an ALLOWAPPL or a RESTRICTAPPL statement in the Telnet profile.
- If the USS Command rules in *z/OS Communications Server: IP Configuration Reference* cannot be followed, use an interpret table to convert the character-coded command into a formatted SNA request.

#### *Considerations when using mixed-case passwords*

Mixed-case passwords can be used by applications if an SAF-compliant security product (such as RACF) has enabled this support. In some cases, the USS LOGON DATA parameter is used to send the password to the application. If a terminal user enters a mixed-case password on the USS LOGON command and it is translated to uppercase by the translation table, the logon will fail if the target application expects the password in mixed case.

The USS LOGON command is displayed on the terminal as it is typed, so the password is displayed unless the 3270 format is used and the password is entered into a field with a non-display attribute. For additional security, inform the terminal user to stop entering the password as part of the USS LOGON. Instead, the application should prompt the terminal user for the password in a non-displayed field. If mixed-case passwords are used and the terminal user continues to enter the password as part of the USS LOGON command, the logon will fail when using TRANSLATE=YES (the default) on the USSPARM, because the password has been translated to uppercase.

If you want to continue allowing the terminal user to enter the password on the LOGON command, use one of the following methods to support mixed-case passwords:

- If the current USS translate table is used to set all characters to uppercase, the TRANSLATE=NO operand can be added to the USSPARM macros for the corresponding USSCMD, to prevent the specified DATA USSPARM containing the password from being translated to uppercase. For details, see *z/OS Communications Server: IP Configuration Reference*.
- Do not change the USS command and inform the terminal user to enter the DATA portion of the USS LOGON in single quotes. USS will not translate data within single quotes, and the quotes are removed before the data is passed to the application.
- If the terminal user is specifying only APPLID and DATA on the USS LOGON command, you can use an interpret table. The Telnet Interpret function passes all entered data without translation to the

application. Specify REMOVE=Y on the LOGCHAR macro to remove the first non blank string from the entered data. Because the terminal user could enter the APPLID in lowercase, you should set up an interpret table that searches for both an uppercase and a lowercase APPLID.

With each of these methods, if the user ID is entered with the password, you must first verify whether the application supports translating the user ID to uppercase. A simple test is to enter the DATA portion of the USS LOGON in single quotes with the user ID specified in lowercase. USS will not translate data within single quotes and the quotes are removed before the data is passed to the application. If the logon fails, the application does not support translating the user ID to uppercase and the terminal user must enter the user ID in uppercase and the password in mixed case for the methods suggested.

#### *INTERPRET table customization*

The standard Telnet USS logon support should meet the needs of most installations. However, Telnet does support INTERPRET table function if special circumstances require accepting a sequence of characters outside the normal USS command format. For example, the user might want to enter logon data that includes blanks. The INTERPRET table defines all entered data, including blanks, as a USSPARM DATA entry. The PL1 USSCMD format treats each blank as a parameter delimiter and cannot properly process a variable number of parameters. The INTERPRET table character sequences are scanned whenever the client is mapped to both a USS table and an INTERPRET table. Both must be mapped because the INTERPRET function is a subset of the USS function. INTERPRET is not a stand-alone function. The sample INTERPRET table found in SEZAINST(EZBTPINT) is not assembled and linked, and it is not loaded into Telnet as a default INTERPRET table. The table must be assembled, linked, loaded, and mapped in the Telnet profile to be used.

#### *Creating an INTERPRET table*

Telnet INTERPRET function supports all functions provided by the VTAM INTERPRET definitions. See [z/OS Communications Server: IP Configuration Reference](#) for macro details. The following macro instructions are used to create an INTERPRET table:

- INTAB indicates the beginning of the INTERPRET table.
- LOGCHAR defines a single logon message and name of an application program.
- ENDINTAB indicates the end of the INTERPRET table.

Below are some of the more common rules to consider when coding a new INTERPRET table. Also, see the sample found in SEZAINST(EZBTPINT) as a guide.

- The LOGCHAR APPLID= supports APPLICID, ROUTINE and USERVAR.
- Code the most restrictive, or longest, LOGCHAR SEQNCE values first. Otherwise, unexpected matches can occur. The table is scanned from top to bottom until a match is found whether or not it is the most exact match. For example, assume sequence 'LOGA' is assigned APPL1 and any other 'LOG' sequence is assigned APPL2. If sequence 'LOG' is before 'LOGA', entry 'LOGA' will never be found even when the user enters 'LOGA' because entry 'LOG' will be the first match. All sessions will go to APPL2. The problem is corrected by putting 'LOGA' before 'LOG' in the table.

#### *Assemble, link, and load a table*

Use the sample JCL in SEZAINST(EZBUSJCL). In the sample, the USS table is in USER1.TABLES(USSTEST). It must be assembled and link-edited into the system's linklist or into a library concatenated as a STEPLIB in the TCP/IP startup procedure. In the sample, the table is link-edited into USER1.LINKLIB(USSTEST). The same procedure can be used for the INTERPRET table. Change the name of the input file source and the link-edit target member. The VTAM USS and INTERPRET macros used for the assemble can be found in *hlq.SISTMAC1*.

## **SMF**

The Telnet server writes the following SMF records:

- [“Client activity records” on page 672](#)
- [“Profile configuration records” on page 672](#)

Network management applications can send these records to a TCP/IP stack for NETMONITOR processing. For more information, see [“Real-time SMF information service access control”](#) on page 169.

## Client activity records

SMF records are written when a user establishes a session (SMF LOGN or Telnet SNA Session Initiation record) and when the session is ended (SMF LOGF or Telnet SNA Session Termination record). Optional SMF recording is controlled by using the SMFINIT and SMFTERM statements.

Two different record formats are available: SMF type 118 and 119. The type 119 records were first introduced in z/OS V1R2 Communications Server, and are controlled by use of the TYPE119/NOTYPE119 operands on the SMFINIT and SMFTERM statements. The subtypes cannot be changed for type 119 records and are set to the STD values. The use of the STD operand or the specification of a nonstandard subtype number on the SMFINIT and SMFTERM parameters control the usage of the older type 118 record processing. Data that are recorded include the application name, Telnet LU name, client and host IP address and port, time of logon or logoff, and data count in and out. Combined with the SMF utility exit routine, SMF data can be used to track Telnet usage by a number of variables. If statements for both format types are coded, then both record types are written. Use that capability sparingly because of the additional processing cost that is involved in generating both types of records. For more information about the layouts for [type 118](#) and [Type 119 SMF records](#) SMF records, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

## Profile configuration records

You can control the writing of SMF type 119 Telnet profile configuration records by using the SMFCONFIG statement in the TELNETGLOBALS statement block. The data that is recorded in this SMF record includes the following data:

- Profile data sets used
- Options and values in the TELNETGLOBALS, TELNETPARMS, and BEGINVTAM blocks
- LU mapping statements
- Client identification statements

For more information about the [Type 119 SMF records](#) Telnet profile configuration records, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

## Connection monitoring mapping statement

Telnet collects monitoring data for any client connection that is mapped to a MONITORGROUP Object. The collected data can be retrieved several ways:

- Display the data for a single connection using the D TCPIP,*tnproc*,TELNET,CONN,CONN=*connid* command.
- A network management agent can request the data from the Telnet SNMP subagent, after the subagent is started by specifying the TNSACONFIG statement. TCPIPJOBNAME must be specified for the subagent to connect with the agent. For information about the TNSACONFIG statement and the parameters needed to start the subagent, see [z/OS Communications Server: IP Configuration Reference](#). For details about configuring the SNMP agent, see [Chapter 23, “Simple Network Management Protocol,”](#) on page 1267.
- The Network Management Interface (NMI) Application Programming Interface (API), EZBNMIFR, can be used instead of SNMP to retrieve the data. In this case, the TNSACONFIG statement is not needed. For details about configuring [EZBNMIFR](#) and the parameters needed to issue the call, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).
- The Telnet SMF119 session termination record contains two optional sections that can be used to retrieve life-of-session performance data. Life-of-session data is a subset of life-of-connection data. Sliding-window data is not available because data is reported only at the end of the session and not at periodic intervals. One optional section contains response time statistics (excluding sliding-window) and a second optional section contains response time counts by time bucket. For details on the [Telnet](#)

server SNA session termination record, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Telnet is capable of collecting two types of response time data at the connection level.

- Response time statistics
  - Life-of-connection response time averages
  - Sliding-window response time averages
  - Sum of squares for variance and standard deviation calculations
- Response time counts by time bucket

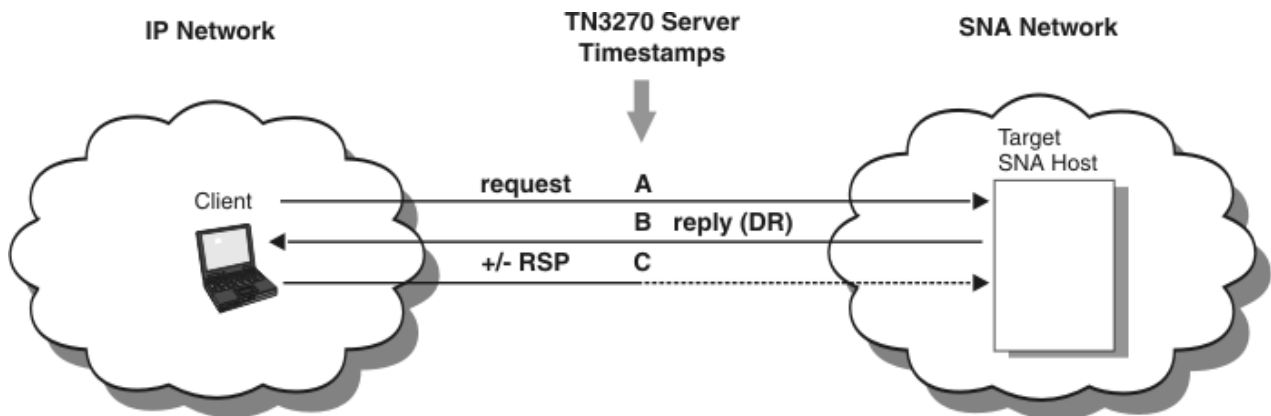

The MONITORGROUP Object statement in BEGINVTAM is used to set the criteria for monitoring. Options allow the inclusion or exclusion of averages, counts by time bucket, and whether or not the IP network should be included in measurements. When a MONITORGROUP is mapped to Client Identifiers with the MONITORMAP mapping statement, the requested data will be collected for those connections.

Up to 255 MonitorGroups can be active at one time for all ports per Telnet instance. When 255 MonitorGroups are active, no additional groups can be created until some groups are no longer in use by Telnet. A MonitorGroup is considered no longer in use when the group is not defined in a current profile and no connections are using the non-current profile where the MonitorGroup was defined. After being notified that no entries are available, it is up to the operator to manage the removal of some entries by ending connections to free a profile. The operator does not get a notification when an entry becomes available.

Each MonitorGroup entry in the table is assigned an index number. The index number coincides with one of the 255 slots available in the MonitorGroup table. Each Telnet connection entry saves the index number of the MonitorGroup mapped to the connection. When the management application queries a connection for data, it can also query the MonitorGroup table to get the group name and configuration values based on the index found in the connection entry. With the data from the connection and the MonitorGroup criteria from the MonitorGroup table, a management application can generate several summary reports. If a management application is not being used to collect the connection monitoring data, the `D TCPIP,tnproc,TELNET,CONN,CONN=connid` command can be used to view all the collected data and MonitorGroup information for a single connection.

### **Collecting response time data**

The typical Telnet data flow can be represented as shown in [Figure 98 on page 673](#).

*Figure 98. Typical Telnet data flow*

Telnet saves timestamp A when it sends a client data request to VTAM, saves timestamp B when the target SNA host application returns data, and saves timestamp C when the client responds to the definite response request that flowed with the reply.

There are many clients, mostly those not supporting TN3270E negotiation, that do not support the Definite Response (DR) function. In this case, Telnet approximates IP response time by appending a TIMEMARK request immediately after the data. A Telnet TIMEMARK acts as a synchronization mark or as

an "are you there" function for almost all clients. Almost all clients respond to the TIMEMARK request. Timestamps B and C are set based on when the TIMEMARK request is sent and a TIMEMARK response is received. In rare cases, a client does not respond to a TIMEMARK request. If Telnet does not receive a response to the TIMEMARK, a flag in the connection data indicates that IP transit time measurements were not attempted.

Some installations might not want to incur the additional network traffic of DRs or TIMEMARKs to measure IP transit time, and are interested only in the SNA application side transit time. In this case, turn off IP response measurements by specifying NOINCLUDEIP within MonitorGroup. Total response times will be the SNA response time only.

Specify INCLUDEIP within the MonitorGroup to include IP response measurements when monitoring a connection. It does not matter whether the SNA host application requested a definite response on its reply. Many applications save processing time and IP transactions by not requesting Definite Response. If IP response time monitoring is wanted and the client supports DR, specify DYNAMICDR within MonitorGroup to add the definite response request to ensure that a response is received from the client. In this case, Telnet does not forward the response to the target SNA host application, as indicated by the dotted line in [Figure 98 on page 673](#). Specify NODYNAMICDR to turn off dynamic DR creation. If INCLUDEIP and NODYNAMICDR are specified and data from the application does not include a DR request, the TIMEMARK method is used.

If chained data is sent from the host application, Telnet collects the entire chain before sending the complete data stream to the client. Telnet will save timestamp B when the entire data chain is sent.

It should be pointed out that the measured response time might not be exactly what the user sees. The first timestamp, A, is recorded when the data passes from Telnet to VTAM on its way to the SNA VTAM application. For various SNA reasons, Telnet might have received the data much earlier and had to queue it before it could be sent to VTAM. The most common reason for this is the application might not have given Telnet direction (the ability to send data). SNA applications often use a Change Direction Indicator (CDI) to manage which side can send data. The current sender can send data until it sends a CDI, which gives the other side permission to send. There might be scenarios where a client data request comes in, Telnet does not have direction, and must queue the data until the application sends a CDI. The measured response time will not include this queue time.

### ***Average response time data collection***

Specify AVERAGE within MonitorGroup to collect average response time data. Specify NOAVERAGE to turn off average response time data collection. If average response time data is requested, the following data is available on a per connection basis:

- Life-of-connection response time averages
- Sliding-window response time averages
- Variance and standard deviation of response time averages

#### *Life-of-connection response time averages*

These averages are based on data collected since the beginning of the connection. Data collected for this average includes:

- Total transaction count.
- Sum of the round-trip response times. Round-trip response time is the time difference between timestamp C and timestamp A.
- Sum of the IP response times. IP response time is the time difference between timestamp C and timestamp B. Sum of the SNA response times can be derived by subtracting the IP sum from the round-trip sum.

With this data collected, the average round-trip time, average IP time, and average SNA time can be calculated by dividing each sum by the transaction count. The data accumulation values might wrap. It is up to the management application to detect this. The Telnet connection display will indicate the wrapped condition instead of displaying averages.

### *Sliding-window response time averages*

These averages give higher significance to more recent data without ever completely losing the impact of earlier data. The sliding-window methodology calculates an average over an interval of time instead of over the life of the connection. An interval is made up of a specified number of equal time periods. Use AVGSAMPMULTIPLIER to specify how many periods are in the interval. Use AVGSAMPPERIOD to specify the time length of a period. An interval should be long enough to have several data flows measured. Data collected during the period includes:

- Transaction count in the period (pTX).
- Sum of round-trip response times in the period (pRT).
- Sum of IP response times in the period (pIP). Sum of SNA response times can be derived.

In addition, there are three sliding-window variables that represent the interval and are used to calculate the sliding-window average. These variables are updated at the end of each period. They are:

- Sliding-window transaction count (swTX).
- Sliding-window sum of round-trip response times (swRT).
- Sliding-window sum of IP response times (swIP). Sliding-window sum of SNA response times can be derived.

When the interval has moved one period, subtracting the oldest period of collected data from the total and adding the newest period is one method for determining the new interval averages. However, this simple method loses all impact of earlier periods on the averages. Instead of dropping the collected data from the oldest period in the interval and completely losing its effect on the average, an average period of data is subtracted from the sliding-window totals. With this method, even the oldest period data continues to have a declining effect on the latest average calculations. And, by using an average period amount, the unique data for each period does not need to be retained. Only a total for the entire interval needs to be saved. Average period data is determined based on the fact that a period is a fraction of the total interval time. A period of data is  $1/n$  of the current sliding-window totals, where  $n$  is the number of periods in the interval. The sliding-window average is derived from the new sliding-window values. At the end of each period the following calculations occur:

- Calculate the average period values:

```
avTX = swTX * (1/n)
avRT = swRT * (1/n)
avIP = swIP * (1/n)
```

- Remove an average period amount from the sliding-window totals and add the new period values:

```
swTX = swTX - avTX + pTX
swRT = swRT - avRT + pRT
swIP = swIP - avIP + pRT
```

- Calculate and report new sliding-window averages:

```
sliding-window round-trip average = swRT/swTX
sliding-window IP average = swIP/swTX
sliding-window SNA average = (swRT-swIP)/swTX
```

After the calculations are done, the period variables are reset and the next period of data collection begins. At the end of that period, the sliding-window variables are updated again with new information. The cycle continues for the life of the connection.

AVGSAMPMULTIPLIER 1 is a special case where 100% of the existing interval data is subtracted before the new period data is added. The result is an average for just that interval and the effect of older data is completely ignored.

AVGSAMPMULTIPLIER 0 is a special case that tells Telnet to include all data equally. The result is a life-of-connection average that is already available. A very large multiplier will have a similar effect.

A sliding-window round-trip average example follows. Assume an interval is made up of 5 periods. Each period is 2 minutes. Specify AVGSAMPMULTIPLIER 5 and AVGSAMPPERIOD 120. For illustrative purposes

in this example, the average response time starts low and then increases to a steady state value. The data collected for each period is the sum of all response times in milliseconds (ms) and the number of transactions (tx).

| <i>Table 30. Sliding-window round-trip average example</i> |                                   |                                    |                                      |
|------------------------------------------------------------|-----------------------------------|------------------------------------|--------------------------------------|
| <b>Period</b>                                              | <b>Sum of response times (ms)</b> | <b>Number of transactions (tx)</b> | <b>Average response time (ms/tx)</b> |
| 1                                                          | 1000                              | 10                                 | 100                                  |
| 2                                                          | 1650                              | 15                                 | 110                                  |
| 3                                                          | 2800                              | 20                                 | 140                                  |
| 4                                                          | 3500                              | 25                                 | 140                                  |
| 5                                                          | 4200                              | 30                                 | 140                                  |
| 6                                                          | 4900                              | 35                                 | 140                                  |
| 7                                                          | 5600                              | 40                                 | 140                                  |

The sliding-window average response time for period 1:

$$1000\text{ms}/10\text{tx} = 1000\text{ms}/10\text{tx} = 100 \text{ ms/tx}$$

The sliding-window average response time for period 2:

$$(1000 - (1000 * (1/5)) + 1650)\text{ms} / (10 - (10 * (1/5)) + 15)\text{tx} = 2450\text{ms}/23\text{tx} = 106.5 \text{ ms/tx}$$

The sliding-window average response time for period 3:

$$(2450 - (2450 * (1/5)) + 2800)\text{ms} / (23 - (23 * (1/5)) + 20)\text{tx} = 4760\text{ms}/38.4\text{tx} = 124.0 \text{ ms/tx}$$

The sliding-window average response time for period 4:

$$7308\text{ms}/55.7\text{tx} = 131.2 \text{ ms/tx}$$

The sliding-window average response time for period 5:

$$10046.4\text{ms}/74.6\text{tx} = 134.7 \text{ ms/tx}$$

The sliding-window average response time for period 6:

$$12937.1\text{ms}/94.7\text{tx} = 136.6 \text{ ms/tx}$$

The sliding-window average response time for period 7:

$$15949.7\text{ms}/115.7\text{tx} = 137.9 \text{ ms/tx}$$

The sliding-window method continues to include the effects of the earlier response time averages. The greater the number of periods (AVGSAMPMULTIPLIER), the longer older data will continue to impact new average calculations. Decreasing the number of periods (AVGSAMPMULTIPLIER) gives less emphasis to older data. The AVGSAMPMULTIPLIER gives the system administrator control over the emphasis placed on old data.

Each of the last five periods in the example had average response times of 140 ms/tx. Different multiplier values give the following results after seven periods. It is clear that the greater the number of periods in the interval, the greater the impact of the older data.

- 2 period interval - 139.7 ms/tx
- 5 period interval - 137.9 ms/tx
- 10 period interval - 136.6 ms/tx

### *Variance and standard deviation of response time averages*

It is useful to know the dispersion of the response time data. The variance is a measure of how variable the data is. The square root of the variance is the standard deviation. Assuming the distribution is a normal distribution, you can have the following confidence level:

- 68% that a response time value will fall within the average, plus or minus 1 standard deviation
- 95% that a response time value will fall within the average, plus or minus 2 standard deviations
- 99% that a response time value will fall within the average, plus or minus 3 standard deviations

The data that is saved for variance and standard deviation includes the data that is saved for life-of-connection averages, and the sum of each response time squared for the following data:

- Complete round-trip.
- IP portion of the transaction.
- SNA portion of the transaction. The sum of squares cannot be derived in this case and must be separately maintained.

These values might wrap. It is up to the management application to detect this. The Telnet connection display will indicate the wrapped condition instead of displaying these values or the standard deviation. The typical formula used for variance is:

$$\text{VARIANCE} = \text{SUM}((X_i - X_m)^2) / (n - 1)$$

However, that would require keeping all the individual response times to calculate the sum of the squares. The same formula can be expanded and rewritten to not need individual response times. The formula used by Telnet is:

$$\text{VARIANCE} = [\text{SUM}(X_i^2) - (\text{SUM}(X_i))^2 / n] / (n - 1)$$

The values needed in this formula are saved by Telnet for each connection requesting average response time monitoring.

### ***Time buckets***

Five time buckets, each defined by a maximum response time, are used. Every transaction has a total response time, and that time fits into one of the five configurable time buckets. The bucket boundaries are created by specifying the maximum response time for the first four buckets. The fifth bucket has an open-ended maximum value. The minimum response time boundary for each bucket is the maximum of the previous bucket. The first bucket has a minimum value of 0. A bucket transaction count is incremented by one when a response time is greater than the minimum and less than or equal to the maximum. Figure 99 on page 677 depicts the time buckets. For default values, see [z/OS Communications Server: IP Configuration Reference](#).

Figure 99. Time buckets

### **Reducing demand for ECSA storage**

Telnet server configurations that support a large number of connections can place a high demand on ECSA storage. To reduce this demand, configure the Telnet server to enable multiple Telnet LUs to share an ACB.

To configure the Telnet server to enable LUs to share an ACB, specify SHAREACB in the TELNETGLOBALS statement block. Replace any predefined (static) VTAM APPL definitions that are being used to represent

Telnet LUs with corresponding model application program definitions; the latter are required when using the SHAREACB function.

## Configuring the z/OS UNIX Telnet server

---

The z/OS UNIX Telnet server (otelnetsd) provides access to z/OS UNIX shell applications on the host using the Telnet protocol. The z/OS UNIX Telnet server lets hosts in an IP network log on to the z/OS shell environment directly, without going through TSO. The z/OS UNIX Telnet server supports AIX and UNIX full-screen applications such as the vi editor, so that AIX and UNIX users can use familiar Telnet commands. The z/OS UNIX Telnet server runs in both line mode and raw mode, but does not support TN3270 or TN3270E, as the TN3270E Telnet server does.

### Installation information

The files used in the z/OS UNIX Telnet server and their locations in the z/OS UNIX file system are as follows:

#### **/etc/services**

The ports for each application are defined here. For example:

```
otelnetsd xxxx/tcp
```

where xxxx is the port that inetd should listen on for otelnetsd.

#### **/etc/syslog.conf**

The configuration parameters for usage of syslogd are defined in this file. otelnetsd writes to syslog facility local1.

#### **/etc/inetd.conf**

The configuration parameters for all applications started by inetd are defined in this file.

#### **/usr/sbin/otelnetsd**

This is a symbolic link to /usr/lpp/tcpip/sbin/otelnetsd. /usr/lpp/tcpip/sbin/otelnetsd is a sticky-bit file. The OTELNETD member of SEZALOAD contains the executable code for the Telnet server.

#### **/etc/banner**

This file contains a login message that is printed to the client's screen after the client logs in, unless the -h option is specified. Store the banner in this file.

#### **/etc/otelnetsd.banner**

This file contains a message that is printed to the client's screen prior to the login prompt when the user connects to the server, unless the -h option is specified. Store the banner in this file.

#### **/etc/utmpx**

This file is updated by the call to fsumoclp. It contains a list of all the users who are logged in with their associated tty.

#### **/dev/ptypXXXX and /dev/ttypXXXX**

These special device files represent pseudoterminals (ptys); they are used by the z/OS UNIX Telnet server and other programs.

**Note:** For information on allocating more of these files for more connections, see [z/OS UNIX System Services Planning](#).

#### **/usr/share/lib/terminfo**

The descriptions of supported terminals are stored here. For more information, see [z/OS UNIX System Services Planning](#).

#### **/usr/lib/nls/msg/C/tnmsgs.cat**

The message catalog used by the z/OS UNIX Telnet server is stored here.

If the message catalog does not exist, the software will use the messages hard-coded within the software by default. These messages duplicate the English message catalog that is shipped with the product.

## **/usr/man/C/cat1/otelnetd.1**

This file contains the associated manual (man) pages for the z/OS UNIX Telnet server. It provides online help for the user.

## **Environment variables**

Table 31 on page 679 provides a list of environment variables that can be explicitly set by z/OS UNIX Telnet.

| <i>Table 31. Environment variables for z/OS UNIX Telnet</i> |                                                                                                                                                                                                                                                                                                                                                                        |
|-------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Environment variable</b>                                 | <b>Description</b>                                                                                                                                                                                                                                                                                                                                                     |
| _BPX_SHAREAS                                                | Controls whether a spawned child process is started in the same address space as the login shell.                                                                                                                                                                                                                                                                      |
| KRB5_SERVER_KEYTAB                                          | Specifies the location of the key table.                                                                                                                                                                                                                                                                                                                               |
| LC_ALL                                                      | Determines the values for all local categories.                                                                                                                                                                                                                                                                                                                        |
| LC_COLLATE                                                  | Determines the local category for character collation.                                                                                                                                                                                                                                                                                                                 |
| LC_CTYPE                                                    | Determines the local category for character handling functions, such as tolower(), toupper(), and isalpha(). Also determines the interpretation of sequences of bytes of text data as characters (for example, single as opposed to multibyte characters), the classification of characters (for example, alpha, digit, graph), and the behavior of character classes. |
| LC_MESSAGES                                                 | Determines the local category for processing affirmative and negative responses, and the language and cultural conventions in which messages should be written.                                                                                                                                                                                                        |
| LC_NUMERIC                                                  | Determines the local category for numeric formatting information (for example, thousands separator and radix character) in various utilities, as well as the formatted I/O operations in printf() and scanf() and the string conversion functions in strtod().                                                                                                         |
| LC_TIME                                                     | Determines the local category for date and time formatting information. It affects the behavior of the time functions in strftime(). Additional semantics of this variable, if any, are implementation defined.                                                                                                                                                        |
| NLSPATH                                                     | Contains a sequence of templates that the catopen() function uses when attempting to locate message catalogs. Each template consists of an optional prefix, one or more conversion specifications, a file name, and an optional suffix.                                                                                                                                |
| TERMINFO                                                    | Specifies the path name for an unsupported terminal that has been added to the terminfo file. Use the TERMINFO variable in /etc/profile or /etc/.login.                                                                                                                                                                                                                |

## **Starting, stopping, and administration of z/OS UNIX Telnet**

The z/OS UNIX Telnet server is started by inetd for each incoming Telnet connection. When the Telnet session is complete, the z/OS UNIX Telnet server will exit. Each active Telnet session will have a separate instance of the Telnet server which will communicate with the Telnet client.

The z/OS UNIX inetd daemon does not propagate environment variables other than PATH and TZ to its child processes, so the NLSPATH and LANG environment variables cannot be used to point to a different message catalog.

The following standards are supported:

- RFC 854 Telnet Protocol Specification
- RFC 855 Telnet Option Specification

- RFC 856 Telnet Binary Transmission
- RFC 857 Telnet Echo Option
- RFC 858 Telnet Suppress Go Ahead Option
- RFC 859 Telnet Status Option
- RFC 860 Telnet Timing Mark Option
- RFC 861 Telnet Extended Options - List Option
- RFC 885 Telnet End of Record Option
- RFC 1073 Telnet Window Size Option
- RFC 1079 Telnet Terminal Speed Option
- RFC 1091 Telnet Terminal type option
- RFC 1096 Telnet X Display Location Option
- RFC 1123 Requirements for Internet Hosts -- Application and Support
- RFC 1184 Telnet Linemode Option
- RFC 1372 Telnet Remote Flow Control Option
- RFC 1571 Telnet Environment Option Interoperability Issues
- RFC 1572 Telnet Environment Option
- RFC 2941 Telnet Authentication Option
- RFC 2942 Telnet Authentication: Kerberos Version 5
- RFC 2946 Telnet Data Encryption Option
- RFC 2952 Telnet Encryption: DES 64 bit Cipher Feedback
- RFC 2953 Telnet Encryption: DES 64 bit Output Feedback

When a z/OS UNIX Telnet session is started up, otelnetd sends Telnet options to the client side that indicate a willingness to do the following options:

- WILL ENCRYPT
- DO ENCRYPT
- DO TERMINAL TYPE
- DO TSPEED
- DO XDISPLOC
- DO NEW-ENVIRON
- DO ENVIRON
- WILL SUPPRESS GO AHEAD
- DO ECHO
- DO LINEMODE
- DO NAWS
- WILL STATUS
- DO LFLOW
- DO TIMING-MARK

The z/OS UNIX Telnet server can enable the following options locally.

- WILL BINARY

This option indicates that the client is willing to send 8 bits of data, rather than the normal 7 bits of network virtual terminal data.

- WILL ECHO

When the LINEMODE option is enabled, a WILL ECHO or WONT ECHO is sent to the client to indicate the current state of terminal echoing. When terminal echo is not wanted, a WILL ECHO is sent to indicate that Telnet takes care of echoing any data that must be echoed to the terminal, and then nothing is echoed. When terminal echo is wanted, a WONT ECHO is sent to indicate that Telnet is not doing any terminal echoing, so the client can do any terminal echoing that is needed.

- WILL LOGOUT

When a DO LOGOUT is received, a WILL LOGOUT is sent in response and the Telnet session is shut down.

- WILL SGA

This option indicates that it will not be sending IAC GA, the go ahead command.

- WILL STATUS

Indicates a willingness to send the client, upon request, the current status of all Telnet options.

- WILL TIMING-MARK

Whenever a DO TIMING-MARK is received, a WILL TIMING-MARK is the response. It is used only in kludge linemode support.

- WILL ENCRYPT

Indicates a willingness to encrypt the data stream.

The z/OS UNIX Telnet server can enable the following options remotely.

- DO BINARY

Sent to indicate that Telnet is willing to receive an 8-bit data stream.

- DO ECHO

If a WILL ECHO is received, a DONT ECHO will be sent in response.

- DO ENVIRON

Indicates a desire to be able to request environment variable information. (See RFC 1408.)

- DO LFLOW

Requests that the client handle flow control characters remotely.

- DO LINEMODE

Supports requests that the client do line-by-line processing.

- DO NAWWS

Requests that the client inform the server when the window size changes.

- DO NEW-ENVIRON

Indicates a desire to be able to request environment variable information. (See RFC 1572.)

- DO SGA

Indicates that it does not need to receive IAC GA, the go ahead command.

- DO TERMINAL-TYPE

Indicates a desire to be able to request the name of the type of terminal that is attached to the client side of the connection.

- DO TERMINAL-SPEED

Indicates a desire to be able to request information about the speed of the serial line to which the client is attached.

- DO TIMING-MARK

Only supported if the client responded with WONT LINEMODE. If the client responds with WILL TM, then it is assumed that the client will support kludge linemode. It is not used for any other purposes.

- DO XDISPLOC

Indicates a desire to be able to request the name of the X Window System display that is associated with the Telnet client.

- DO AUTHENTICATION

Indicates a willingness to receive authentication information for automatic login.

- DO ENCRYPT

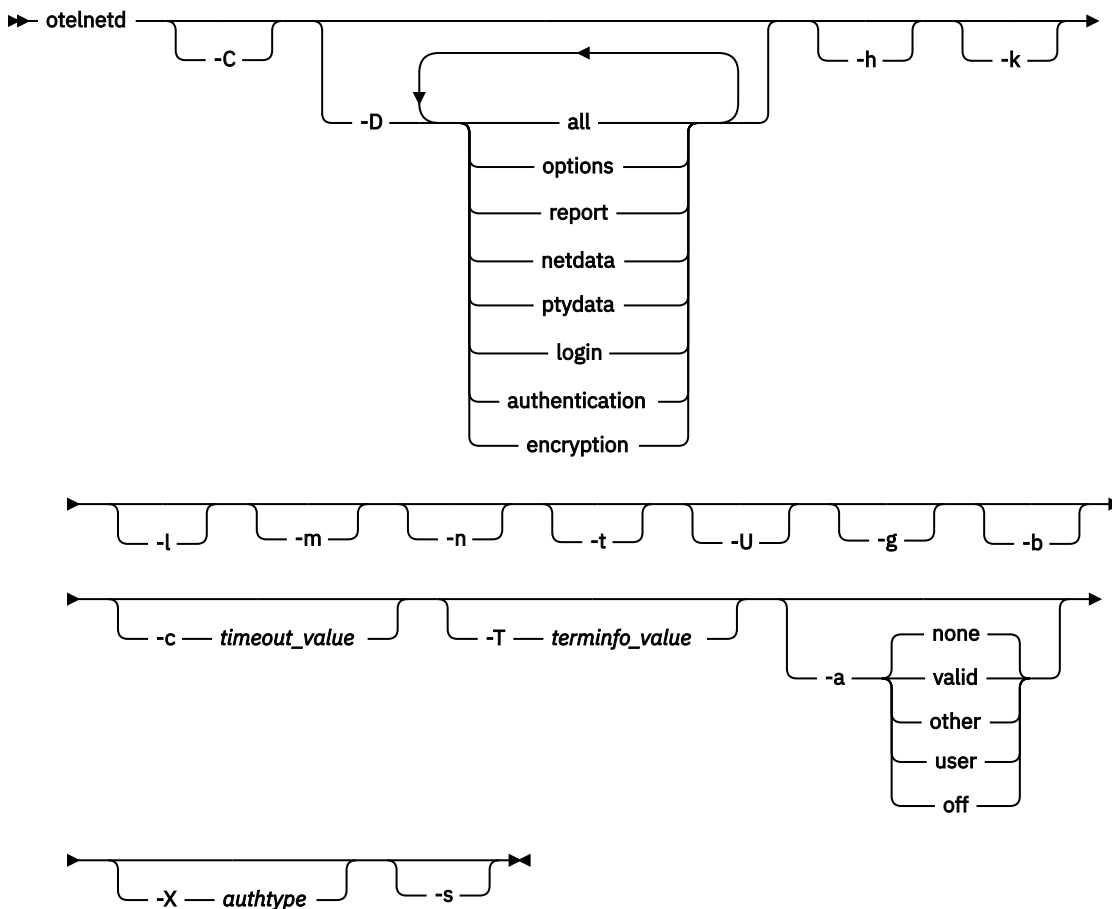

Indicates a willingness to decrypt the data stream.

## otelnetd

**Note:** The user ID associated with the daemon in `/etc/inetd.conf` requires superuser authority. See [z/OS UNIX System Services Planning](#) for a description of the types of authority defined for daemons.

The following syntax is used in the `/etc/inetd.conf` file to define the arguments used to invoke otelnetd.

### Syntax

### Parameters

#### -C

Prints user messages in uppercase. There are several exceptions. Messages issued at startup are not affected by the `-C` option because the `-C` option is not processed during the startup. Also, data transmittal messages will not be uppercase. Data transmittal messages are generated from the `-D` netdata option or the `-D` ptydata option.

## **-D**

The following suboptions apply to -D:

### **options**

Prints information about the negotiation of Telnet options. This information is used for debugging purposes. This suboption allows telnetd to generate debugging information to the connection, which allows the user to view telnetd activity.

### **report**

Prints the options information and additional information about processing. This information also includes print information designated for suboption=options. This can be used for debugging purposes. This suboption telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

### **netdata**

Displays the data stream received by telnetd. This information is used for debugging purposes. It allows telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

### **ptydata**

Displays the data stream written to the pty. This information is used for debugging purposes. It allows telnetd to generate debugging information to the connection, which enables the user to view telnetd activity.

### **all**

Enables options, report, netdata, ptydata, login, authentication and encryption.

### **login**

Records login and logout activity to syslogd facility auth using message EZYTU36I.

### **authentication**

Turns on authentication debugging code.

### **encryption**

Turns on encryption debugging code.

## **-h**

Disables the display of the /etc/banner and /etc/otelnetd.banner files at the terminal of the client.

## **-k**

Disables kludge linemode. The server normally attempts to use kludge linemode when the -l option was specified, but the client does not support line mode. Use the -k option when there are remote clients that do not support kludge linemode, but pass the heuristic for kludge line mode support (for example, if they respond with WILL TIMING-MARK in response to a DO TIMING-MARK). This option does not disable kludge line mode when the client requests it. This is accomplished by the client sending DONT SUPPRESS-GO-AHEAD and DONT ECHO.

## **-l**

Specifies linemode, which tries to force clients to use linemode. If the LINEMODE option is not supported and the -k option was not specified, it will attempt to use kludge linemode.

### **Notes:**

1. Many clients decline the server's request to operate in linemode.
2. Linemode is not appropriate for full-screen applications like the z/OS UNIX vi editor.

## **-m**

Enables the creation of a forked or spawned process to coexist in the same address space. This option can improve performance because the user's login shell runs in the same address space as otelnetd.

## **-n**

Disables TCP keep-alives. Normally, telnetd enables the TCP keep-alive mechanism to probe connections that have been idle for some time to determine if the client is still there. In this way, idle connections from machines that have crashed or can no longer be reached can be cleaned up. The cleanup of disabled connections is controlled by the presence of the INTERVAL parameter on the TCPCONFIG statement in the TCPIP profile.

- t**  
Specifies internal tracing. It also activates the REPORT option, as if the user also specified -D Report.
- U**  
Causes telnetd to drop connections from any IP address that cannot be mapped back into a symbolic name by the gethostbyaddr or getnameinfo routines.
- Result:** If coded, the -U parameter causes the -g parameter to be ignored.
- g**  
Disables the ability to issue the gethostbyaddr or getnameinfo routines that use the client IP address to resolve the client host name.
- Results:**
- If this parameter is coded, the host name does not appear in the trace output (-t parameter) or in the WHO command output.
  - This parameter is ignored if the -U parameter is coded.
- b**  
Forces the server to DO BINARY in the first pass during negotiations with the client.
- c *timeout\_value***  
Specifies the number of seconds to wait before terminating the Telnet session for inactive connections. The *timeout\_value* is a value between 1 and 86400 seconds.
- T *terminfo\_value***  
Sets the TERMINFO environment variable to the specified values at startup. This option is needed when terminfo definitions are located in nonstandard directories.
- a**  
This option may be used for specifying what mode should be used for authentication. There are several valid suboptions for authentication mode:
- valid**  
Allow connections only when the remote user can provide valid authentication information to identify the remote user. Thus, for otelnetd, Kerberos authentication will be required. User verification will still occur through the login and password prompt. However, if the login user ID matches the TSO user ID that was mapped from the name in the Kerberos principal using the SAF R\_usermap function, then no password will be requested. This is the most secure authentication mode.
- other**  
Allow only connections that supply some authentication information. This option is currently not supported by any of the existing authentication mechanisms, and is thus the same as specifying -a valid.
- user**  
Allow connections only when the remote user can provide valid authentication information to identify the remote user, and is allowed access to the specified account without providing a password. Thus, for otelnetd, Kerberos authentication is required. The NAME received during AUTHENTICATION option negotiation must match the name in the Kerberos principal, and the Kerberos principal must map to a valid TSO user ID on the host using the SAF R\_usermap function. No user verification will occur through the login or password prompt.
- none**  
This is the default state. Authentication information is not required. User verification will still occur through the login and password prompt. However, if the login user ID matches the TSO user ID that was mapped from the name in the Kerberos principal using the SAF R\_usermap function, then no password will be requested.
- off**  
This disables the authentication code. All user verification happens through the login and password prompt. During option negotiation, otelnetd will not send DO AUTHENTICATION and, if necessary, will send DONT AUTHENTICATION.

**Note:** Authentication is not supported for IPv6 connections. If tcp6 is specified in inetd.conf, -a should not be used as a start option. If tcp6 and -a are both specified, the suboption will be overridden and forced to OFF.

**-X authtype**

This option disables the use of authtype authentication. Currently the only valid value for authtype is KERBEROS\_V5. Thus, if otelnetd sends the AUTHENTICATION option SEND command, the authentication-type-pair-list will not contain any KERBEROS\_V5 entries and will be empty.

**-s**

Used to set the KRB5\_SERVER\_KEYTAB environment variable. If this environment variable is set, run time security uses a local instance of the Kerberos security server to decrypt service tickets instead of obtaining the key from a key table. To use this capability, the otelnetd application must have at least READ access to the IRR.RUSERMAP resource in the FACILITY class. For more information, see [z/OS Integrated Security Services Network Authentication Service Administration](#).

## SMF record handling

The SMF records generated are the typical set of records that MVS generates for start of job (login) and end of job (logout). Additionally, interval records might be issued during the life of the user login. These records are SMF type 30 and type 72 and not the type 118 or type 119 in the current z/OS UNIX Telnet server. The process of issuing these records is external to the specific daemons.

## BPX.DAEMON considerations

If the BPX.DAEMON FACILITY class profile is defined, perform the following additional configuration steps:

1. Provide read access to BPX.DAEMON for the user ID specified in /etc/inetd.conf for otelnetd.
2. Define SEZALOAD to program control.
3. Define the C run-time library, *hlq.SCEERUN* to program control.

See [z/OS UNIX System Services Planning](#) for more information about the BPX.DAEMON FACILITY class profile, the security product commands used to perform the required configuration, and the diagnosis procedure for resolving related problems.

## Kerberos

otelnetd supports Kerberos Version 5 for authentication on IPv4 connections. Authentication is not supported on IPv6 connections (that is, if tcp6 is specified for otelnetd in inetd.conf). On z/OS, Kerberos is implemented by Security Server. See [z/OS Integrated Security Services Network Authentication Service Administration](#) for more information.

If you plan to use Kerberos authentication with otelnetd, you need to ensure that the user ID under which inetd runs has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID of inetd has read access to the following ICSF SAF resources:

CSF1TRC, CSF1SKE, CSF1SKD, CSF1TRD, and CSFOWH

The Kerberos principal used by otelnetd will generally be of the form "host/<hostname>@realm". That is, the first component of the Kerberos principal is "host"; the second component is the fully qualified lowercase hostname of the server; and the realm is the Kerberos realm to which the server belongs.

otelnetd will not accept forwarded credentials from the client.

Successful AUTHENTICATION option negotiation is required for successful ENCRYPT option negotiation. The ENCRYPT option must be negotiated in both directions.

---

## Chapter 12. Transferring files using FTP

The File Transfer Protocol (FTP) allows a user to copy files from one machine to another. The protocol allows for data transfer between the client (the user) and the server in either direction. In addition to copying files, the client can issue FTP commands to the server to manipulate the underlying file system of the server (for example, to create or delete directories, delete files, rename existing files, and so on.) FTP is the most common TCP/IP application for moving files between computers.

Copying files from one machine to another is one of the most frequently used operations. The data transfer between client and server can be in either direction. The client can send a file to the server machine. It can also request a file from this server.

To access remote files, the user must identify himself or herself to the server. At this point the server is responsible for authenticating the client before it allows the file transfer.

From an FTP user's point of view, the link is connection-oriented. FTP uses TCP as a transport protocol to provide reliable end-to-end connections. Both hosts must run TCP/IP to establish file transfer.

The z/OS model for the FTP server includes a daemon process and a server process. The daemon process starts when you start your cataloged procedure (for example, START FTPD) and it listens for connection requests on a specific port. The port is the well-known port 21 unless otherwise specified. For methods of choosing a different port number, see [“Configuring ETC.SERVICES” on page 689](#) and [“Configuring the FTPD cataloged procedure” on page 689](#). When the daemon accepts an incoming connection, it creates a new process (server's address space) for the FTP server, which handles the connection for the rest of the FTP login session. Each login session has its own server process.

The server process inherits the accepted connection from the daemon process. This connection is called the control connection. The server receives commands from the client and sends replies to the client using the control connection. The control connection port is the same as the daemon's listening port.

The client and server use a different connection for transferring data; this connection is called the data connection. By default, the data port is one less than the control connection port. For example, if the control connection port is 21, the data port is 20. An FTP client can override the default data port by directing the server to run in passive mode. In passive mode, the server uses an ephemeral port for the data port. Passive mode is requested by firewall friendly clients and by clients initiating three-way data transfers.

### Notes:

1. This topic discusses RACF configuration required for FTP. References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on configuration.
2. If you use the environment variable `_BPX_JOBNAME` when you start FTPD, the server's address space is known as the job name specified in the `_BPX_JOBNAME` variable. You might need to have a common naming convention for your installation's FTP address spaces if your installation uses syslogd isolation or has other workload management requirements.

If you do not use the `_BPX_JOBNAME` environment variable, the server's address space assumes the name of the user. For example, if a user logs into an FTP server with the user ID TCP0001, the FTP server address space servicing the request is also known as TCP0001.

If the FTP daemon accepts a connection that is protected by the TLS security mechanism and you are not using the `_BPX_JOBNAME` environment variable, the server's address space name is a name derived from the FTP server job name. The name is in the form *jobnamex*, where the *jobname* value is the job name, and the *x* value is a number in the range 1 – 9. If the FTP daemon accepts a connection that is protected by the TLS security mechanism and you are using the `_BPX_JOBNAME` environment variable, the server's address space name is a name derived from the `_BPX_JOBNAME` environment variable. The name is in the form *bpxjobnamex*, where the *bpxjobname* value is the value specified for the `_BPX_JOBNAME` environment variable, and the *x* value is a number in the range 1-9.

## Configuring PROFILE.TCPIP for FTP

If you have configured the FTP server to have affinity to a specific stack, or you have configured the FTP server to be a generic server in a single stack environment, the FTP server can be started automatically when the TCP/IP address space is started by specifying the name of the FTP server cataloged procedure in the AUTOLOG statement. If you have configured the FTP server as a generic server in a multiple stack environment, you should not use the AUTOLOG statement to automatically start the server. Instead, use some other automation outside of AUTOLOG to automatically start the server.

In the following example, if your procedure is called FTPD, the following statement allows TCP/IP to issue the MVS START command for procedure FTPD. The job name of FTPD1 will be used on the port statement shown below. If the daemon job name is fewer than eight characters, the FTP daemon forks a process that has the job name of the original daemon appended with the numeral 1.

```
AUTOLOG
 FTPD JOBNAME FTPD1
ENDAUTOLOG
```

To reserve ports 21 and 20 for the FTP server, add the following statement:

```
PORT
 21 TCP FTPD1 ; FTP server control port
 20 TCP OMVS NOAUTOLOG ; FTP server data port
```

Specifying FTPD1 on the PORT and AUTOLOG statements directs TCP/IP to restart FTPD if it should end.

To allow FTP to detect data connection errors when there has been no activity on the data connection for a certain amount of time, set the INTERVAL parameter on the TCPCONFIG statement to a relatively low value. The keepalive packets that the stack sends as specified on the INTERVAL parameter enable the stack to detect errors, such as a reset or terminated peer connection, instead of waiting indefinitely. Be careful when choosing an INTERVAL value on the TCPCONFIG statement because this value will affect all TCP connections at the host for which the interval has been activated, not just FTP connections.

The control connection can also benefit from keepalive packets. Many firewalls require periodic activity on any connection that is made and the control connection can appear idle during a long data transfer. Coding the INTERVAL parameter on the TCPCONFIG statement will, of course, cause keepalive packets to be sent on the control connection as well as the data connection. You can override the keepalive interval that you have configured in the stack for the FTP control connection and data connection with the FTPKEEPALIVE (control connection) and DATAKEEPALIVE (data connection) statements in the FTP.DATA file or data set.

Optimally, FTP needs a buffer size of at least 180K for data connections. You should not set the TCPMAXRCVBUFRSIZE parameter below 180K. The default value for the parameter is 256K. IBM Health Checker for z/OS can be used to check whether the TCPMAXRCVBUFRSIZE value is sufficient to provide optimal support to the z/OS Communications Server FTP server. For more details about [IBM Health Checker for z/OS](#), see [z/OS Communications Server: IP Diagnosis Guide](#) and [IBM Health Checker for z/OS User's Guide](#).

For more information about the AUTOLOG, PORT, and TCPCONFIG statements, see [z/OS Communications Server: IP Configuration Reference](#).

If your FTP server accepts connections on a distributed Dynamic VIPA (DVIPA), SYSPLEXPORTS must be specified for the distributed DVIPA if either of the following conditions are true:

- The DVIPA is an IPv6 address.
- Passive mode FTP is used.

For more information about the [VIPADYNAMIC statement summary](#) and specifying the SYSPLEXPORTS option on the VIPADISTRIBUTE parameter, see [z/OS Communications Server: IP Configuration Reference](#).

## Configuring ETC.SERVICES

The ETC.SERVICES file contains the relationship between service names (servers) and port numbers in the z/OS UNIX environment. If necessary, update your ETC.SERVICES file to include the control port that the FTP server is to use. For the search order used to locate the ETC.SERVICES file, see [“Configuration files for TCP/IP applications”](#) on page 25. For example, add the following line:

```
ftp 21/tcp
```

### Notes:

1. In the ETC.SERVICES file, only one port (the one for the control connection) is listed.
2. If the ETC.SERVICES file is changed such that a port other than 21 is specified, that port will become the FTP port for that z/OS host.
3. The port specified for FTP in the ETC.SERVICES file can be overridden by the FTP start parameter, `PORT nnnn`. In either case, the port that is specified should match the port specified for FTP on the `PORT` statement in `PROFILE.TCPIP`.

## Configuring /etc/syslog.conf

**Note:** For FTP syslog, you should consider the fact that FTP writes log messages to the system console if syslogd is not running. If you enable FTP server traces without syslogd active, large amounts of data might be written to the system console.

The `daemon.priority` entries in `/etc/syslog.conf` determine where FTP messages and trace entries are written. The FTP server issues info, warning, and error messages. All trace entries are written with debug priority. To direct trace entries (and all messages) to `/tmp/daemon.trace`, include the following line in `/etc/syslog.conf`:

```
..daemon.debug /tmp/daemon.trace
```

Log messages can be isolated within syslogd. For FTP, an installation might want FTP log messages to be written to different files depending on the user ID, or separately for the FTP daemon. If FTP messages are to be isolated for `user1`, use the first statement below. If FTP messages are to be logged for all the FTP applications, use the second statement below.

```
user1.*.daemon.debug /tmp/daemon.trace
```

```
.FTPD.daemon.debug /tmp/daemon.trace
```

In this statement, it is assumed that `_BPX_JOBNAME` is set to `FTPD`.

## Configuring the FTPD cataloged procedure

The FTPD cataloged procedure is sample JCL that you can use to start the FTP server. To use the sample, you must modify it to suit your needs.

### Before you begin

You must configure TCP/IP and your security product. You will modify the configuration of your security product for use with your FTP server.

### Procedure

Perform the following steps to configure the FTPD cataloged procedure:

1. Copy the sample in `SEZAINST(FTPD)` to your system or recognized `PROCLIB`.
2. Update the `SYSFTPD DD` and `SYSTCPD` statements.

See [“Configuring FTP.DATA”](#) on page 701 to configure SYSFTPD DD and [“Configuring TCPIP.DATA for FTP”](#) on page 700 to configure SYSTCPD DD.

3. Decide whether you will pass start parameters in the FTPD catalogued procedure.

- If you are not going to pass start parameters, add your parameters to the FTP.DATA file.
- If you are going to pass start parameters, add your parameters to the PARMS parameter in the PROC statement of the FTPD catalogued procedure.

Any parameters that you modify in the PROC statement override parameters that are set in the FTP.DATA file.

The system parameters required by the FTP server are passed by the PARM parameter on the EXEC statement of the FTPD catalogued procedure. For example, the entry `//FTPD PROC MODULE='FTPD',PARMS='TRACE ANONYMOUS PORT 21'` starts FTP with tracing active, anonymous support enabled, and using control port 21.

For more information about the FTP server catalogued procedure (FTPD) parameters, see [z/OS Communications Server: IP Configuration Reference](#).

4. Define the FTPD catalogued procedure to the security program.

Add the FTPD catalogued procedure to the RACF STARTED class facility or to the started procedures table.

The user ID that is associated with the FTP server STARTED class must have UID 0. If the FACILITY class is active and the BPX.DAEMON or BPX.POE profiles are defined, the user ID that is associated with the FTP server must have READ access to them.

5. (Optional) If the daemon address space will be configured to run as nonswappable, provide at least READ access to the FACILITY class resource BPX.STOR.SWAP.
6. Set up security for the FTP server.

See [“Security for the FTP server”](#) on page 690 for information about setting up security.

7. (Optional) Define environment variables.

See [“Defining environment variables for the FTP server \(optional\)”](#) on page 699 for information about defining environment variables for the FTP server.

## Results

When you are done, you should be able to start the FTPD catalogued procedure with no errors. If you receive errors, then ensure that you have completed all the steps correctly.

See SEZAINST(EZARACF) for more information about SAF resource requirements needed for FTP.

**Restriction:** The Language Environment runtime option NATLANG(JPN) is not supported. If you specified NATLANG(JPN) as a Language Environment runtime option, then you need to specify `PARM='NATLANG(ENU)'` in the FTPD catalogued procedure to override the runtime option for FTP.

## Security for the FTP server

To provide security for the FTP server, you must perform the following tasks:

1. (Optional) Activate and define the SERVAUTH class (see [“\(Optional\) Steps for activating and defining the SERVAUTH class”](#) on page 691).
2. Set up security for the FTP server (see [“Steps for setting up security for your FTP server”](#) on page 691).
3. Provide and control user access to the FTP server (see [“Steps for controlling user access to the FTP server”](#) on page 692).
4. Set up a port of entry for users of the FTP server (see [“Steps for setting up a port of entry for users of the FTP server”](#) on page 693).
5. Provide and control user access to the z/OS UNIX file system (see [“\(Optional\) Steps for controlling user access to the z/OS UNIX file system”](#) on page 694).

6. Provide and control user access to FTP JES mode (see [“\(Optional\) Steps for controlling user access to FTP JES mode”](#) on page 695).
7. Prevent exploitation of your FTP server (see [“Preventing exploitation of your FTP server”](#) on page 696).
8. (Optional) Assign password phrases to user IDs that are used to log in to the FTP server (see [“\(Optional\) Assigning password phrases to user IDs that are used to log in to the FTP server”](#) on page 697).

FTP uses resource profiles in the System Authorization Facility (SAF) SERVAUTH class to control access to certain facilities and servers. When access to a resource is controlled by a profile in the SERVAUTH class, you must activate and RACLIST the SERVAUTH class. You do not have to use the SERVAUTH class, but when a profile is defined in that class, all FTP users who require access to it must be permitted to it.

For more information, see [z/OS UNIX System Services Planning and z/OS Security Server RACF Security Administrator's Guide](#). For more information about network access security zones, see [“Network access control”](#) on page 162. If you are planning to implement a multilevel security environment on your z/OS system, see [Chapter 4, “Preparing for IP networking in a multilevel secure environment,”](#) on page 213.

## (Optional) Steps for activating and defining the SERVAUTH class

FTP uses resource profiles in the System Authorization Facility (SAF) SERVAUTH class to control access to certain facilities and servers.

### Before you begin

You need to know which resource profiles you want to define. You need to install and start your security product.

### Procedure

Perform the following steps to activate and RACLIST the SERVAUTH class, if you have not already done so:

1. Issue the following command from a RACF special user to activate the SERVAUTH class:

```
SETROPTS CLASSACT (SERVAUTH)
```

**Requirement:** If you change the SERVAUTH class after you activate it, you must refresh the class. Changes include, but are not limited to, adding a resource profile to the SERVAUTH class or changing access to a profile in the SERVAUTH class. To refresh the class, issue the following command from a RACF special user:

```
SETROPTS RACLIST (SERVAUTH) REFRESH
```

2. Issue the following command from a RACF special user to RACLIST the SERVAUTH class:

```
SETROPTS RACLIST (SERVAUTH)
```

## Steps for setting up security for your FTP server

You need to provide appropriate access to the user ID that is associated with the FTP daemon.

### Before you begin

You need to know the user ID that is associated with the FTP daemon and how TCP/IP is configured for security. You should also know the resource profiles that are in the SAF classes.

### Procedure

To set up security for your FTP server, perform one or more of the following tasks:

- If the SERVAUTH class is activated and a profile is defined for the EZB.STACKACCESS.*mvname.tcpname* resource, you must grant the user ID that is associated with the FTP daemon READ access to the profile.
- If the SAF class APPL is activated and the OMVSAPPL resource profile is defined, grant the user ID that is associated with the FTP daemon READ access to the OMVSAPPL resource profile.  
For more information on [defining the OMVSAPPL profile](#), see [z/OS UNIX System Services Planning](#).
- If the SAF class APPL is activated and you have a resource profile defined in that class that matches the job name of the address space that the FTP server starts when a user logs into FTP, a user ID should have READ access to that resource profile.
- The FTP daemon listening port should be reserved for the FTPD job by a PORT statement in the TCPIP PROFILE. If the PORT statement for the FTPD port is protected with the SAF keyword, you must define a SERVAUTH profile for the EZB.PORTACCESS.*sysname.tcpname.SAFkeyword* resource. The user ID associated with the FTP daemon must have READ access to that resource.
- If your IP network is configured to use named security zones, grant the user ID that is associated with the FTP daemon READ access to the security zone that maps its bind address (0.0.0.0/32 for INADDR\_ANY or ::/128 for the IPv6 unspecified address, in6addr\_any), unless these addresses are overridden by the PORT statement in the TCP/IP profile.

## Results

You know you are done when you can start the FTP server without receiving an error.

## Steps for controlling user access to the FTP server

Every user that logs in to your FTP server requires access to that server. Use these steps to provide and control user access to your server.

### Before you begin

You need to know which users you want to allow to log in to your FTP server. You need to know whether your IP network is configured to use named security zones.

## Procedure

Perform the following steps to control user access to the FTP server:

1. Provide each user who is going to log in to the FTP server with a z/OS UNIX UID.  
You can either provide a UID to the user, or the user can use the default UNIX UID.
2. If your IP network is configured to use named security zones, each defined security zone has a SERVAUTH profile for the resource named EZB.NETACCESS.*sysname.tcpname.zonename*. If the client IP address is mapped into a network access security zone, grant each login user ID READ access to the SERVAUTH profile that corresponds to the security zone.  
For more information about security zones, see [“Network access control” on page 162](#).
3. Do one or more of the following items to allow only certain users to log in to the FTP server:
  - Code an FTCHKPWD user exit routine to allow or deny access to users, based on user ID.  
For more information about user exits, see [FTP server user exits in z/OS Communications Server: IP Configuration Reference](#) and [“Configuring the optional FTP user exits” on page 734](#).
  - Use the SERVAUTH resource profile that FTP uses for TLS level 3 authentication to control which users can log in to FTP:
    - a. Define a profile in the SERVAUTH class for the FTP port.
    - b. Grant at least READ access to the profile to the users that you want to permit to log in to FTP.

For example, if your security product is RACF, your FTP port is port 21, and the profile that you defined is EZB.FTP.\*.PORT21, issue the following command to grant the user ID FTPUSER access to the profile:

```
PERMIT EZB.FTP.*.PORT21 CL(SERVAUTH) ID(FTPUSER)
```

See [z/OS Security Server RACF Command Language Reference](#), [z/OS Security Server RACF Security Administrator's Guide](#), or the documentation for your SAF-compliant security product for more information.

c. Code VERIFYUSER TRUE in the server's FTP.DATA file.

FTP verifies the user's access to the profile for every session, whether or not that session is secured. TLS-secured sessions are also verified, even when level 3 authentication has not been requested.

4. (Optional) Set up transport layer security (TLS) support or Kerberos support for the FTP server.

The FTP server supports TLS. TLS enables secure file transfer by providing data privacy, message authentication, and message integrity services for data sent and received using the FTP control and data connections. For information about setting up TLS support for the FTP server, see [“Customizing Transport Layer Security and Kerberos security”](#) on page 711.

You can use the Generic Security Service Application Programming Interface (GSSAPI) to authenticate FTP clients to FTP servers. For more information about setting up GSS support for the FTP server, see [“Customizing Transport Layer Security and Kerberos security”](#) on page 711.

## Results

When you are finished, only certain users will be able to log in to your FTP server.

## Steps for setting up a port of entry for users of the FTP server

The *port of entry* is the origin of work for the FTP server. You must establish a port of entry for each user who logs in to your FTP server.

### Before you begin

You must know:

- The IP addresses of the clients that are to log in to your FTP server
- Whether your connection partners are in a network access security zone
- Whether your RACF SETROPTS options are TERMINAL(READ) or TERMINAL(NONE)

For IPv4 connection partners, you can establish either terminal access or SERVAUTH access. IPv6 connection partners must use SERVAUTH access, which is established automatically for them.

## Procedure

Perform the following steps to set up the port of entry for IPv4 and IPv6 users of the FTP server.

- To establish terminal access for IPv4 connection partners, take one of the following actions:

- If your RACF SETROPTS options are TERMINAL(NONE):

1. Define profiles for the IP addresses that you want to permit to your system in the TERMINAL class.

Translate all the IP addresses of any clients that connect to the FTP server to an 8-byte hexadecimal character strings that contain an IPv4 address. Add the strings to the TERMINAL class.

For example, the IP address 163.97.227.17 is translated to A361E311. To allow all addresses in the 163.97.227.17 subnet, code the following statement:

```
RDEFINE TERMINAL A361E3* UACC(READ)
```

2. Ensure that login user IDs have READ access to the TERMINAL profile that includes their client system IP address.
  - If your RACF SETROPTS options are TERMINAL(READ), then all terminals are allowed access to your system and you do not need to add extra resource definitions to your RACF database.
- To establish SERVAUTH access, instead of terminal access, for IPv4 connection partners, specify PORTOFENTRY4 SERVAUTH in the FTP.DATA file. The FTP server will use the UNIX System Services \_poe() service to identify the control socket as the port of entry.
- To establish SERVAUTH access for IPv6 connection partners, you do not need to do anything; IPv6 connection partners automatically establish SERVAUTH access. If the IPv6 connection partner is not in a network access security zone, the \_poe() service does not pass a port of entry resource name and the port of entry is not checked. For information about network access security zones, see [“Network access control” on page 162](#).

For IPv4 and IPv6 users with either terminal or SERVAUTH access, you can optionally restrict access to DATASET resources during the login session by adding WHEN(TERMINAL=...) or WHEN(SERVAUTH=...) conditions to DATASET resource profiles in RACF.

## Results

When you are finished, access to the FTP server is controlled based on the client's port of entry.

## (Optional) Steps for controlling user access to the z/OS UNIX file system

FTP uses the resource profile EZB.FTP.sysname.ftpddaemonname.ACCESS.HFS in the SAF SERVAUTH class to control access to the z/OS UNIX file system. If you do not control access to this profile, then all users can access your z/OS UNIX file system.

## Before you begin

If the FTP.DATA file for the server specifies STARTDIRECTORY HFS and the user is not permitted to the SERVAUTH class profile, FTP makes the TSO user ID the starting directory.

You must have the authority to issue the necessary RACF commands.

## Procedure

Perform the following steps to control access to the z/OS UNIX file system:

1. Define the profile for the FTP user access to the z/OS UNIX file system.

The profile has the following form:

```
RDEFINE SERVAUTH EZB.FTP.sysname.ftpddaemonname.ACCESS.HFS
```

For example, the profile name for FTP daemon FTPD running on system MVSA is the following name:

```
EZB.FTP.MVSA.FTPD1.ACCESS.HFS
```

**Tip:** The profile name can contain wildcard values as allowed by the security product. All security-product rules (for example wildcards, PROTECTALL, and so on) apply. For example, if all systems will use the same access list and RACF generic profile checking is active for the SERVAUTH class, you could use the following profile name:

```
EZB.FTP.*.FTPD.ACCESS.HFS
```

2. Permit the user IDs that require access to the z/OS UNIX file system to the profile:

```
PERMIT EZB.FTP.sysname.ftpddaemonname.ACCESS.HFS CL(SERVAUTH)
ID(ftpuser)
```

3. Issue the following command to activate the RACF SERVAUTH class, if it is not already activated:

```
SETROPTS CLASSACT (SERVAUTH)
```

4. Take one of the following actions:

- RACLIST the SERVAUTH class, if this is a new profile:

```
SETROPTS RACLIST (SERVAUTH)
```

- Refresh the SERVAUTH class, if you have changed an existing profile:

```
SETROPTS RACLIST (SERVAUTH) REFRESH
```

## Results

When you are finished, only certain users will be able to access the z/OS UNIX file system.

## (Optional) Steps for controlling user access to FTP JES mode

FTP uses the SAF resource `EZB.FTP.sysname.ftpdemonname.ACCESS.JES` in the SERVAUTH class to control access to FTP JES mode. If you do not control access to this resource, then all users can use FTP JES mode. While in JES mode a user can submit a job, display job output, and delete job output. You are strongly encouraged to define a profile to control access to the `EZB.FTP.sysname.ftpdemonname.ACCESS.JES` resource and grant read access only to users with a legitimate need to use JES mode.

## Before you begin

You must have the authority to issue the necessary RACF commands.

The following procedure assumes that you are using RACF as your security product. You can, however, use any SAF-compliant security product.

## Procedure

Perform the following steps to control access to FTP JES mode.

1. Define the profile for the FTP user access to FTP JES mode.

The profile has the following form:

```
RDEFINE SERVAUTH EZB.FTP.sysname.ftpdemonname.ACCESS.JES
```

For example, the profile name for FTP daemon FTPD running on system MVSA is the following name:

```
EZB.FTP.MVSA.FTPD1.ACCESS.JES
```

**Tip:** The profile name can contain wildcard values as allowed by the security product. All security-product rules (for example wildcards, PROTECTALL, and so on) apply. For example, if all systems will use the same access list and RACF generic profile checking is active for the SERVAUTH class, you could use the following profile name:

```
EZB.FTP.*.FTP1.ACCESS.JES
```

2. Permit the user IDs that require access to JES mode to the profile:

```
PERMIT EZB.FTP.sysname.ftpdemonname.ACCESS.JES CLASS(SERVAUTH)
ID(ftpuser) ACCESS(READ)
```

**Tip:**

If you allow anonymous users to login by configuring the ANONYMOUS statement in FTP.DATA, consider whether those users require access to JES mode (such a requirement would be very unusual). If anonymous users do require access to JES mode, the anonymous user ID must be

permitted to the profile. The anonymous user ID is configured on the ANONYMOUS statement or defaults to ANONYMO. See [ANONYMOUS \(FTP server\) statement in z/OS Communications Server: IP Configuration Reference](#) for more information.

3. Take one of the following actions:

- If the RACF SERVAUTH class is not already activated issue the following commands:

```
SETROPTS CLASSACT(SERVAUTH)
SETROPTS RACLIST(SERVAUTH)
```

- Otherwise (the SERVAUTH class is active), refresh the SERVAUTH class if a new profile has been added or an existing profile has changed:

```
SETROPTS RACLIST (SERVAUTH) REFRESH
```

## Results

- When you are finished, only certain users are able to access FTP JES mode.
- When a user issues SITE FILETYPE=JES, the user's access to FTP JES mode is checked. If the user is not allowed to access FTP JES mode, the FILETYPE for the connection remains unchanged.
- When a user logs into an FTP server that is configured with FILETYPE JES, the user's access to FTP JES mode is checked. If the user is not allowed to access FTP JES mode, the FILETYPE for the connection is set to the default value of sequential (SEQ) mode.

## Preventing exploitation of your FTP server

Your FTP server can be used by a client for disruptive purposes. A client can use your server to send random data to other servers, or a client can request that your server be the passive server in a three-way transfer.

Any FTP client that is in PROXY mode with your FTP server can establish a data connection to any server that is listening to a port. This situation could be very disruptive to that server, because the client could then send a very large amount of unexpected data to it. Any malicious FTP client can attack or disrupt the server in a normal server-to-client connection by making the FTP server send a large amount of data to another application server that is listening to a specific port. Because the client itself is not sending the disruptive data, it is difficult to identify the client that is causing the problem. Use the PORTCOMMAND, PORTCOMMANDPORT and PORTCOMMANDIPADDR statements in FTP.DATA to prevent your server from being used in this way.

| Table 32. PORTCOMMAND scenarios  |                                                        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|----------------------------------|--------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| When you want your server to...  | Code the following statements in the server's FTP.DATA | Comments                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| Reject all PORT or EPRT commands | PORTCOMMAND REJECT                                     | If you disable the PORT or EPRT commands, then you prevent your server from being used to send random data to other servers. However, your server loses some ability to transfer data in PROXY mode. If a client sends a PORT or EPRT command to your server to set up a proxy transfer, your server will reject the command and the proxy transfer will fail. If your client is not firewall friendly, and it does not implement the default port number and IP address for data transfer, that client cannot transfer files to and from your server. |

| Table 32. PORTCOMMAND scenarios (continued)                                                                                             |                                                            |                                                                                                                                                                                                                                                                                                                                    |
|-----------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| When you want your server to...                                                                                                         | Code the following statements in the server's FTP.DATA     | Comments                                                                                                                                                                                                                                                                                                                           |
| Reject all PORT or EPRT commands that specify well-known ports (port numbers less than 1024)                                            | PORTCOMMANDPORT NOLOWPORTS                                 | When you specify this combination, your server cannot be used to send random data to servers listening on well-known ports. However, a rogue client can use your server to send random data to servers listening on other ports. The server still supports data transfer in PROXY mode.                                            |
| Reject all PORT or EPRT commands that specify an IP address other than the client's own IP address.                                     | PORTCOMMANDIPADDR NOREDIRECT                               | When you specify this combination, a client can request data transfer in PROXY mode only between your server and a server on its own IP address. Transfers between client and server are not affected.                                                                                                                             |
| Reject all PORT or EPRT commands that specify an IP address other than the client's own IP address or port numbers that are well known. | PORTCOMMANDPORT NOLOWPORTS<br>PORTCOMMANDIPADDR NOREDIRECT | When you specify this combination, a client can request data transfer in PROXY mode only between your server and a server that is on its own IP address; the port numbers cannot be well known. The client cannot use PROXY mode to send random data to a server that is on its own IP address and listening to a well-known port. |

Your FTP server can also be used as a passive server in a three-way transfer. When a client sends a PASV or EPSV command to the server, the server opens a listening data socket. This socket is similar to the listening socket associated with the well-known port, in the sense that any application that knows its IP address and port number can connect to it (not just the client that sent the PASV or EPSV command). The client can exploit this situation to initiate a three-way data transfer, which is a data transfer between two servers. The client sends PASV to one server followed by PORT to the other. The client sets the PORT command IP address and port number to the information it gets from the PASV reply, and the second server connects to the IP address and port number specified in the PORT command, connecting the two servers. The next data transfer command causes data to move directly between the two servers. The client can also use the EPSV and EPRT commands to set up the three-way data transfer.

Three-way transfers are supported functions in the FTP protocol, but you might not want to allow your server to participate in three-way transfers. To prevent your server from being the passive server (the server that receives the PASV or EPSV command) in a three-way data transfer, code PASSIVEDATACONN NOREDIRECT in the server's FTP.DATA file. This directs the server to verify that the data connection comes from the IP address where the original FTP client is (the client that sent the PASV or EPSV command). If that is not where the data connection originates, the server closes the data socket and the next data transfer command fails.

To completely disallow the use of your FTP server in three-way transfers, code the PASSIVEDATACONN statement as described in the preceding paragraph, and the PORTCOMMANDIPADDR NOREDIRECT statement or PORTCOMMAND REJECT statement described in [Table 32 on page 696](#).

## (Optional) Assigning password phrases to user IDs that are used to log in to the FTP server

You can enable users to log in to the FTP server with password phrases by assigning password phrases to the user IDs that are used to log in to the FTP server.

**Guideline:** Use the RACF ALTUSER command to assign a password phrase to a user ID. See [assigning password phrases](#) in the [z/OS Security Server RACF Security Administrator's Guide](#) for more information.

**Rules:**

- Do not assign a character or combination of characters to a password phrase that your FTP clients cannot support.
- The maximum length of a password phrase is 100 characters.

**Tips:**

- Use alphanumeric characters to create password phrases to minimize translation problems when the client and server are using different ASCII code pages.
- If you plan to use the z/OS FTP client in batch mode, the password phrase and optional user data must fit on a single line of the batch file.

**Results:**

- When you assign a password phrase to a user ID, a user can log in with that user ID by using either the password or the password phrase.
- A user can change the password phrase when they log in to FTP.

**Restrictions:**

- The password phrase that a user enters to log in to the z/OS FTP server has restrictions beyond those that are enforced by your security product and those that are enforced by the optional ICHPWX11 user exit. The password phrase must not contain the following characters that have special meaning to the z/OS FTP server:

- NULL (X'00')
- Slash (/)
- Colon (:)
- Carriage return (<cr>)
- Line feed (<lf>)
- Interpret as command (<IAC> or X'FF')
- Telnet command characters (X'FB' - X'FE')

The z/OS FTP server translates all passwords that it receives during a session into EBCDIC before it passes them to the security product and to the FTCHKPWD exit routine.

- A user will not be able to log in to the z/OS FTP server using a password phrase if you assign a character to the password phrase that the server cannot translate from ASCII or UTF-8 to EBCDIC. The user will also not be able to log in if you assign a character that the server translates into an EBCDIC character that is different than the character that you assigned. Untranslatable characters and inconsistent translations can occur if the client and server are using different code pages, or if the character is outside the normal range of printable characters.
- The z/OS FTP server supports quotation marks in password phrases, but your FTP client might not support the use of quotation marks in password phrases.
- The password phrase must not contain leading blanks or trailing blanks.
- The maximum length of a password phrase is 100 characters.
- When you configure the z/OS FTP server for anonymous FTP, the following restrictions apply:
  - You cannot specify a password phrase instead of a password as an FTP daemon start option.
  - You cannot code a password phrase instead of a password on the ANONYMOUS statement in FTP.DATA.

If the server is configured to prompt anonymous users for a password, the user can log in with either the password or the password phrase that is assigned to the anonymous user ID.

## Defining environment variables for the FTP server (optional)

The FTP server optionally uses environment variables to identify the translate table data sets to be used for the control and data connections. The FTP server uses the following environment variables to override a default naming convention.

### Using `_FTPXLATE_name` for translation

In your FTP.DATA file, you can use the CCXLATE or XLATE statements to specify a name that corresponds to a particular data set that is to be used for the initial translate tables for the control or data connections.

#### Rules:

- CCXLATE is ignored if EXTENSIONS UTF-8 or CTRLCONN is coded in FTP.DATA.
- XLATE is ignored if SBDATACONN is coded in FTP.DATA.

FTP searches for an environment variable defined as `_FTPXLATE_name=fully_qualified_dsn` with the following specifications:

#### *name*

The XLATE or CCXLATE parameter value you coded in FTP.DATA. You can code 1 to 8 alphabetic or numeric characters.

#### *fully\_qualified\_dsn*

A fully qualified MVS data set name or z/OS UNIX file name.

#### Requirements:

- You must use uppercase letters for the *name* value of the `_FTPXLATE_name` environment variable.
- The *name* value must follow the rules for an MVS data set qualifier if you do not define the `_FTPXLATE_name` environment variable.

FTP identifies the data set corresponding to the *name* value:

- If the environment variable is defined, FTP uses the data set name that is defined by the environment variable.
- If the environment variable is not defined, FTP uses the data set name *hlq.name.TCPXLBIN*.

You can also issue the SITE XLATE= command from any client to set the translate tables for the data connection for that particular FTP session. The FTP server searches for an environment variable called `_FTPXLATE_name` and uses the data set name that `_FTPXLATE_name` defines. If the `_FTPXLATE_name` environment variable does not exist, the server searches for a data set called *hlq.name.TCPXLBIN*.

### Using TZ and other UNIX environment variables

Use the ENVAR runtime option in your FTPD start procedure to set environment variables for the FTP server. For information about using the ENVAR runtime option to set environment variables, see [z/OS XL C/C++ Programming Guide](#). The following example shows how to use ENVAR to specify environment variables in your FTPD started procedure:

```
//FTPD PROC MODULE='FTPD',PARMS=' '
//FTPD EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
// PARM=(' POSIX(ON) ALL31(ON) ',
// ' ENVAR("TZ=EST")/&PARMS')
```

### Using `_BPX_JOBNAME` for similar job names

If you want all FTP forked tasks to have similar job names, set the `_BPX_JOBNAME` environment variable. For example, for WorkLoad Manager (WLM), accounting, and isolation of syslogd messages, you might not want each FTP user that is logged in to have its user ID for a job name.

The following example shows how to use the `_BPX_JOBNAME` environment variable to assign the job name FTPD to all FTP forked tasks:

```
//FTPD PROC MODULE='FTPD',PARMS=' '
//FTPD EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("_BPX_JOBNAME=FTPD" ',
// '"TZ=EST")/&PARMS')
```

**Requirement:** If you activate the SAF class APPL and define a resource profile in that class for the job name resource that you specify with the `_BPX_JOBNAME` environment variable, you must grant user IDs that log in to FTP at least READ access to that resource.

## Using `_BPXK_SETIBMOPT_TRANSPORT` for an affinity to a specific stack

If you want to ensure that FTP has an affinity to a particular TCP/IP stack, use the `_BPXK_SETIBMOPT_TRANSPORT` environment variable. For more information, see [“Generic server versus server with affinity for a specific transport provider”](#) on page 46.

The following example shows how to use the `_BPXK_SETIBMOPT_TRANSPORT` environment variable to set the FTP server to have an affinity to TCPIPOE:

```
//FTPD PROC MODULE='FTPD',PARMS=' '
//FTPD EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE" ',
// '"TZ=EST")/&PARMS')
```

## Configuring FTP with multiple TCP/IP stacks

Prior to configuring the FTP server with multiple TCP/IP stacks, review [“Considerations for multiple instances of TCP/IP”](#) on page 45.

The FTP server can be configured as a server with affinity to a specific transport provider or as a generic server.

To configure the FTP server to have affinity to a specific transport provider, take the following actions:

- Code the `_BPXK_SETIBMOPT_TRANSPORT` keyword in the FTP cataloged procedure. The example below sets the FTP server to have an affinity to TCPIPOE.

```
//FTPD PROC MODULE='FTPD',PARMS=' '
//FTPD EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("_BPXK_SETIBMOPT_TRANSPORT=TCPIPOE" ',
// '"TZ=EST")/&PARMS')
```

- Reserve ports 21 and 20 for the FTP server in PROFILE.TCPIP as follows:

```
PORT
 21 TCP FTPD1 ; FTP server control port
 20 TCP OMVS NOAUTOLOG ; FTP server data port
```

To configure the FTP server as a generic server, reserve ports 21 and 20 for the FTP server in PROFILE.TCPIP on all transport providers. The FTP server will detect when new transport providers are activated and attempt to bind to port 21. If this port is not reserved for the FTP server, the FTP server will end with the following message:

```
EZYFT13E bind error : EDC5111I Permission denied
```

## Configuring TCPIP.DATA for FTP

The following five statements are used by the FTP server:

### **DATASETPREFIX**

Specifies HLQ for dynamic allocation

**DOMAINORIGIN**

Specifies the domain name to be appended to host name

**HOSTNAME**

Specifies the TCP host name

**LOADDBCSTABLES**

Specifies the DBCS tables used by the client and server

**MESSAGECASE**

Specifies the case that messages should be displayed in

See [Chapter 2, “IP configuration overview,” on page 11](#) for information about TCPIP.DATA or see [z/OS Communications Server: IP Configuration Reference](#) for information about these statements.

## Configuring FTP.DATA

---

The FTP.DATA data set is optional. The FTP daemon looks for this data set during initialization, using the first file it finds in the following search order:

1. A data set specified by the //SYSFTPDD DD statement
2. *ftpserve\_job\_name*.FTP.DATA
3. /etc/ftp.data
4. SYS1.TCPPARMS(FTPDATA)
5. *hlq*.FTP.DATA data set

It is not necessary to include all statements in the FTP.DATA data set. Include the statements only if the default value is not what you want, because the default will be used for any statement not included in the FTP.DATA data set.

To pick up changes made in the FTP.DATA data set, the FTP server must be stopped and restarted. Some FTP server parameters can be changed during an FTP session by the client issuing the SITE subcommand. See [z/OS Communications Server: IP User's Guide and Commands](#) for more information. The FTP client has an FTP.DATA data set which can also be used to change the defaults for the FTP client local site parameters. See the [z/OS Communications Server: IP User's Guide and Commands](#) for more information about using the FTP.DATA data set for the FTP client local site parameters.

## Optionally configuring user-level server options using FTPS.RC

The default values for the site parameters are coded in the server FTP.DATA. These SITE defaults apply to all login sessions to the server. You can customize settings for a specific user or group of users by creating an FTPS.RC configuration data set containing FTP commands specific to that login session. This file may contain a series of CWD and SITE commands. See [z/OS Communications Server: IP User's Guide and Commands](#) for information about these commands.

The FTP server uses the following search order to find the MVS data set or z/OS UNIX file:

1. *tso\_prefix*.FTPS.RC
2. *userid*.FTPS.RC
3. \$HOME/ftps.rc

## Data set attributes

Data set attributes play a significant role in FTP performance. If your environment permits, tune both BLOCKSIZE and LRECL according to the following recommendations:

- Use half a track as the block size.
- For IBM 3380 DASD, use 23424 as the block size with an LRECL of 64 bytes.
- For IBM 3390 DASD or IBM9334, use 27968 as the block size with an LRECL of 64 bytes.
- Use FB as the data set allocation format.

- Use cached DASD controllers.
- If your environment permits, use a preallocated data set for FTP transfers into MVS.

The following configuration data statements apply to FTP server's allocation of data sets.

- AUTOMOUNT
- AUTORECALL
- BLKSIZE
- BUFNO
- CONDDISP
- DATACLASS
- DCBDSN
- DIRECTORY
- DSNTYPE
- EATTR
- LRECL
- MGMTCLASS
- MIGRATEVOL
- PDSTYPE
- PRIMARY
- RECFM
- RETPD
- SECONDARY
- SPACETYPE
- STORCLASS
- UCOUNT
- UMASK
- UNITNAME
- VCOUNT
- VOLUME

See [z/OS Communications Server: IP Configuration Reference](#) for more detailed information about these keywords.

Some of these allocation variables might provide duplicate information. FTP passes all variables that are specified to the z/OS dynamic allocation function to determine which of the specifications take precedence, except for the following exceptions:

- If the data set organization is physical sequential, directory blocks are not sent.
- If neither primary nor secondary space quantities are specified, the allocation units value is not sent.

For example, the model DCB (DCBDSN) might have a record format (RECFM) that differs from the record format specified by a data class and from the one explicitly specified by the client. The order of precedence for dynamic allocation variables are as follows:

1. Any FTP.DATA statements or SITE parameters explicitly specified or in effect by default.
2. Any attributes picked up from the model DCB and not otherwise explicitly specified.
3. Any attributes picked up from the data class and not previously derived from 1 and 2 above.
4. Any system allocation defaults.

## Specifying attributes for new MVS data sets

When allocating new data sets, there are two methods you can use to specify the data set attributes. You can customize the data set attributes for your login session using the SITE command, or you can configure the data set attributes for logging in to your server using statements in FTP.DATA. Or, if your system programmer has used the Storage Management System to group together default attributes into named classes, you can specify those class names on the DATACLASS, STORCLASS, and MGMTCLASS statements.

### Dynamic allocation

The FTP server allows a client program to dynamically allocate a new physical sequential data set, a partitioned data set (PDS), or a partitioned data set extended (PDSE), for the purpose of transferring data to be written to that data set. The following optional allocation variables can be used to override and turn off the defaults that affect the allocation of the data set.

#### Variable

##### FTP.DATA statement

##### allocation units

SPACETYPE

##### blocksize

BLKSIZE

##### data class

DATACLASS

##### directory blocks

DIRECTORY

##### data set name type (physical sequential data sets only)

DSNTYPE

##### extended attributes

EATTR

##### logical record length

LRECL

##### management class

MGMTCLASS

##### model DCB values

DCBDSN

##### PDS type

PDSTYPE

##### primary space

PRIMARY

##### retention period

RETPD

##### secondary space

SECONDARY

##### space type

SPACETYPE

##### unit count

UCOUNT

##### volume count

VCOUNT

##### record format

RECFM

**retention period**

RETPD

**storage class**

STORCLASS

**unit**

UNITNAME

**volume serial number or list**

VOLUME

Some of these allocation variables might provide duplicate information. For example, the model DCB might have a record format (RECFM) that differs from the record format specified by a data class and from the one explicitly specified by the client. FTP passes all variables that are specified to dynamic allocation and lets it determine which of the specifications take precedence. The following list describes the exceptions to that policy:

- If neither the primary nor secondary space quantity is specified, the allocation units value is not sent.
- If the data set organization is physical sequential, directory blocks specification is not sent.
- Otherwise, all variables are sent to dynamic allocation where the order of precedence is:
  1. Any FTP.DATA statements or SITE parameters explicitly specified or specified by default
  2. Any attributes picked up from the model DCB and not otherwise explicitly specified
  3. Any attributes picked up from the data class and not previously derived from 1 or 2
  4. Any allocation defaults

## Storage Management Subsystem

You can specify one or more of the following Storage Management Subsystem (SMS) classes to manage characteristics that are associated with or assigned to data sets.

- Data class is an SMS construct that an installation can define to control data set allocation attributes used by SMS for the creation of data sets. An installation can override all or part of an SMS DATA CLASS definition by using FTP.DATA statements. Note that there is an order of precedence for dynamic allocation. (See [“Data set attributes” on page 701](#) for more information on the precedence.) The fields listed are available attributes that serve as a template for allocation. Each is optional and is overridden by any explicit specification of FTP-allocation variables. Except for the DSNTYPE and EATTR fields, the listed variables can be overridden by a model DCB (DCBDSN).

**Variable****FTP.DATA statement****directory blocks**

DIRECTORY

**data set name type**

DSNTYPE

**extended attributes**

EATTR

**logical record length**

LRECL

**primary space**

PRIMARY

**record format**

RECFM

**retention period**

RETPD

**secondary space**

SECONDARY

## **pds type**

PDSTYPE

**Note:** If either primary or secondary space is explicitly specified, the primary and secondary values from data class are not used.

- Management class (MGMTCLASS) is an SMS construct that determines DFHSM action for data set retention, migration, backup, and release of allocated but unused space. Management class replaces and expands attributes that otherwise would be specified. That is, management class might override any other specification of retention period.
- Storage class (STORCLASS) is a list of storage performance and availability services requests for an SMS-managed data set that SMS attempts to honor when selecting a volume or volumes for the data set. It might conflict with an explicit specification of volume and unit. If storage class is used, volume and unit should not be specified.

## **Translation of data**

Selecting an appropriate translate table for conversion of data from host to network format, and from network to host format, will ensure that data read from or written to the z/OS system are in correct format. The following statements apply to translation of data for the FTP server. See [z/OS Communications Server: IP Configuration Reference](#) for more information on these statements. The statements are:

- ASATRANS
- CTRLCONN
- DBSUB
- ENCODING
- EXTENSIONS UTF8
- MBDATACONN
- MBSSENDEOL
- MBREQUIRELASTEOL
- SBDATACONN
- SBSSENDEOL
- SBSUB
- SBSUBCHAR
- UCSHOSTCS
- UCSSUB
- UCSTRUNC
- UNICODEFILESYSTEMBOM

## **z/OS UNIX named pipes**

FTP can transfer data to and from z/OS UNIX System Services named pipes. The following statements apply to the creation of named pipes:

- UMASK
- UNIXFILETYPE

The following statements apply to the transfer of data to and from named pipes:

- CONDDISP
- FIFOIOTIME
- FIFOOPENTIME

For more information about these FTP.DATA data set statements, see [z/OS Communications Server: IP Configuration Reference](#). For information about using z/OS UNIX System Services named pipes, see [z/OS Communications Server: IP User's Guide and Commands](#).

## FTP code page conversion

Code page conversion must be performed for:

- FTP commands and replies sent over the control connection
- Data transferred over the data connection

FTP uses the iconv function to establish ASCII-to-EBCDIC and EBCDIC-to-ASCII translate tables for the control connection. The default network transfer code page for the control connection is 7-bit ASCII. In addition, FTP maintains support for the use of translate tables by the CONVXLAT utility. After a user has logged in, a SITE subcommand can be used to change the code page being used on the control connection.

FTP uses the iconv function to establish network transfer to file system and file system to network transfer translate tables for the data connection. In addition, FTP maintains support for the use of translate tables by the CONVXLAT utility.

**Note:** Using iconv conversion to retrieve EBCDIC data that was created with CONVXLAT-generated conversion tables could result in data corruption due to possible conversion table differences.

After a user has logged in, SITE and LOCSITE subcommands can be issued to change the translation tables being used for single-byte translation.

### Code page conversions for the control connection

For the control connection, FTP generally uses ASCII for the network code page, as specified in the FTP RFCs. For the host/ASCII conversion for the control connection, FTP uses either iconv() or the support for single-byte translation tables. However, when EXTENSIONS UTF8 is coded in FTP.DATA, FTP starts the connection in 7-bit ASCII and negotiates a switch to UTF-8 encoding of the control connection, as described in RFC 2640. FTP uses iconv() for the host/UTF-8 conversion.

#### Priority

The priority for establishing the conversion tables used for the control connection is:

1. FTP start parameter (FTP client only)
2. EXTENSIONS UTF8 coded in FTP.DATA
3. CTRLCONN or CCXLATE keyword in FTP.DATA
4. Search order used to locate a TCPXLBIN data set:
  - a. Original jobname.SRVRFTP.TCPXLBIN
  - b. *hlq*.SRVRFTP.TCPXLBIN
  - c. Original jobname.STANDARD.TCPXLBIN
  - d. *hlq*.STANDARD.TCPXLBIN
5. 7-bit ASCII
6. Internal (hard-coded) 7-bit tables

### Code page conversions for the data connection

For the transfer of data on the data connection, FTP supports:

- All single-byte conversions available through iconv. For example, iconv supports conversions between IBM-1047 and IBM-850, so conversions between IBM-1047 and IBM-850 are available for data transfer.

- UNICODE conversions available through iconv: UTF-8, UTF-16, UTF-16BE, and UTF-16LE for network transfer, and UTF-8 and UTF-16 for file storage.
- Multibyte conversions for the Chinese standard GB18030 using code page IBM-5488 with code page IBM-1388 or UTF-8, as well as certain double-byte character set (DBCS) code page pairs that are equivalent to supported DBCS languages.
- Both single-byte and double-byte data conversions are supported with the translate tables provided with TCP/IP or generated by the CONVXLAT utility.

### ***Priority for single-byte conversions***

How to build single-byte translate tables for converting network transfer data and file system data is determined by the following priority:

- SYSFTSX DD statement in the startup procedure, where the named data connection is CONVXLAT-generated translate tables. The data set can be an MVS data set or a z/OS UNIX file.
- SBDATACONN or XLATE keyword in FTP.DATA.
- Search order to locate a TCPXLBIN data set, where the MVS data set contains CONVXLAT-generated translate tables:
  1. Original jobname.SRVRFTP.TCPXLBIN
  2. *hlq*.SRVRFTP.TCPXLBIN
  3. Original jobname.STANDARD.TCPXLBIN
  4. *hlq*.STANDARD.TCPXLBIN
- The same conversions established for the control connection.

### ***Multibyte character sets (MBCS) support***

MBCS support in the FTP server is provided for the following code page pairs:

| <b>Support for:</b>      | <b>TYPE command</b> | <b>File system code page</b> | <b>Network transfer code page</b>     |
|--------------------------|---------------------|------------------------------|---------------------------------------|
| Chinese standard GB18030 | Not applicable      | IBM-1388 or UTF-8            | IBM-5488                              |
| BIG5                     | TYPE B 8            | IBM-937                      | IBM-950 or BIG5                       |
| EUCKANJI                 | TYPE B 2            | IBM-930                      | IBM-eucJP                             |
| JIS78KJ (JISROMAN)       | TYPE B 4 R          | IBM-930                      | IBM-5053                              |
| JIS78KJ (ASCII)          | TYPE B 4 A          | IBM-939                      | IBM-5055                              |
| JIS83KJ (JISROMAN)       | TYPE B 3 R          | IBM-930                      | IBM-5052                              |
| JIS83KJ (ASCII)          | TYPE B 3 A          | IBM-939                      | IBM-5054                              |
| KSC5601                  | TYPE B 6            | IBM-933                      | IBM-949                               |
| SCHINESE                 | TYPE B 9            | IBM-935                      | IBM-1381                              |
| SJISKANJI                | TYPE B 1            | IBM-930 or IBM-939           | IBM-932 or IBM-eucJC                  |
| TCHINESE                 | TYPE B 7            | IBM-937                      | IBM-948                               |
| UNICODE                  | Not applicable      | UTF-8, UTF-16                | UTF-8, UTF-16, UTF-16BE, and UTF-16LE |

#### **Rules:**

- ENCODING must be specified as MBCS, either in FTP.DATA or on a SITE command.

- The data type must be ASCII.
- The file structure must be FILE (not RECORD), and the transfer mode must be STREAM (not BLOCK or COMPRESS).
- The FTP file type must be SEQ (not JES or SQL).
- If the file is transferred to or from an MVS data set, the record format of the data set must be V, VB, or U.
- If a file is transferred outbound and is an MVS data set with record format V or VB, the request for RDWs is not allowed.
- Translation of ASA or machine control characters is not allowed.
- MBCS can be used as a migration path for the DBCS languages listed that have an associated TYPE B x command.

**Restriction:** The DBCS languages can be migrated to the MBCS support only if they do not use the following parameters on the TYPE B x command:

**S A**

SOSI ASCII characters X'1E' and X'1F' in the ASCII data stream

**S E**

SOSI EBCDIC characters X'0E' and X'0F' in the ASCII data stream

**S S**

SOSI SPACE characters X'20' and X'20' in the ASCII data stream

**N**

No SOSI characters in the ASCII data stream and none written to the file system

## Master catalog access

---

FTP uses the IGGCSI00 function to request catalog processing. This accesses both the user and master catalog. Users require READ access to the master catalog as well as their own user catalog.

## Customizing FTP message catalogs

---

FTP messages and replies are contained in two z/OS UNIX message catalogs as follows:

- ftpdmsg.cat

Contains messages that the FTP daemon, server, and client issue.

- ftpdrply.cat

Contains replies that the server sends to the client.

If messages in either of these catalogs need to be modified, the timestamp that is contained in the shipped level of the FTP catalog must be preserved in the modified catalog.

This timestamp is included within and is unique to each catalog. When FTP (client or daemon) is started, FTP verifies that this timestamp matches the timestamp that it expects. This prevents FTP from presenting the wrong message when the z/OS UNIX message catalogs and FTP are not synchronized.

When you apply a service update to FTP load modules that requires a service update to a catalog, you must install both at the same time. Otherwise, FTP will report an error and use default messages instead of messages from the catalog.

If you are using a modified FTP catalog, the catalog that matches the service level of FTP load modules needs to be updated with your local modifications, and the timestamp of the catalog must be preserved.

## Steps for creating a message catalog from the shipped catalog and preserving its timestamp

After using these steps you can then update the file with your local modifications and create a new FTP catalog with the preserved timestamp. Perform all of these steps from the z/OS UNIX shell; the commands indicated are z/OS UNIX commands.

### Before you begin

This example assumes that the FTP code and catalog are at the correct levels and that only local customization to the catalog is to be performed. Also, if you customize a catalog, IBM Service personnel might require that you use the shipped level of the catalog to recreate and diagnose a reported problem.

### Procedure

Perform the following steps to create a file from the shipped catalog and preserve its timestamp:

1. Copy the official z/OS UNIX catalog that is shipped with the release or service to a backup file.

```
cp /usr/lpp/tcpip/lib/nls/msg/C/ftpdmsg.cat /tmp/ftpdmsg.cat.backup
```

2. Using the **dspcat** command, convert a copy of the backup catalog that you just copied to a copy that you can edit.

This is the file that you need to update to preserve the timestamp, and that you will update to support any local user message changes.

```
dspcat -t -g /tmp/ftpdmsg.cat.backup >/tmp/ftpdmsg.cat.copy
```

3. Change the first line in the catalog from a comment to a z/OS UNIX **gencat** command, which enables the timestamp to be imbedded in the catalog when it is rebuilt.

- a) Edit the file to be updated.

```
oedit /tmp/ftpdmsg.cat.copy
```

- b) Change the first line comment to add a **gencat** command to preserve the timestamp when the directory is built.

The first line in the file will be similar to the following line:

```
The time stamp of catalog /tmp/ftpdmsg.cat.backup is: 2006 095 20:30 UTC
```

Replace the leading text on the line with the **gencat** subcommand **\$timestamp** as follows:

```
$timestamp 2006 095 20:30 UTC
```

If this step is omitted and the original line is left in the catalog, when an attempt is made to generate a catalog from this file, you will see a message similar to the following message:

```
FSUM5108 gencat: Invalid message number.
```

- c) Save the file.

4. Update the catalog (/tmp/ftpdmsg.cat.copy) with any local modifications and save the file.
5. Build a new and customized catalog using the z/OS UNIX **gencat** command, and save a copy of the shipped level of the catalog.

```
gencat /tmp/ftpdmsg.cat /tmp/ftpdmsg.cat.copy
```

The correct response is:

```
FSUM5105 gencat: Message catalog generated normally.
```

6. Browse the new catalog and verify that the timestamp from step “3” on page 709 matches what is in the file.

```
obrowse /tmp/ftpdmsg.cat
```

The first record contains the time stamp (*yyyy ddd hh:mm* UTC). For example:

```
...2006 095 20:30 UTC
```

7. Replace the official z/OS UNIX catalog that is shipped with the release with the updated catalog that you created in step “5” on page 709.

## Results

You know you are done when you test the catalogs to verify correct synchronization by performing the following actions:

1. Start the FTP server and inspect the syslog output (console if no syslog is running). Message EZYFS30W should not appear.
2. Using the FTP client, connect to the FTP server and inspect the SYSPRINT output. Message EZYFS31W should not appear.

For more information about the **dspscat** and **gencat** utilities, see [z/OS UNIX System Services Command Reference](#).

## Accounting

---

The following parameters apply to SMF data:

- SMF
- SMFAPPE
- SMFDEL
- SMFEXIT
- SMFJES
- SMFLOGN
- SMFREN
- SMFRETR
- SMFSQL
- SMFSTOR

See [z/OS Communications Server: IP Configuration Reference](#) for more information on these statements.

## Configure the FTP server for SMF (optional)

The FTP server can write SMF type 118 (X'76') or type 119 (X'77') records to record transactions made by the FTP server. SMF records can be written for the following commands:

- APPE (append)
- DELE (delete)
- RNTD (rename)
- RETR (retrieve)
- STOR (store)
- STOU (store unique)

Information about the previous commands can be recorded for:

- FTP server running in normal data transfer mode (FILETYPE=SEQ)
- FTP server running remote job submission (FILETYPE=JES)
- FTP server running Structured Query Language (SQL) queries (FILETYPE=SQL)

- Any combination of SEQ, JES, and SQL

For commands involving data transfer (APPEND, RETR, STOU or STOR) an SMF record will be written for both successfully and unsuccessfully completed data transfer commands which have begun data transfer. For data transfer commands which have completed unsuccessfully, the byte count of transmission field will contain the number of bytes transferred before the failure, and the recent server reply field will contain the 3-digit error reply code sent to the client. See the information about [type 118](#) and [Type 119](#) SMF records in [z/OS Communications Server: IP Programmer's Guide and Reference](#) to find the particular offsets for the record type being used.

The FTP server can also write SMF records when a login attempt fails.

The capability also exists for a user-written exit routine to get control before the SMF records are written. See [“Configuring the optional FTP user exits”](#) on page 734 for more information.

If you want the FTP server to write SMF type 118 (X'76') or type 119 (X'77') SMF records, you must include at least one of the SMF subtype statements (SMF, SMFAPPE, SMFDEL, SMFLOGN, SMFREN, SMFRETR, or SMFSTOR) in the FTP.DATA data set.

If SMF subtype statements are not coded in the FTP.DATA data set, no SMF records are written by the FTP server.

For more information about enabling SMF TYPE 119 records for FTP Server, see [SMF \(FTP server\) statement](#) in [z/OS Communications Server: IP Configuration Reference](#).

## Customizing Transport Layer Security and Kerberos security

---

The following terms apply to Transport Layer Security (TLS) and Kerberos.

### **Integrity protected, data integrity, or data authentication**

Indicates an algorithm is applied to the data being transferred, which modifies the data such that the receiving program can verify the data was not modified or changed during the transfer.

### **Privacy protected**

Indicates an algorithm is applied to the data being transferred, which encrypts or scrambles the data such that only the receiving program can use a special key to decrypt or unscramble the data to its original format. The original data cannot be seen or interpreted while the data is in transit.

### **Raw**

Indicates data is transmitted without being modified by any encryption or data integrity algorithms.

### **Encipher or cipher algorithm**

Data being transferred is encrypted, integrity protected, or both. This term does not imply which algorithm is used and does not imply the data is encrypted.

## Steps for customizing the FTP server for TLS

You can customize the FTP server for TLS using AT-TLS.

### **Before you begin**

Understand the following information:

- The FTP server must be enabled to support both TLS and Kerberos. Some of the configuration statement settings apply to both TLS and Kerberos and affect the behavior of both.
- To support TLS, the FTP server must be configured to use Application Transparent TLS (AT-TLS) as a controlling application. For more information about AT-TLS, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149.

**Note:** The use of TLS requires the use of X.509 digital certificates. For more about certificates and key ring databases, see [Appendix B, “TLS/SSL security,”](#) on page 1359.

**Requirement:** AT-TLS requires Policy Agent to be configured, and the TCP/IP stack to be enabled for AT-TLS. To configure AT-TLS, see [“Configuring the server system”](#) on page 1154.

## Procedure

Perform the following steps to customize the FTP server for TLS:

1. Decide what level of RFC 4217, *On Securing FTP with TLS*, that you want the server to support.
  - To have the server support *On Securing FTP with TLS* at the Internet draft level, code the following statement in the server's FTP.DATA configuration file:

```
TLSRFCLEVEL DRAFT
```

This is the default. The z/OS FTP server has supported TLS security at this level since V1R2. Code this statement in FTP.DATA to maintain this level of support.

- To have the server support *On Securing FTP with TLS* at the RFC 4217 level, code the following statement in the server's FTP.DATA configuration file:

```
TLSRFCLEVEL RFC4217
```

The RFC *On Securing FTP with TLS* was published as RFC 4217 in October, 2005. The RFC differs from the Internet draft in its description of the AUTH, CCC, and REIN commands. RFC 4217 is less restrictive than the Internet draft regarding when the AUTH and CCC commands can be sent to the server, and more explicit about the details of the server REIN implementation. For more information, see RFC 4217.

2. Code the following statement in the server's FTP.DATA configuration file to enable the server for TLS:

```
EXTENSIONS AUTH_TLS
```

3. Decide what level of authentication you will use for TLS sessions:

- Server authentication only
- Client authentication level 1
- Client authentication level 2
- Client authentication level 3

For more information about server authentication and client authentication, see [“Secure Socket Layer overview” on page 1359](#).

4. Create the server key ring database and add the certificates you will need to the server key ring database.

Every TLS session handshake includes server authentication, so you must always add a certificate for this server to the server key ring database. If a server certificate is self signed, you must also export that certificate to the key ring databases of those clients that will log in using TLS. If a server certificate is signed by a certificate authority (CA), the CA certificate used to sign the server certificate needs to be in the client key ring databases, rather than the server certificate. For more information about server authentication, see [“Server authentication” on page 1359](#).

If you are using client authentication and self-signed certificates, you must import the client certificates into the server key ring database. If a client certificate is signed by a CA, the CA certificate used to sign the client certificate needs to be in the server key ring database, rather than the client certificate. For more information, see [“Client authentication” on page 1360](#).

5. Code TLSMECHANISM ATTLS in the FTP.DATA. This is the default setting.
6. Decide whether clients logging in to this server should be required to use the TLS protocol.

The default is to allow the client to decide whether to use TLS. This setting is customized by using the SECURE\_FTP configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

To allow the client to decide whether to use TLS, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_FTP ALLOWED
```

This is the default setting, and indicates:

- If the server is enabled for TLS only, clients must either log in using TLS, or with no security mechanism.
- If the server is enabled for Kerberos only, clients must either log in using Kerberos, or with no security mechanism.
- If the server is enabled for both TLS and Kerberos, clients can log in using TLS, Kerberos, or with no security mechanism.

To require that clients log in using a security mechanism, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_FTP REQUIRED
```

This setting indicates:

- If the server is enabled for TLS only, clients must log in using TLS.
  - If the server is enabled for Kerberos only, clients must log in using Kerberos.
  - If the server is enabled for both TLS and Kerberos, clients must log in using either TLS or Kerberos.
7. If you do not want to use client authentication, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN NO_CLIENT_AUTH
```

This is the default.

If you do want to use client authentication, the following levels of client authentication are possible:

- Level 1 authentication is performed by system SSL. The client passes an X.509 certificate to the server. To pass authentication, the Certificate Authority that signed the client certificate must be considered trusted by the server. To use level 1 client authentication, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN REQUIRED
```

- Level 2 authentication provides level 1 authentication, and additionally requires that the client certificate be registered with RACF (or another SAF compliant security product) and mapped to a user ID. The client certificate received during the SSL handshake is used to query the security product to verify that the certificate maps to a user ID known to the system prior to connection negotiation. To use level 2 client authentication, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN VERIFY_USER
```

- Level 3 authentication provides level 1 and 2 authentication. In addition, it provides the capability to restrict access to the server based on the user ID returned from RACF. If the SERVAUTH class of RACF is active and the server's port profile is defined, a connection is accepted only if the requester's user ID associated with the client certificate is defined in the server's port profile. To use level 3 client authentication, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_LOGIN VERIFY_USER
```

Also, define the server's port profile in the SERVAUTH class of RACF.

If you choose to use client authentication, you can also use the client certificate authentication process to eliminate the client login password prompt so that a client supplies only the login user ID to establish the session. The certificate received from the client must be registered in the security product and must be associated with the login user ID. You can use the RACDCERT ADD command to register and associate the certificate. If either the certificate is not registered or is not associated with the user ID, you will be prompted for a password.

If you do not want to use the client authentication process to eliminate the client password prompt, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_PASSWORD REQUIRED
```

This is the default.

If you want to use the client authentication process to eliminate the client password prompt, along with your client authentication statement (either SECURE\_LOGIN REQUIRED or SECURE\_LOGIN VERIFY\_USER), code the following statement in the server's FTP.DATA configuration file:

```
SECURE_PASSWORD OPTIONAL
```

## 8. Configure the AT-TLS policy for the FTP server.

To configure AT-TLS, see [“Configuring the server system” on page 1154](#).

### Requirements:

- The FTP server is a controlling application. For more information about controlling applications, see [“Advanced application considerations” on page 1173](#).

Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicationControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.

- The FTP server requires that the HandshakeRole parameter with the value Server or ServerWithClientAuth be coded on the TTLSEnvironmentAction statement. If the SECURE\_LOGIN statement is coded in FTP.DATA with the parameters REQUIRED or VERIFY\_USER, the HandshakeRole parameter value must be ServerWithClientAuth.
- The TTLSRule statement for the FTP server requires the Direction parameter with the value Inbound.

A sample Policy Agent AT-TLS configuration showing the required policy configuration statements for AT-TLS is as follows:

```
TTLSGroupAction secure_ftp_server_group
{
 TTLSEnabled On
}
TTLSEnvironmentAction secure_ftp_server_env
{
 TTLSKeyringParms
 {
 Keyring FTPD/server-keyring-database
 }
 HandshakeRole Server # When Secure_Login NO_CLIENT_AUTH is coded
 #HandshakeRole ServerWithClientAuth # When Secure_Login Required or Verify_User is coded
 TTLSEnvironmentAdvancedParms
 {
 ApplicationControlled On
 SecondaryMap On
 TLSv1 Off
 TLSv1.1 On
 TLSv1.2 On
 TLSv1.3 On
 }
 TTLSCipherParmsRef ftp_server_ciphers # Used to customize ciphersuites for the FTP
 # server
}
TTLSCipherParms ftp_server_ciphers
{
 # Sample ciphers. Should be customized!
 V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
 V3CipherSuites TLS_DHE_DSS_WITH_AES_256_CBC_SHA
 V3CipherSuites TLS_DHE_RSA_WITH_AES_256_CBC_SHA
 V3CipherSuites TLS_RSA_WITH_AES_128_CBC_SHA
 V3CipherSuites TLS_DHE_DSS_WITH_AES_128_CBC_SHA
 V3CipherSuites TLS_DHE_RSA_WITH_AES_128_CBC_SHA
 V3CipherSuites TLS_AES_128_GCM_SHA256
 V3CipherSuites TLS_AES_256_GCM_SHA384
}
TTLSRule secure_ftp_server_rule
```

```

{
 LocalPortRange 21 # This should be set to the port the FTP server is
 # listening on
 Direction Inbound
 TTLSGroupActionRef secure_ftp_server_group
 TTLSEnvironmentActionRef secure_ftp_server_env
}

```

**Tip:** You can configure many other TLS settings in AT-TLS policy.

When you define your AT-TLS policy rules for your FTP server, you need to decide on a variety of important TLS settings, such as the acceptable TLS protocol versions and the acceptable cipher suites. If need be, work with your network security administrator to determine the proper values for these settings. For more information about AT-TLS policy statements, see [AT-TLS policy statements](#) in *z/OS Communications Server: IP Configuration Reference*.

#### 9. Decide the level of security for the data connection.

You can choose to require enciphered data transfers, or to allow the client to decide the level of security for data transfers. The default is to allow the clients to decide the level of security.

This setting is customized by using the SECURE\_DATACONN configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

If you want the server to require that data is transferred raw with no cipher algorithm applied to the data and that clients attempting to use ciphers are rejected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN NEVER
```

If you want the client to decide whether data is transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN CLEAR
```

This is the default.

For TLS, the client decides whether data is enciphered or not. If it indicates it should be enciphered, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that data is transferred enciphered and that clients attempting to send raw data are rejected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the data must be transferred using both integrity and privacy protection. Clients attempting to send data that is only integrity protected are rejected.

#### 10. Decide whether the server requires session reuse when SSL/TLS is used to protect the control and data connections.

By default, the server is enabled to reuse either of the following SSL session IDs on the data connections within an FTP session:

- The SSL session ID of the control connection
- The SSL session ID of a previous data connection

This setting is customized by using the SECURE\_SESSION\_REUSE configuration statement.

- To enable the server to reuse either of the following SSL session IDs on the subsequent data connections within an FTP session, code ALLOWED on the SECURE\_SESSION\_REUSE statement in the FTP.DATA configuration file of the server:
  - The SSL session ID of the control connection
  - The SSL session ID of a previous data connection

This is the default.

- To require the server to reuse the SSL session ID of the control connection on the subsequent data connections within an FTP session, code `REQUIRED` on the `SECURE_SESSION_REUSE` statement in the `FTP.DATA` configuration file of the server.

This setting might cause data connections and FTP transfers to fail when the remote side does not support reusing the session ID.

For information about the `SECURE_SESSION_REUSE` statement, see [z/OS Communications Server: IP Configuration Reference](#).

11. For information about configuring your security product for TLS, see [Appendix B, “TLS/SSL security,”](#) on page 1359.

## Steps for customizing the FTP server for Kerberos

The FTP server can be enabled to support both TLS and Kerberos.

### Before you begin

Some configuration statement settings apply to both TLS and Kerberos and affect the behavior of both.

Decide which RACF ID the service principal is to be associated with, which helps determine whether a keytab file is required. If the service principal is associated with the FTP startup procedure ID, a keytab file is not required. If a keytab file is not required and you do not plan to use one, decide how the FTP startup procedure is to be updated to identify the environment variable (ENVAR) `KRB5_SERVER_KEYTAB`.

### Procedure

Perform the following steps to customize the FTP server for Kerberos:

1. Code the following statement in the server's `FTP.DATA` configuration file to enable the server for Kerberos:

```
EXTENSIONS AUTH_GSSAPI
```

2. Decide whether clients should be required to use the Kerberos protocol.

The default is to allow the client to decide whether to use Kerberos.

This setting is customized using the `SECURE_FTP` configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

To allow the client to decide whether to use Kerberos, you can code the following statement in the server's `FTP.DATA` configuration file:

```
SECURE_FTP ALLOWED
```

This is the default setting, and indicates:

- If the server is enabled for TLS only, clients must either log in using TLS, or with no security mechanism.
- If the server is enabled for Kerberos only, clients must either log in using Kerberos, or with no security mechanism.
- If the server is enabled for both TLS and Kerberos, clients can log in using TLS, Kerberos, or with no security mechanism.

To require that clients log in using Kerberos, code the following statement in the server's `FTP.DATA` configuration file:

```
SECURE_FTP REQUIRED
```

This setting indicates:

- If the server is enabled for TLS only, clients must log in using TLS.

- If the server is enabled for Kerberos only, clients must log in using Kerberos.
  - If the server is enabled for both TLS and Kerberos, clients must log in using either TLS or Kerberos.
3. Decide whether to use the client authentication process to eliminate the client login password prompt so that a client supplies only the login user ID to establish the session.

The Kerberos principal that is received from the client is used to query the security product (either RACF or another SAF-compliant security product) to determine whether the Kerberos principal maps to a user ID that is known to the system. If the Kerberos principal maps to a user ID, and that user ID matches the user name passed from the client on the USER command, you can eliminate the password prompt.

If the client principal is for the same realm as the FTP server, the principal is correlated to the user ID using the KERBNAME option of the ADDUSER or ALTUSER commands. If the client principal is a cross-realm principal, it is correlated to the user ID using the RDEFINE KERBLINK command.

If you want to require the client to provide a password or password phrase even when the client authentication process does not require it, code the following statement in the server's FTP.DATA configuration file. This is the default.

```
SECURE_PASSWORD_KERBEROS REQUIRED
```

If you want to use the client authentication process to eliminate the client password prompt, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_PASSWORD_KERBEROS OPTIONAL
```

4. Decide the level of security for the data connection.

You can choose to require enciphered data transfers, or to allow the client to decide the level of security for data transfers. The default is to allow the clients to decide the level of security.

This setting is customized using the SECURE\_DATACONN configuration statement. You should understand that its setting affects both TLS security behavior and Kerberos security behavior.

If you want the server to require that data is transferred raw with no cipher algorithm applied to the data and that clients attempting to use ciphers are rejected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN NEVER
```

If you want the client to decide whether data is transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN CLEAR
```

This is the default.

For TLS, the client decides whether data is enciphered or not. If it indicates it should be enciphered, the cipher algorithm is negotiated between the server and the client using TLS protocols. For Kerberos, the client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that data is transferred both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols, and clients attempting to send raw data are rejected. For Kerberos, the data must be transferred using both integrity and privacy protection, and clients attempting to send raw data or data that is only integrity protected are rejected.

If you want the server to require that data is transferred integrity protected only or both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_DATACONN SAFE
```

For TLS, specifying this option is identical to specifying SECURE\_DATACONN PRIVATE. For Kerberos, specifying this option indicates the data can be transferred integrity protected only, or both integrity and privacy protected. Clients attempting to send raw data are rejected.

5. Ensure that the RACF user ID under which the FTP client will execute has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID has read access to the following ICSF SAF resources:  
CSF1TRC, CSF1SKE, CSF1SKD, CSF1TRD, and CSFOWH
6. Decide the level of security for the control connection (that is, for FTP commands and replies).  
You can choose to require enciphered control connection data, or to allow the client to decide the level of security. The default is to allow the clients to decide the level of security.

This setting is customized using the SECURE\_CTRLCONN configuration statement. This setting applies only to Kerberos. For TLS, the control connection is required to be enciphered and this setting has no effect on TLS behavior.

If you want the client to decide whether control data is transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_CTRLCONN CLEAR
```

This is the default.

The client can specify whether data is transferred raw, integrity protected only, or both integrity and privacy protected.

If you want the server to require that control data is transferred both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_CTRLCONN PRIVATE
```

Clients attempting to send raw data or data that is only integrity protected are rejected.

If you want the server to require that data is transferred integrity protected only or both integrity and privacy protected, code the following statement in the server's FTP.DATA configuration file:

```
SECURE_CTRLCONN SAFE
```

Clients attempting to send raw data are rejected.

7. Create the service principal against a RACF ID for use with a keytab (see step 7 for using Kerberos with no keytab).
  - a) Create a RACF user ID to associate with the FTP service principal.

```
adduser FTP NOPASSWORD DFLTGRP(SYS1) omvs(autouid home('/u/ftp') prog('/bin/sh'))
```

- b) After the FTP RACF user ID is created, add the Kerberos principal to it.

```
ALTUSER FTP KERB(KERBNAME(ftp/<hostname>))
```

- c) To ensure the Kerberos segment was added, use the following command to display the ID.

```
LU FTP NORACF KERB
```

**Result:**

```
USER=FTP
```

```
KERB INFORMATION

KERBNAME= ftp/<hostname>
KEY VERSION= 001
KEY ENCRYPTION TYPE= DES DES3 DESD
```

d) To add the FTP service principal to the keytab file, take the following actions:

- i) The keytab file is located in the /etc/skrb directory. Switch to that directory using the following command:

```
cd /etc/skrb
```

- ii) Use the following command to see what is currently in the keytab file:

```
keytab list
```

If nothing is currently in the keytab file, the following information is returned:

```
Key table: /etc/skrb/krb5.keytab
```

- iii) Add the FTP service principle using the following command:

```
keytab add ftp/<hostname>
```

You will be prompted for the principals' password. For this example, that password is FTP. The password must be entered in uppercase. This password was assigned with the RACF ALTUSER command when the FTP service principal was created.

- iv) Issue the keytab list command again.

The following information is displayed when the FTP service principal is present:

```
Key table: /etc/skrb/krb5.keytab

Principal: ftp/<hostname>@<realm>
 Key version: 1
 Key type: 56-bit DES
 Entry timestamp: 2005/02/04-16:21:10

Principal: ftp/<hostname>@<realm>
 Key version: 1
 Key type: 56-bit DES using key derivation
 Entry timestamp: 2005/02/04-16:21:10

Principal: ftp/<hostname>@<realm>
 Key version: 1
 Key type: 168-bit DES using key derivation
 Entry timestamp: 2005/02/04-16:21:10
```

8. An alternate way to run without a keytab file is to associate the FTP service principal to the ID under which the FTP started task runs.

If the ID that the FTP started task runs under is FTPD, issue the following command to create the FTP service principal and have it associated to that ID.

```
ALTUSER FTPD PASSWORD(ftp) NOEXPIRED KERB(KERBNAME(ftp/<hostname>))
```

**Rule:** In this setup, you must set the KRB5\_SERVER\_KEYTAB environment variable. Specify it directly in the FTP startup procedure as follows:

```
//FTPD EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
// PARM=(' POSIX(ON) ALL31(ON)',
// ' ENVAR("KRB5_SERVER_KEYTAB=1")&PARMS')
```

Another way of specifying the environment variable directly in the startup procedure is to specify a file where the environment variables are listed.

```
//FTPD EXEC PGM=&MODULE,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("_CEE_ENVFILE=/etc/ftp.envvars")/&PARMS')
```

Then, within the /etc/ftp.envvars file, add the following entry:

```
KRB5_SERVER_KEYTAB=1
```

9. Ensure that the FTP RACF user ID has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID has read access to the following ICSF SAF resources:

CSF1TRC, CSF1SKE, CSF1SKD, CSF1TRD, and CSFOWH

## Results

You know you are done when a client is able to successfully log in to the FTP server using Kerberos. An example of the login is as follows:

1. Obtain the Kerberos credentials by issuing the following command:

```
kinit joe
```

2. You will be prompted for the password. Enter it.
3. Issue the **ftp** command:

```
ftp <hostname>
```

You should see the following information:

```
Using /u/JOE/ftp.data for local site configuration parameters.
IBM FTP CS V1R9
FTP: using TCP/IP
Connecting to: <hostname><ip address> port: <port number>.
220-FTPD1 IBM FTP CS V1R9 at <hostname>, 21:51:51 on 2007-04-04.
220 Connection will close if idle for more than 5 minutes.
>>> AUTH GSSAPI
334 Using authentication mechanism GSSAPI
>>> ADAT
235 ADAT=YGgGCSsqGSib3EgECAGIAb1kwV6ADAgEFoQMCAQ+iSzBJoAMC7moS==
Authentication negotiation succeeded
NAME (<hostname>:USER):
JOE
>>> USER JOE
331 Send password please.
PASSWORD:

>>> PASS
230 JOE is logged on. Working directory is "JOE".
Command:
```

**Tip:** The password prompt is skipped if the server is configured with SECURE\_PASSWORD\_KERBEROS OPTIONAL and the client's Kerberos ticket principal name matches the logon user ID.

## Steps for customizing the FTP client for TLS

You can customize the FTP client for TLS, but a better way to implement TLS security is by using AT-TLS.

### Before you begin

Understand the following information:

- The FTP client can be enabled to use either TLS or Kerberos, but not both at the same time.
- To support TLS, the FTP server always provides server certificate authentication to all the clients to validate that the server is what it says it is. Therefore, a client key ring database is required to contain at least the certificate for the CA that signed the server certificate (or the server certificate if the server certificate is self-signed). For more information about key ring databases, see [Appendix B, “TLS/SSL security,”](#) on page 1359.

- The FTP client can implement TLS security by itself, or the FTP client can be configured to use Application Transparent Transport Layer Security (AT-TLS) as a controlling application. For more information on AT-TLS, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149.

**Guideline:** Using AT-TLS is the best way to implement TLS security. With AT-TLS, for example, you can have the following implementation:

- Specify the label of the certificate to be used for authentication instead of using the default certificate
- Support SSL Session Key Refresh
- Support SSL Sysplex Session ID Caching
- Trace decrypted SSL data for FTP in a data trace
- Receive more detailed diagnostic messages in syslogd

**Requirement:** AT-TLS requires Policy Agent to be configured, and the TCP/IP stack to be enabled for AT-TLS. To configure AT-TLS, see [“Configuring the client systems”](#) on page 1156.

## Procedure

Perform the following steps to customize the FTP client for TLS:

1. Decide what level of RFC 4217, *On Securing FTP with TLS*, that you want the client to support.

- To have the client support *On Securing FTP with TLS* at the Internet draft level, code the following statement in the client's FTP.DATA configuration file:

```
TLSRFCLEVEL DRAFT
```

This is the default. The z/OS FTP client has supported TLS security at this level since V1R2. Code this statement in FTP.DATA to maintain this level of support.

- To have the client support *On Securing FTP with TLS* at the RFC 4217 level, code the following statement in the client's FTP.DATA configuration file:

```
TLSRFCLEVEL RFC4217
```

The RFC *On Securing FTP with TLS* was published as RFC 4217 in October, 2005. The RFC differs from the Internet draft in its description of the AUTH, CCC, and REIN commands. This has implications for client subcommands such as AUTH and CCC. Generally, RFC 4217 is less restrictive than the Internet draft. For more information, see RFC 4217. For more information on RFC 4217 and [using security mechanisms](#), see [z/OS Communications Server: IP User's Guide and Commands](#).

2. Code the following statement in the client's FTP.DATA configuration file to enable the client for TLS:

```
SECURE_MECHANISM TLS
```

3. Decide what level of authentication you will use for TLS sessions:

- Server authentication only
- Client authentication level 1
- Client authentication level 2
- Client authentication level 3

For more information about server authentication and client authentication, see [“Secure Socket Layer overview”](#) on page 1359.

4. Use a CERTAUTH virtual key ring, or create a client key ring database and add the certificates that you need to that database.

If you are using server authentication only and the FTP server certificate is signed by a certificate authority (CA), the FTP client can use a CERTAUTH virtual key ring and you do not need to create a client key ring database. To use a CERTAUTH virtual key ring, use the key ring name `*AUTH*/*`.

If you cannot use a virtual key ring, create the client key ring database and add the certificates that you need to that database.

Every TLS session handshake includes server authentication. If a server certificate is self-signed, you must import that certificate to the key ring database of any client that will log in using TLS. If the server certificate is signed by a CA, the CA certificate used to sign the server certificate (rather than the server certificate itself) needs to be in the client key ring database. For more information, see [“Server authentication” on page 1359](#).

If you are using client authentication, you must add a certificate for the client to the client key ring database.

If you are using client authentication and self-signed client certificates, you must add a certificate for the client to the server key ring database. If a client certificate is signed by a CA, the CA certificate used to sign the client certificate needs to be in the server key ring database, rather than the client certificate.

For information about the client certificates you must create, see [“Client authentication” on page 1360](#).

5. Decide whether FTP will implement TLS security or AT-TLS will implement TLS security.

The default is to have FTP implement TLS security. This setting is customized using the TLSMECHANISM configuration statement.

- To configure the FTP client to use AT-TLS for TLS security, code the following statement in FTP.DATA:

```
TLSMECHANISM ATTLS
```

- To configure the FTP client to implement TLS security by itself, code the following statement in FTP.DATA:

```
TLSMECHANISM FTP
```

This is the default setting.

6. If using TLSMECHANISM FTP, you must configure the FTP client with the name of the key ring database.

Code the following statement in FTP.DATA:

```
KEYRING client-keyring-database
```

For information about the [KEYRING statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

**Tip:** The key ring name can optionally be qualified with the user ID that owns the key ring (*userID/client-keyring-database*). If the FTP.DATA data set will be shared by multiple z/OS users, then omitting *userID* ensures that each user will use their own instance of the keyring. If the FTP.DATA data set is used by a single z/OS user, then including the *userID* can help simplify diagnostic efforts.

7. If you specified TLSMECHANISM ATTLS, configure the AT-TLS policy for the FTP client.

To configure AT-TLS, see [“Configuring the client systems” on page 1156](#).

#### Requirements:

- The FTP server and client are controlling applications. For more information about controlling applications, see [“Advanced application considerations” on page 1173](#).

Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicationControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.

- The FTP client requires the HandshakeRole parameter with the value Client to be coded on the TTLSEnvironmentAction statement.
- The TTLSRule statement for the FTP client requires the Direction parameter with the value Outbound.

A sample Policy Agent AT-TLS configuration showing the required policy configuration statements for AT-TLS is as follows:

```

TTLSGroupAction secure_ftp_client_group
{
 TTLSEnabled On
}
TTLSEnvironmentAction secure_ftp_client_env
{
 TTLSKeyringParms
 {
 # The key ring value can optionally be qualified with
 the user ID that # owns the key ring (userID/client-keyring-
 database). # If the AT-TLS rule will be shared by
 multiple z/OS users, then # omitting userID ensures that each user
 will use their own instance of # the keyring. If the AT-TLS rule is used
 by a single z/OS user, then # including the userID can help simplify
 diagnostic efforts.
 Keyring client-keyring-database
 }
 HandshakeRole Client
 TTLSEnvironmentAdvancedParms
 {
 ApplicationControlled On
 SecondaryMap On
 TLSv1 Off
 TLSv1.1 On
 TLSv1.2 On
 TLSv1.3 On
 }
 TTLSCipherParmsRef ftp_client_ciphers # Used to customize ciphersuites
}
TTLSCipherParms ftp_client_ciphers
{
 # Sample ciphers. Should be customized!
 V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
 V3CipherSuites TLS_DHE_DSS_WITH_AES_256_CBC_SHA
 V3CipherSuites TLS_DHE_RSA_WITH_AES_256_CBC_SHA
 V3CipherSuites TLS_RSA_WITH_AES_128_CBC_SHA
 V3CipherSuites TLS_DHE_DSS_WITH_AES_128_CBC_SHA
 V3CipherSuites TLS_DHE_RSA_WITH_AES_128_CBC_SHA
 V3CipherSuites TLS_AES_128_GCM_SHA256
 V3CipherSuites TLS_AES_256_GCM_SHA384
}

TTLSRule secure_ftp_client_rule
{
 RemotePortRange 21 # This should be set to the port the FTP server is
 # listening on
 Direction Outbound
 TTLSGroupActionRef secure_ftp_client_group
 TTLSEnvironmentActionRef secure_ftp_client_env
}

```

**Tip:** You can enable additional security settings with AT-TLS, such as LDAP servers and handshake timeout values. The sample configuration is only the minimum required to allow the FTP client to use AT-TLS. You can add additional configuration statements.

8. Decide which cipher algorithms the client should use to encipher data transfers and control information.

FTP and AT-TLS support TLS through the system SSL cryptographic services base element of z/OS. System SSL supports multiple cipher algorithms that provide both encryption and data authentication (that is, data integrity). Encryption scrambles the data so it is transferred confidentially and cannot be interpreted without a special key. Data authentication algorithms ensure that the data was not

modified during transfer. Some of the supplied cipher algorithms provide only data authentication, and some provide both encryption and authentication. Be aware that the actual cipher algorithm used for the session is determined by a negotiation between the server and client. For example, if you configure an FTP client to use the Triple DES encryption, SHA authentication algorithm, but the server does not support that cipher algorithm, Triple DES encryption, SHA authentication will not be used for sessions between the client and that server.

If using TLSMECHANISM FTP, select which cipher algorithms you prefer to use by coding a CIPHERSUITE configuration statement in the FTP.DATA file for each cipher algorithm the client can use. For a list of the cipher algorithms you can specify on the [CIPHERSUITE \(FTP client\) statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

#### Restrictions:

- Only RSA key exchange is supported.
- The following algorithms are subject to export regulations and might not be available to your system:
  - Triple DES encryption, SHA authentication
  - RC4 (128-bit) encryption, SHA authentication
  - RC4 (128-bit) encryption, MD5 authentication
  - AES (128-bit and 256-bit) encryption, SHA authentication

If you specify TLSMECHANISM ATTLS, select which cipher algorithms you want to use by coding a TTLSCipherParms configuration statement to specify the cipher algorithms the client can use. For a list of the cipher algorithms you can specify with the [TTLSCipherParms statement](#), see [z/OS Communications Server: IP Configuration Reference](#). List the ciphers in the order of preference, your most preferred cipher algorithm first. The cipher algorithm is negotiated with the server on behalf of the client using the same order of preference as is indicated by the order of the TTLSCipherParms statement.

#### 9. Decide whether the client should be required to use the TLS protocol.

If the FTP server does not support TLS, you can choose to allow the client to log in without using the TLS security, or require the client to use a secure session, thus failing the login. The default is to not require the client to use TLS. This setting is customized using the SECURE\_FTP configuration statement.

To have the client log in using the TLS protocol when the server supports TLS, and log in without TLS when the server does not support TLS, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_FTP ALLOWED
```

This is the default.

To have the client log in using the TLS protocol, but close the server connection and prevent logging in when the server does not support TLS, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_FTP REQUIRED
```

#### 10. Decide the level of security for the data connection.

You can choose to require enciphered data transfers, or to allow the FTP user to decide the level of security for data transfers. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

Note that the level of security for data connections is determined by both the SECURE\_DATACONN statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

The following subcommands can be issued by the user:

**clear**

Resets the security level so that data is transferred raw.

**private**

Resets the security level so that data is transferred enciphered. The cipher algorithm is negotiated between the server and the client using the TLS protocol negotiation.

If you want the client to transfer data raw with no cipher algorithm applied to the data, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN NEVER
```

To indicate the data can be transferred raw or enciphered, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN CLEAR
```

This is the default.

By default, data is transferred raw. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level, so that data is transferred enciphered. The user can also issue the `clear` subcommand to reset the data connection security level back, so that data is transferred raw again. For TLS, if the `private` subcommand is issued, the cipher algorithm is negotiated between the server and the client using TLS protocols.

If you want to require that data is transferred enciphered, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

For TLS, the cipher algorithm is negotiated between the server and the client using TLS protocols.

11. Decide whether the client requires session reuse when SSL/TLS is used to protect the control and data connections.

By default, the setting is not enabled for the client to reuse either of the following SSL session IDs on subsequent data connections within an FTP session:

- The SSL session ID of the control connection
- The SSL session ID of a previous data connection

This setting is customized by using the `SECURE_SESSION_REUSE` configuration statement.

- If you do not require the client to reuse either of the following SSL session IDs on subsequent data connections within an FTP session, code `NONE` on the `SECURE_SESSION_REUSE` statement in the FTP.DATA configuration file of the client:
  - The SSL session ID of the control connection
  - The SSL session ID of a previous data connection

This is the default.

- To enable the client to reuse either of the following SSL session IDs on subsequent data connections within an FTP session, code `ALLOWED` on the `SECURE_SESSION_REUSE` statement in the FTP.DATA configuration file of the client:
  - The SSL session ID of the control connection
  - The SSL session ID of a previous data connection
- To require the client to reuse the SSL session ID of the control connection on the subsequent data connections within an FTP session, code the `SECURE_SESSION_REUSE REQUIRED` statement in the FTP.DATA configuration file of the client.

This setting might cause data connections and FTP transfers to fail when the remote side does not support reusing the session ID.

For information about the `SECURE_SESSION_REUSE` statement, see [z/OS Communications Server: IP Configuration Reference](#).

## Steps for customizing the FTP client for Kerberos

The FTP client can be enabled to use either TLS or Kerberos, but not both at the same time.

### Procedure

Perform the following steps to customize the FTP client for Kerberos:

1. Code the following statement in the client's FTP.DATA configuration file to enable the client for Kerberos:

```
SECURE_MECHANISM GSSAPI
```

2. Decide whether the client should be required to use the Kerberos protocol.

If the FTP server does not support Kerberos, you can choose to allow the client to log in without using Kerberos security, or require the client to use a secure session, thus failing the login. The default is to not require the client to use Kerberos. This setting is customized using the `SECURE_FTP` configuration statement.

To have the client log in using the Kerberos protocol, but if the server does not support Kerberos allow the client to complete the login without using it, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_FTP ALLOWED
```

This is the default.

To have the client log in using the Kerberos protocol, but if the server does not support Kerberos have the login fail and not allow the client to log in, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_FTP REQUIRED
```

3. Decide the level of security for the data connection.

You can choose to require enciphered data transfers, or to allow the FTP user to decide the level of security for data transfers. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

Note that the level of security for data connections is determined by both the `SECURE_DATACONN` statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

The following subcommands can be issued by the user:

#### **clear**

Resets the security level so that data is transferred raw.

#### **private**

Resets the security level so that data is transferred enciphered. If the client is using the Kerberos security mechanism, the data is transferred both integrity protected and privacy protected. If the client is using the TLS security mechanism, the cipher algorithm is negotiated between the server and the client using the TLS protocol negotiation.

#### **safe**

Resets the security level so that data is transferred integrity protected only.

If you want the client to transfer data raw with no cipher algorithm applied to the data, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN NEVER
```

To indicate the data can be transferred raw or enciphered, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN CLEAR
```

This is the default.

By default, data is transferred raw. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level, so that data is transferred both integrity and privacy protected. The user can also issue the `safe` subcommand to change the data connection security level so that data is transferred integrity protected only, or the `clear` subcommand to reset the data connection security level back so that data is transferred raw again.

If you want to require that data is transferred both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN PRIVATE
```

If you want to require that data is transferred integrity protected only, or both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_DATACONN SAFE
```

By default, data is transferred integrity protected only. However, the user can issue the `private` subcommand during the FTP session to change the data connection security level so that data is transferred both integrity and privacy protected. The user can also issue the `safe` subcommand to reset the data connection security level back, so that data is transferred integrity protected only.

#### 4. Decide the level of security for the control connection (that is, for FTP commands and replies).

You can choose to require enciphered data, or to allow the FTP user to decide the level of security. The default is to not encipher the data, but allow the data to be enciphered at the server's request or at the FTP user's request during the FTP session.

Note that the level of security for data connections is determined by both the `SECURE_CTRLCONN` statement in FTP.DATA and by subcommands an FTP user might issue during an FTP session.

The following subcommands can be issued by the user:

##### **cprotect clear**

Resets the security level so that data is transferred raw.

##### **cprotect private**

Resets the security level so that data is transferred both integrity protected and privacy protected.

##### **cprotect safe**

Resets the security level so that data is transferred integrity protected only.

To indicate the data can be transferred raw or enciphered, you can code the following statement in the server's FTP.DATA configuration file:

```
SECURE_CTRLCONN CLEAR
```

This is the default.

By default, data is transferred raw. However, the user can issue the `cprotect private` subcommand during the FTP session to change the security level so that data is transferred both integrity and privacy protected. The user can also issue the `cprotect safe` subcommand to change the security level so that data is transferred integrity protected only, and the `cprotect clear` subcommand to reset the security level back so that data is transferred raw again.

If you want to require that data is transferred both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_CTRLCONN PRIVATE
```

If you want to require that data is transferred integrity protected only, or both integrity and privacy protected, code the following statement in the client's FTP.DATA configuration file:

```
SECURE_CTRLCONN SAFE
```

By default, data is transferred integrity protected only. However, the user can issue the `cprotect private` subcommand during the FTP session to change the data connection security level so that data is transferred both integrity and privacy protected. The user can also issue the `cprotect safe` subcommand to reset the data connection security level, so that data is transferred integrity protected only.

## Port 990

The use of port 990 to implicitly protect FTP sessions was included in the early drafts of the IETF documents that describe how to use TLS with FTP, but has been removed from later drafts and from RFC 4217. For more information, see Information APAR II13516.

Port 990 is known as the protected port, or the TLSPORT. You can disable implicit security for port 990, or reassign the protected port, by coding the TLSPORT statement in the server's FTP.DATA configuration file.

**Rule:** If you start the FTP server on the protected port, you should code a SECUREIMPLICITZOS statement in the server's FTP.DATA file to specify when the server should expect the client to negotiate TLS security.

The FTP server can provide explicit TLS security on a different port by specifying the following definitions in FTP.DATA:

```
EXTENSIONS AUTH_TLS
SECURE_FTP REQUIRED
SECURE_CTRLCONN PRIVATE
SECURE_DATACONN PRIVATE
```

## Steps for migrating the FTP client to use AT-TLS

Application Transparent Transport Layer Security (AT-TLS) is the best way to implement TLS security for the FTP server and client. AT-TLS provides additional functionality and performance for TLS secured connections.

### Procedure

Perform the following steps to migrate from an existing configuration using TLS security for the FTP client to a configuration using AT-TLS:

1. Configure AT-TLS and Policy Agent.

For details about AT-TLS setup, see [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#). For [Policy Agent and policy applications setup](#) and [AT-TLS policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

#### Requirements:

- The FTP client is a controlling application. For more information about controlling applications, see [“Advanced application considerations” on page 1173](#).

Code a TTLSEnvironmentAdvancedParms statement with the ApplicationControlled and SecondaryMap parameters; both parameters should specify the value On. The ApplicationControlled parameter allows FTP to start and stop TLS security on a connection. The SecondaryMap parameter enables active or passive data connections to use the AT-TLS policy that is used for the control connection. You do not need to code any additional TTLSRule statements for the data connections.

- The FTP client requires the HandshakeRole parameter with the value Client to be coded on the TTLSEnvironmentAction statement.

- The TTLSRule statement for the FTP client requires the Direction parameter with the value Outbound.

**Guideline:** The FTP client does not support SSLv2 when using TLSMECHANISM FTP. By default, AT-TLS does not enable SSLv2. SSLv2 should not be enabled in AT-TLS unless explicitly required by a remote system. If SSLv2 is required by a remote system, use a specific TTLSRule statement for the remote system that points to a TTLSConnectionAction statement enabling SSLv2.

2. Configure the FTP client to use AT-TLS by coding TLSMECHANISM ATTLS in FTP.DATA.
3. If TLSRFCLEVEL CCCNONOTIFY is configured in FTP.DATA, update TLSRFCLEVEL to use a value that is supported with AT-TLS.
4. Use [Table 33 on page 729](#) to migrate the existing FTP client configuration to AT-TLS.  
Remove the statements from FTP.DATA and code the AT-TLS equivalent statement.

| <i>Table 33. Migrating existing FTP client configuration</i> |                             |                                                                                                                            |
|--------------------------------------------------------------|-----------------------------|----------------------------------------------------------------------------------------------------------------------------|
| FTP.DATA statement                                           | AT-TLS equivalent statement | AT-TLS policy statement                                                                                                    |
| KEYRING                                                      | Keyring                     | TTLSKeyRingParms -><br>TTLSEnvironmentAction                                                                               |
| CIPHERSUITE                                                  | V3CipherSuites              | TTLSCipherParms -><br>TTLSEnvironmentAction or<br>TTLSConnectionAction                                                     |
| TLSTIMEOUT                                                   | GSK_V3_SESSION_TIMEOUT      | TTLSGskAdvancedParms -><br>TTLSEnvironmentAction                                                                           |
| SSLV3                                                        | SSLv3                       | TTLSEnvironmentAdvancedParms-><br>TTLSEnvironmentAction<br><br>Or<br>TTLSConnectionAdvancedParms-><br>TTLSConnectionAction |
| TLSV1                                                        | TLSV1                       | TTLSEnvironmentAdvancedParms-><br>TTLSEnvironmentAction<br><br>Or<br>TTLSConnectionAdvancedParms-><br>TTLSConnectionAction |

5. Use [Table 34 on page 729](#) to migrate existing ciphers coded on CIPHERSUITE statements in FTP.DATA to AT-TLS TTLSCipherParms statements.

| <i>Table 34. Migrating existing ciphers</i> |                                    |                   |
|---------------------------------------------|------------------------------------|-------------------|
| CIPHERSUITE cipher                          | V3CipherSuites cipher              | Hexadecimal value |
| SSL_DES_SHA                                 | TLS_RSA_WITH_DES_CBC_SHA           | 09                |
| SSL_3DES_SHA                                | TLS_RSA_WITH_3DES_EDE_CBC_SHA      | 0A                |
| SSL_NULL_MD5                                | TLS_RSA_WITH_NULL_MD5              | 01                |
| SSL_NULL_SHA                                | TLS_RSA_WITH_NULL_SHA              | 02                |
| SSL_RC2_MD5_EX                              | TLS_RSA_EXPORT_WITH_RC2_CBC_40_MD5 | 06                |
| SSL_RC4_MD5                                 | TLS_RSA_WITH_RC4_128_MD5           | 04                |
| SSL_RC4_MD5_EX                              | TLS_RSA_EXPORT_WITH_RC4_40_MD5     | 03                |
| SSL_AES_128_SHA                             | TLS_RSA_WITH_AES_128_CBC_SHA       | 2F                |

| Table 34. Migrating existing ciphers (continued) |                              |                   |
|--------------------------------------------------|------------------------------|-------------------|
| CIPHERSUITE cipher                               | V3CipherSuites cipher        | Hexadecimal value |
| SSL_AES_256_SHA                                  | TLS_RSA_WITH_AES_256_CBC_SHA | 35                |

For example, for an FTP.DATA file that contains the following statements:

```
CIPHERSUITE SSL_AES_256_SHA
CIPHERSUITE SSL_3DES_SHA
CIPHERSUITE SSL_NULL_SHA
```

The equivalent TTLSCipherParms statement:

```
TTLSCipherParms
{
 V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
 V3CipherSuites TLS_RSA_WITH_3DES_EDE_CBC_SHA
 V3CipherSuites TLS_RSA_WITH_NULL_SHA
}
```

6. AT-TLS supports more secure TLS versions and ciphers. Consider enabling TLSv1.2 or later on the TTLSEnvironmentAdvancedParms or TTLSConnectionAdvancedParms statement. Consider enabling support for additional ciphers on the TTLSCipherParms statement.

## Traversing firewalls with SSL/TLS secure FTP

This topic describes functions in FTP that enable you to use FTP sessions that are secured by SSL/TLS using both network address translation (NAT) and filtering firewalls.

FTP requires the following TCP connections to transfer a file:

- Control connection
- Data connection

The control connection is established from the FTP client to the FTP server (default port 21). The data connection is established either from the FTP client to the FTP server, or from the FTP server to the FTP client; the direction is based on whether the client selects active mode or passive mode FTP.

- Active mode

With active mode FTP, the data connection is established from the FTP server to the FTP client, which is the opposite direction of the control connection. The active mode data connection is established from a well-known port on the server host (default port 20) to an ephemeral port on the client host.

- Passive mode

With passive mode FTP, the data connection is established from the FTP client to the FTP server, which is the same direction as the control connection. The data connection is established from an ephemeral port on the server host to an ephemeral port on the client host.

Passive mode is also referred to as firewall-friendly FTP. An intranet FTP client connecting to an Internet FTP server can establish connections outbound through the company firewall, but not inbound through the firewall. With passive mode, both the control and data connections are established outbound through the firewall to the Internet.

The FTP client user decides which mode to use. Active mode is the default, but the user can usually change to passive mode. The z/OS FTP client user can switch between active and passive modes by issuing the LOCSITE subcommand with the NOFWFRIENDLY and FWFRIENDLY parameters.

Both active mode and passive mode FTP require the exchange of IP address and port information over the control connection. For active mode, the FTP client sends a PORT command specifying the IP address and port number to which the server must connect to establish the data connection. For passive mode, the FTP client sends a PASV command to the server, and the server replies with the IP address and port number to which the client should connect to establish the data connection.

Firewalls are often aware of FTP; they monitor the exchanges over the FTP control connection to learn the IP address and port number to which the data connection is to be established. NAT firewalls change the IP addresses on the PORT command or in the PASV reply. Filtering firewalls install dynamic filters based on the IP addresses and port information to enable the data connection to be established.

When you use SSL/TLS for FTP, the control connection is typically encrypted, so firewalls between the FTP client and server cannot see the data that is exchanged on the PORT command and the PASV reply. The firewalls cannot perform NAT successfully and they cannot install dynamic filters for the data connection, so the result is that your data connection very likely fails.

z/OS FTP includes the following support for functions that are specifically aimed at enabling FTP sessions through such firewalls:

- Extended passive mode (EPSV)

Extended passive mode works very much like passive mode. Instead of sending a PASV command to the server, the client sends an EPSV command to the server. The server EPSV reply includes only a port number. The client always uses the same IP address for the data connection that it used for the control connection. A z/OS FTP client user switches to extended passive mode for IPv4 connections by issuing the LOCSITE subcommand with the EPSV4 and FWFRIENDLY parameters. These options can also be configured in the z/OS FTP client FTP.DATA file.

EPSV allows sessions secured by SSL/TLS through NAT firewalls, but EPSV alone does not allow FTP sessions that are secured by SSL/TLS through firewalls that also implement dynamic filters.

- The PASSIVEIGNOREADDR configuration option

This z/OS FTP client option directs the z/OS FTP client to ignore the IP address in the PASV reply and use only the port number when FTP is in passive mode. The client uses the same IP address that it used to log in to the FTP server for the data connection. A z/OS FTP client user enables this support by issuing a LOCSITE subcommand with the PASSIVEIGNOREADDR option. You can also configure this option in the z/OS FTP client FTP.DATA file.

The PASSIVEIGNOREADDR configuration enables sessions secured by SSL/TLS through NAT firewalls in the same way that extended passive mode enables them, subject to the same limitations. You can use the PASSIVEIGNOREADDR option when the server does not support the EPSV command.

- The PASSIVEDATAPORTS statement in FTP.DATA

This z/OS FTP server option enables you to define a range of port numbers that the z/OS FTP server can use in PASV and EPSV replies for passive mode data connections. If the PASSIVEDATAPORTS statement on the z/OS FTP server is used in combination with EPSV from the FTP client, the two techniques together allow FTP sessions secured with SSL/TLS through NAT firewalls that also implement static IP filters, assuming that the firewall administrators add static filter rules that allow FTP data connections access to one or more of the ports in the PASSIVEDATAPORTS range.

- The clear command channel (CCC) command

The CCC command can be used on a control connection secured by SSL/TLS to disable SSL/TLS security. The control connection starts out as secured by SSL/TLS, and stays that way until a user ID and password or password phrase have been exchanged with the server. At that point, the FTP client can send a CCC command to the server, which disables SSL/TLS for the control connection and enables PORT commands and replies to PASV and EPSV commands to flow in the clear on the control connection. When these exchanges occur in the clear, firewalls between the FTP client and FTP server can perform NAT processing and dynamic filter processing as if the connection is not secured with SSL/TLS. The CCC command does not turn off security for the data connection.

To enable the z/OS FTP server to accept the CCC command, configure TLSRFCLEVEL RFC4217 at the FTP server.

To enable the z/OS FTP client to support the CCC command, configure TLSRFCLEVEL RFC4217 (or, if TLSMECHANISM FTP is specified, TLSRFCLEVEL CCCNONOTIFY) at the FTP client, matching the client TLSRFCLEVEL value to the server TLSRFCLEVEL value. You can use the LOCSITE subcommand to change the TLSRFCLEVEL value. When TLSRFCLEVEL RFC4217 (or TLSRFCLEVEL CCCNONOTIFY, when using

TLSMECHANISM FTP) is configured at the z/OS FTP client, use the CCC subcommand after logging in to the FTP server to send a CCC command to the FTP server.

The support that you use depends on your network topology. The following scenarios are a few selected scenarios to consider for making sure that FTP sessions secured by SSL/TLS can get through your network. The scenarios assume that z/OS is at least one of the endpoints of the secure FTP session. The partner endpoint can be z/OS or any secure FTP product on the market that supports the same RFC levels as z/OS (primarily RFC 4217).

- Your firewall performs NAT only (minimal or no filtering), your FTP client is in a private network behind the NAT firewall, and the FTP server is in a public network such as the Internet, as shown in [Figure 100 on page 732](#).

*Figure 100. SSL/TLS-secured FTP session scenario 1*

Normal passive mode (PASV) usually works in such a scenario. Extended passive mode (EPSV) also works, but is generally not required.

- Your firewalls perform NAT only (minimal or no filtering), your FTP client is in one private network, your FTP server is in another private network, and you have two NAT firewalls between the client and server networks that are connected over a public network, as shown in [Figure 101 on page 732](#).

*Figure 101. SSL/TLS-secured FTP session scenario 2*

If your partner's secure FTP product supports extended passive mode, use extended passive mode (EPSV) from the FTP client. If the FTP client is the z/OS FTP client and the partner's secure FTP server product does not support EPSV, configure the PASSIVEIGNOREADDR option at your z/OS FTP client to simulate EPSV processing.

- Your firewall performs NAT and static filtering (predefined filter rules). Your FTP client is in a private network behind the NAT firewall, with a z/OS FTP server that is in a public network such as the Internet, as shown in [Figure 102 on page 732](#).

*Figure 102. SSL/TLS-secured FTP session scenario 3*

Use the PASSIVEDATAPORTS statement in the z/OS FTP server's FTP.DATA file to predefine a range of port numbers that the z/OS FTP server can use for data connections. Your firewall administrator needs to add static filter rules for the passive data port range. Normal passive mode (PASV) usually works in such a scenario, but extended passive mode (EPSV) can also be used if supported by the FTP client.

- Your firewalls perform NAT and static filtering (predefined filter rules). Your FTP client is in one private network, your z/OS FTP server is in another private network, and you have two NAT firewalls between the client and server networks that are connected over a public network, as shown in [Figure 103 on page 733](#).

Figure 103. SSL/TLS-secured FTP session scenario 4

Use the `PASSIVEDATAPORTS` statement in the z/OS FTP server's `FTP.DATA` file to predefine a range of port numbers that the z/OS FTP server can use for data connections. Your firewall administrator needs to add static filter rules for the passive data port range. In this case, you must use extended passive mode. If the FTP client does not support extended passive mode, this scenario is not likely to work.

- Your firewalls perform dynamic filtering (with or without NAT) and your partner's secure FTP product supports the `CCC` command, as shown in Figure 104 on page 733.

Figure 104. SSL/TLS-secured FTP session scenario 5

Use the `CCC` command from the FTP client. This scenario is not likely to work without `CCC` command support.

- You do not know what your firewalls do and your partner's secure FTP product does support the `CCC` command, as shown in Figure 105 on page 733.

Figure 105. SSL/TLS-secured FTP session scenario 6

Use the `CCC` command from the FTP client. This scenario is not likely to work without `CCC` command support.

Firewalls reject FTP sessions secured by SSL/TLS in the following additional scenarios:

- Some firewalls are known to apply various validity checks on the FTP control connection data stream. One known check verifies that all interactions on the FTP control connection are terminated with an ASCII newline (NL) character. Most of these checks fail when the control connection is secured with SSL/TLS, because the data is encrypted. If you use the information in this topic and still run into problems establishing FTP sessions secured by SSL/TLS through firewalls, verify with your firewall administrators whether your firewalls implement such validity checks on the FTP control connection, and consider disabling those validity checks.
- Some firewalls are known to disable active mode data connections by default, and block all active mode data connections. Use passive mode or extended passive mode FTP instead.
- Many firewalls monitor activity on TCP connections and terminate connections that are idle for a certain period of time. During a large data transfer over an FTP data connection, the FTP control connection is idle. To avoid having firewalls terminate idle FTP connections, consider coding the `FTPKEEPALIVE` statement in the z/OS `FTP.DATA` file for the client or the server. For more information about the `FTPKEEPALIVE` statement, see [“Configuring PROFILE.TCPIP for FTP” on page 688](#).

## Db2 and JES

The following statements are used when FTP interfaces with Db2 and JES, respectively. For more information, see [z/OS Communications Server: IP Configuration Reference](#) and the optional steps in this information.

- DB2®
- DB2PLAN

- JESGETBYDSN
- JESINTERFACELEVEL
- JESLRECL
- JESPUTGETTO
- JESRECFM
- SPREAD and SQLCOL

## Configuring the optional FTP user exits

---

This information describes exit routines that you can code and install. For information about [FTP server user exits](#) and for a list of [sample user exits](#), see [z/OS Communications Server: IP Configuration Reference](#).

**Tip:** You can find the sample user exit routines in SEZAINST.

### The FTPSMFEX user exit (for the FTP server)

Note the FTP server SMF user exit is called before an SMF type 118 record that contains information about an FTP server session is written to the SYS1.MANx data set. The user exit allows site specific modifications to the record and controls whether the record is written to the SYS1.MANx data set.

Note that the exit is called only for type 118 records. SMF type 119 FTP records must use the system-wide SMF user exits (IEFU83, IEFU84, and IEFU85) to obtain this same functionality. For information on these SMF user exits, see [z/OS MVS System Management Facilities \(SMF\)](#).

### The FTCHKIP user exit (for the FTP server)

The FTCHKIP user exit is called when a user attempts to log in to the FTP server or when a user issues the OPEN subcommand to establish a new connection. The following information is passed to the exit:

- Client IP address \*
- Client port number \*
- Server IP address \*
- Server port number \*
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier

**Note:** Fields above marked with an asterisk (\*) are valid only for IPv4 addresses, including IPv4-mapped IPv6 addresses.

An installation can use this exit to determine if a particular IP address or port number is allowed to access the FTP site. If the connection is denied by the user exit, the following message is sent to the user:

```
421 User Exit rejects open for connection
```

### The FTCHKPWD user exit (for the FTP server)

The FTCHKPWD user exit is called immediately after the user enters the password, password phrase, or email address while logging in to the FTP server. The following information is passed to the exit:

- The user ID
- The user password

This field will be set to an asterisk (\*) if an email address is entered instead of a password.

This field will be set to the first eight characters of the password phrase if the user provides a password phrase instead of a password. The entire password phrase is passed to this exit as another parameter.

- A userdata buffer

If an email address is entered to log in, the userdata buffer contains the email address.

- The number of incorrect passwords or password phrases entered during this session
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- The user password or password phrase used to log in to the FTP server

The exit can be used to restrict access to a site based on user ID, password or password phrase, number of bad passwords or password phrases entered, or anything in the socket address information for the client or server. If the login is denied by the user exit, the following reply is sent to the user:

```
530 PASS command failed
```

**Result:** If you coded ACCESSERRORMSG TRUE in FTP.DATA, an additional 530 reply with information about why the PASS command failed might precede the reply above.

## The FTCHKCMD user exit (for the FTP server)

The FTCHKCMD user exit is called whenever the server receives an FTP command. The following information is passed to the user exit:

- The user ID
- The FTP command to be processed
- The command's arguments
- The directory type (MVS or HFS)
- The FILETYPE (SEQ, JES, or SQL)
- The current working directory
- A buffer to hold a modified argument string
- A buffer to hold a 500 reply extension to explain why the exit denied the request
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer

The user exit enables an installation to modify the arguments of an FTP command or to deny a user from issuing the command. For example, if the server receives a LIST \* command, the exit can either deny the command or modify it to LIST 'USER1.\*'. If the user exit denies the request by this user to issue this command, one or both of the following replies will be sent to the user. The first reply is optional and is sent only if the user exit returns a string in the 500 reply extension buffer.

```
500-UX-buffercontents
500 User Exit denies Userid userid from using Command command
```

## The FTCHKJES user exit (for the FTP server)

FTCHKJES is called if the server is in FILETYPE=JES mode and the client tries to submit a job. The following information is passed to the exit:

- The user ID
- A buffer containing the current JCL statement
- Size of statement in the buffer
- JESLrecl value

- Number of this buffer in current series
- Bytes transferred so far (including this buffer)
- Client identifier (see also session instance identifier)
- JESRecfm value
- FTCHKJES exit-specific workarea (4 bytes)
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer

The exit can allow or refuse the job to be submitted to the JES internal reader based on any information passed to the exit. For example, the exit can look for a `USER=` parameter on the `JOB` statement and check it against the client's user ID. If the remote job submission is denied, the exit sends the user the following reply:

```
550 User Exit refuses this job to be submitted by userid
```

## The FTPOSTPR user exit (for the FTP server)

FTPOSTPR is called after execution of the FTP commands `RETR`, `STOR`, `STOU`, `APPE`, `DELE`, and `RNTO`. The following information is passed to the exit:

- The user ID
- Client IP address \*
- Client port number \*
- The directory type (MVS or HFS)
- The current working directory
- The FILETYPE (SEQ, JES, or SQL)
- Most recent reply code number
- Most recent reply text string
- Current FTP command
- Current CONDDISP setting
- Close reason code
- Name of data set or z/OS UNIX file retrieved or stored
- Bytes transferred
- The socket address structure of the client's control connection
- The socket address structure of the server's control connection
- Session instance identifier
- A 256-byte scratchpad buffer
- The 1-byte description of the confidence-of-successful-completion level assigned to this file transfer

### Notes:

1. Fields above marked with an asterisk (\*) are valid only for IPv4 addresses, including IPv4-mapped IPv6 addresses.
2. The directory type reflects the current working directory. The MVS data set or z/OS UNIX file that is retrieved or stored can be located in a different type of directory.

The exit allows for post processing at the termination of data transfer functions within the server.

## The EZAFCCMD user exit (for the FTP client)

The EZAFCCMD user exit is called by the FTP client before an FTP command is sent to the FTP server. The following information is passed to the exit:

- The number of parameters that are passed to the exit
- The TCP connection ID
- The remote user ID
- The FTP command to be processed
- The arguments of the command
- The directory type (MVS or HFS)
- The z/OS UNIX file type (FILE or FIFO)
- The current local directory
- The fully qualified MVS data set name or z/OS UNIX absolute path name of the client
- The current configuration of the FTP client
- The socket address structure of the control connection for the client
- The socket address structure of the control connection for the server
- The socket address structure of the connection for the SOCKS server
- FTP client application data for the control connection
- A buffer to hold a modified argument string
- A buffer to hold a 71-byte message from the user exit

This exit can inspect an FTP command, modify the arguments of an FTP command, reject an FTP command, or end the FTP client before the command is sent to the server. For example, if the client is sending a LIST \* command, the exit can inspect the LIST command, change the command argument to LIST 'USER11.\*', reject the LIST command, or end the FTP client.

### Restrictions:

- This user exit cannot end the client when the QUIT command is generated by the QUIT subcommand, but the client does end as part of QUIT subcommand processing.
- This user exit cannot reject the QUIT command that is generated by the QUIT subcommand or by the CLOSE subcommand.
- This user exit cannot change the FTP command, but can change the arguments of the FTP command.
- This user exit cannot modify the arguments of the AUTH, EPRT, EPSV, MODE, PBSZ, PORT, PROT, REST, SITE, STRU, TYPE, and XLMT commands.
- This user exit cannot inspect the PASS or ACCT command arguments, but can modify the arguments of these commands.
- This user exit cannot inspect or modify the ADAT command arguments.
- This user exit cannot modify the RETR or STOR command arguments when the transferred MVS data set is a load module.

For more information about the [EZAFCCMD user exit](#), see [z/OS Communications Server: IP Configuration Reference](#).

## The EZAFCREP user exit (for the FTP client)

The EZAFCREP user exit is called when the FTP client receives a single-line reply or one line of a multiple-line reply from the server over the control connection. The following information is passed to the user exit:

- The number of parameters that are passed to the user exit
- The TCP connection ID

- The FTP server reply line that is received by the FTP client
- FTP client application data for the current control connection
- A 71-byte buffer to hold a message from the user exit

Use the EZAFCREP user exit to inspect the FTP server reply or to end the FTP client after the FTP client receives a particular line of the reply from the server. If the user exit ends the FTP client, one or both of the following messages are displayed to the user. Message EZA1556I is optional and is displayed only when the user exit returns text in the 71-byte buffer.

```
EZA1556I EZAFCREP message: message text provided by user exit routine
EZA1546I User exit EZAFCREP module modname ended the FTP client - exit reason code
x'hexadecimal-rsncode' (decimal-rsncode)
```

#### Restrictions:

- This user exit cannot modify FTP server replies.
- This user exit cannot end the client when the reply is generated by the QUIT subcommand, but the client does end as part of QUIT subcommand processing.
- This user exit cannot end the client when the input to the exit is a reply with a reply code in the range 100–199.

For more information about the [EZAFCREP user exit](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Customizing the FTP-to-JES interface for JESINTERFACELevel 2 (optional)

---

If JESINTERFACELEVEL is set or defaulted to 1, the FTP user is allowed to submit jobs to JES, retrieve held output matching their logged-in user ID plus one character, and delete held jobs matching their logged-in user ID plus one character.

If JESINTERFACELevel is set to 2, FTP users have the ability to retrieve and delete any job in the system permitted by the System Authorization Facility (SAF) resource class JESSPOOL. For that reason, JESINTERFACELevel=2 should be specified only if the appropriate JES and SDSF security measures are in place to protect access to JES output. The SAF controls used for JESINTERFACELevel=2 are essentially a subset of those used by SDSF. Therefore, if an installation has customized SAF facilities for SDSF, they are configured for FTP JES level 2.

**Note:** You are not required to have SDSF to use JESINTERFACELEVEL 2. If you do not use SDSF, you still need to create SAF profiles. Both SDSF and JESINTERFACELEVEL 2 use the same SAF profile names.

Before customizing the FTP-to-JES interface, complete JES customization. For example, JESJOBS is an SAF class that controls which users can submit jobs to JES. JESSPOOL is the SAF class that controls which users can access output jobs. Customize these SAF classes before beginning customization of the FTP-to-JES interface.

JESSPOOL defines resource names as <nodeid>.<userid>.<jobname>.<Dsid>.<dsname>. An FTP user can delete an output job if they have UPDATE access to the resource that matches their nodeid, userid, and job name. If the FTP user has READ access to the resource, they can list, retrieve, or GET the job output. For more information on JES security, see [z/OS JES2 Initialization and Tuning Guide](#). For more information on the SAPI interface, see [z/OS MVS Using the Subsystem Interface](#).

There are three filters used by the FTP server to control the display of jobs:

- JESSTATUS
- JESOWNER
- JESJOBNAME

SAF resources in the SDSF class are employed for this.

JESSTATUS can be changed by an FTP user with the SITE command to filter jobs in INPUT, ACTIVE, or OUTPUT state. The SAF resources checked for these states are ISFCMD.DSP.INPUT.jesx,

ISFCMD.DSP.ACTIVE.jesx, and ISFCMD.DSP.OUTPUT.jesx, respectively. The default value is set to ALL if READ access is allowed to all three classes. Otherwise it attempts to set the default value to OUTPUT, ACTIVE, and then INPUT if the appropriate READ access is allowed. If no READ access is allowed to any of the classes, JESSTATUS is set to OUTPUT but JESOWNER and JESJOBNAME cannot be changed from the default. In this way, SAF controls can be put in place to limit FTP users to whatever status of jobs an installation requires.

By default, JESOWNER has the value of the logged-in user ID. Authority to change JESOWNER is obtained through READ access to SAF resource ISFCMD.FILTER.OWNER. An FTP user who has READ access to ISFCMD.FILTER.OWNER will be allowed to change the JESOWNER parameter with the SITE command.

By default, JESJOBNAME has the value of the logged-in user ID plus an asterisk (\*). Authority to change JESJOBNAME is obtained through READ access to SAF resource ISFCMD.FILTER.PREFIX. An FTP user who has READ access to ISFCMD.FILTER.PREFIX will be allowed to change the JESJOBNAME parameter with the SITE command.

For example, to allow all users except USER1 to be allowed to change JESOWNER enter the following commands:

```
SETRPTS CLASSACT(SDSF) REFRESH
RDEFINE SDSF (ISFCMD.FILTER.OWNER) UACC(READ)
PERMIT ISFCMD.FILTER.OWNER ACCESS(NONE) CLASS(SDSF) ID(USER1)
SETRPTS CLASSACT(SDSF) REFRESH
```

For more information on SDSF security, see [z/OS SDSF Operation and Customization](#).

## Configuring the FTP server for anonymous FTP (optional)

You can configure the FTP server to allow users to log in anonymously. A user logs in anonymously by logging in as anonymous instead of as a user ID defined to the system. To enable users to log in anonymously, code the ANONYMOUS statement in the server FTP.DATA data set.

You can specify three levels of anonymous support on the ANONYMOUSLEVEL statement.

- ANONYMOUSLEVEL 1

That is, the ANONYMOUS statement is supported. If no operands are specified on the ANONYMOUS statement, the anonymous user needs no password and has access to MVS data sets and the z/OS UNIX file system.

- ANONYMOUSLEVEL 2

You should not specify ANONYMOUSLEVEL 2; ANONYMOUSLEVEL 2 is provided for migration purposes only. Consider ANONYMOUSLEVEL 3 if ANONYMOUSLEVEL 1 does not meet your anonymous login security requirements.

- ANONYMOUSLEVEL 3

ANONYMOUSLEVEL 3 is the default. If you specify ANONYMOUSLEVEL 3, the anonymous user cannot issue the USER command to leave anonymous mode, nor can another user issue USER anonymous to enter anonymous mode.

If you specify ANONYMOUSLEVEL 3 and STARTDIRECTORY HFS in FTP.DATA, the following rules apply:

- The anonymous user's z/OS UNIX file system access is restricted to the anonymous user's home directory and home directory subtrees. The anonymous user's home directory is the home directory of the user ID coded on the ANONYMOUS statement or the home directory of the user ID ANONYMO if you code the ANONYMOUS statement without a user ID.
- You must create an anonymous directory structure in the z/OS UNIX file system. See [“Creating an anonymous directory structure in the z/OS UNIX file system” on page 741](#) for more information.

If you specify ANONYMOUSLEVEL 3 and STARTDIRECTORY MVS in FTP.DATA, you must create a shadow copy of the /usr/sbin/ftpdns path and file under the home directory of the anonymous user in the z/OS UNIX file system. For more information, see step 2 in [“Creating an anonymous directory structure in the z/OS UNIX file system” on page 741](#)

The ANONYMOUSLEVEL 3 server recognizes additional statements that restrict the anonymous user's access to FTP resources. The following statements are ignored when ANONYMOUSLEVEL is 1 or 2:

- ANONYMOUSFILEACCESS allows the system programmer to preclude access to either the z/OS UNIX file system or MVS data sets.
- ANONYMOUSFILETYPEJES, ANONYMOUSFILETYPESQL, and ANONYMOUSFILETYPESEQ control whether the anonymous user can set filetype JES, SQL, or SEQ, respectively.
- ANONYMOUSHFSFILEMODE defines the mode bits used for files written to the z/OS UNIX file system.
- ANONYMOUSHFSDIRMODE defines the mode bits used for directories created in the z/OS UNIX file system.

When ANONYMOUSLEVEL is set to 3, the user's email address is requested in lieu of a password in the following situations:

- ANONYMOUS is specified without any parameters.
- ANONYMOUS is specified with user ID/password.
- ANONYMOUS is specified with user ID/SURROGATE.

You can control the degree of verification of the email address that an anonymous user enters as a password by using the EMAILADDRCHECK keyword in FTP.DATA. See [z/OS Communications Server: IP Configuration Reference](#) for details about the EMAILADDRCHECK keyword. The email address entered is logged to the syslog daemon and is also passed to a user exit routine, FTCHKPWD, for user processing.

The FTP server can be defined to process users without passwords by using the ANONYMOUS SURROGATE support. In order to support this, ANONYMOUSLEVEL must be set to 3 in FTP.DATA on the server and BPX.SRV surrogate must be defined in RACF.

z/OS UNIX uses profiles defined to the RACF SURROGAT class to authorize the server to act as a surrogate of a client. Profiles defined to the SURROGAT class are of the form:

```
BPX.SRV.<userid>
```

in which <userid> is the MVS user ID of the user that the server will support without a password.

The following steps are for a sample user ID of the FTP daemon (the user ID associated with the FTP started task procedure) called FTPD with the ability to support user ID GUEST without a password. As you add more servers, you will need to follow similar procedures.

1. Activate the SURROGAT class support in RACF:

```
SETOPTS CLASSACT(SURROGAT)
```

This has to be done only once on the system. The SURROGAT class may already have been set up on your system. If a daemon or server you are running will be using the SURROGAT support heavily, consider using the RACLIST command to keep the SURROGAT profiles in storage. The following example shows how to cache the SURROGAT profiles in storage:

```
SETOPTS RACLIST(SURROGAT)
```

2. If the SURROGAT profile is in the RACLIST, any changes to the SURROGAT profiles must be followed by a REFRESH command. To create the SURROGAT class profile for user ID GUEST, issue:

```
RDEFINE SURROGAT BPX.SRV.GUEST UACC(NONE)
SETOPTS RACLIST(SURROGAT) REFRESH
```

A similar SURROGAT profile is required for each user ID that a server must support without a password.

3. To permit the user ID of the FTP daemon (the user ID associated with the FTP started task procedure), FTPD, to create a security environment for user ID GUEST, issue the PERMIT command:

```
PERMIT BPX.SRV.GUEST CLASS(SURROGAT) ID(FTPD) ACCESS(READ)
SETOPTS RACLIST(SURROGAT) REFRESH
```

## Creating an anonymous directory structure in the z/OS UNIX file system

The sample shell script, ftpandir.scp, will create an anonymous directory structure for you, containing required and optional structures. Or, a superuser can create the anonymous directory structure. In this topic, the steps a superuser would follow to create an anonymous directory structure are outlined.

For the following steps, assume that the RACF user ID that is used when an anonymous user logs in is called GUEST, that the HOME directory in that user's OMVS segment in RACF is /u/guest, and that FTP.DATA contains a statement similar to this: ANONYMOUS GUEST

1. Create a bin subdirectory in the anonymous root containing the executable files ls and sh. This is a required directory. ls can be copied from the standard directory. sh is part of the standard MVS search order, so you need only create an empty file with the sticky bit.

The following example shows how to create ls and sh in the user GUEST's home directory:

```
===> cd /u/guest
===> mkdir bin
===> chmod 711 bin
===> cd bin

===> cp /bin/ls ls
===> chmod 711 ls
===> touch sh
===> chmod 711 sh
===> chmod +t sh
```

An **ls -al** command should give the following results. Owner and group attributes may be different in your system.

```
ls -al
total 280
drwx--x--x 2 USER22 0 8192 Sep 21 17:39 .
drwx--x--x 7 USER22 0 8192 Nov 1 14:44 ..
-rwx--x--x 1 USER22 0 126976 Sep 21 17:39 ls
-rwx--x--t 1 USER22 0 0 Sep 21 17:39 sh
```

2. Create a usr/sbin subdirectory of the anonymous root containing the executable file ftpdms. This is a required subdirectory. The file ftpdms can be empty with the sticky bit on.

The following example is for anonymous user GUEST:

```
===> cd /u/guest
===> mkdir usr
===> chmod 711 usr

===> cd usr
===> mkdir/sbin
===> chmod 711/sbin
===> cd/sbin
===> touch ftpdms
===> chmod 711 ftpdms
===> chmod +t ftpdms
```

If you do not configure the subdirectories, bin and usr/sbin, and their contents correctly, the FTP server will not be able to accept anonymous logins and message EZYFT731 will be displayed.

3. Create a dev subdirectory within the anonymous root. This is a required subdirectory. A null file is created in this directory and used during the open of syslog.

The following example is for anonymous user GUEST:

```
===> cd /u/guest
===> mkdir dev
===> chmod 711 dev
```

If you do not have the dev subdirectory, syslog might not open correctly. Messages such as EZA2830I will not be logged out correctly.

4. Set up the public directory structure. This is a required directory.

This is the directory structure into which you place files that can be downloaded by the anonymous FTP user. It does not have to be named pub; it can be any name you choose. A general convention for anonymous FTP sites is to call it pub:

```
===> cd /u/guest
===> mkdir pub
===> cd pub
```

If you want to structure the files you allow to be accessed, you can create multiple subdirectories underneath this directory.

For simplicity, assume a single level directory, the pub directory. Into this directory you copy the files you want to allow the anonymous user to download:

```
===> cp /x/y/z/prodinfo1.txt prodinfo1.txt
===> cp /x/y/z/prodinfo2.txt prodinfo2.txt
===> cd ..
```

Make sure that the permission bits are set correctly by using the following shell command when executed in the /u/guest directory. This will set the permission bits of all files in the pub directory and its subdirectories to 755:

```
===> chmod -R 755 pub
```

If your system does not require an incoming or extract directory, the system is configured for anonymous FTP. An **ls -al** command of the pub directory should give the following results:

```
drwxr-xr-x 3 IBMUSER SYS1 8192 May 13 21:15 .
drwxr-xr-x 6 IBMUSER SYS1 8192 May 20 14:51 ..
-rwxr-xr-x 1 IBMUSER SYS1 12 May 11 12:41 prodinfo1.txt
-rwxr-xr-x 1 IBMUSER SYS1 12 May 11 12:41 prodinfo2.txt
```

#### 5. Set up an incoming directory (optional).

If you want anonymous users to be able to upload files to your FTP server, you need some additional setup. The objective is to allow an anonymous user to upload a file, but not to allow another anonymous user to download or even be aware of the existence of the file until after an administrative user has verified that the content of the file is acceptable. You do not want your FTP server site to become a store-and-forward site for files of questionable ethical content.

Positioned at the /u/guest directory, a superuser issues the following shell command:

```
===> cd /u/guest
===> mkdir incoming
===> chmod 733 incoming
```

It does not have to be named incoming; it can be any name you choose. A general convention for anonymous FTP sites is to call it incoming.

The 733 permission bits means that a non-superuser cannot list the content of the incoming directory, but can write a file to it. Because the FTP server enforces a UMASK of 777 when an anonymous user logs in, these files will be written with permission bits 000, which means that they cannot be accessed by the anonymous user or by any other user except a superuser.

An FTP client user can usually change the UMASK value with a SITE UMASK command or the user can change the permission bits of files they own through a SITE CHMOD command.

If you define ANONYMOUSLEVEL 3, you can use the ANONYMOUSHFSDIRMODE keyword to set the permission bits of any directory created by an anonymous user, and the ANONYMOUSHFSFILEMODE to set the permission bits of any file created by an anonymous user.

If you do allow anonymous users to store files on your FTP server, you should ensure that the directory into which these files are stored is a separate z/OS UNIX file system that can fill up without impacting other work on your z/OS system. The best way to do that is to allocate the /u/guest/incoming directory in its own z/OS File System, HFS data set, or Network File System. If an anonymous user uploads large amounts of data to the incoming directory, only this separate z/OS UNIX file system will be filled up.

Filling this separate z/OS UNIX file system prevents other anonymous users from storing new files on the server, but will not affect other functions on your system. At a minimum, you should make sure that the incoming directory is not located on the same physical device as your /tmp directory.

6. Set up the extract directory (optional).

If you need to make files available to certain anonymous users, but not to everyone, you can create a directory that cannot be listed, but files in it can be downloaded if the anonymous user knows the name of the file.

Positioned at the /u/guest directory, a superuser issues the following shell commands:

```
===> cd /u/guest
===> mkdir extract
===> chmod 711 extract
```

It does not have to be named extract; it can be any name you choose. A general convention for anonymous FTP sites is to call it extract.

A superuser can then copy files into this directory, ensure they have permissions of 755, inform the intended anonymous user of the file name, and that user can then log on as anonymous and retrieve the file.

An **ls -al** command at the /u/guest location should give the following result, if you created all four subdirectories:

```
drwxr-xr-x 6 IBMUSER SYS1 8192 May 20 14:51 .
dr-xr-xr-x 6 IBMUSER SYS1 0 Jun 10 15:43 ..
drwx--x--x 2 IBMUSER SYS1 8192 May 11 12:44 bin
drwx--x--x 3 IBMUSER SYS1 8192 May 11 13:39 extract
drwx-wx-wx 3 IBMUSER SYS1 8192 May 25 09:35 incoming
drwxr-xr-x 3 IBMUSER SYS1 8192 May 13 21:15 pub
```

## Configure the welcome banner page, login, and directory message (optional)

---

The FTP server provides support to enable FTP administrators to provide useful information about the site to FTP users. The following FTP.DATA statements are available:

- BANNER
- LOGINMSG
- ANONYMOUSLOGINMSG
- MVSINFO
- ANONYMOUSMVSINFO
- HFSINFO
- ANONYMOUSHFSINFO

You can use the LOGINMSG statement in FTP.DATA to point to a set of messages displayed when a known user logs in to FTP. Similarly, ANONYMOUSLOGINMSG can point to a set of messages displayed when an anonymous user logs in to FTP.

You can use the MVSINFO statement to point to a set of messages displayed when a known user changes the working directory to a particular MVS data set path. Likewise, use the ANONYMOUSMVSINFO statement to point to a set of messages displayed when an anonymous user changes working directory to a particular MVS data set path.

You can use the HFSINFO statement to point to a set of messages displayed when a client changes the working directory to a particular z/OS UNIX directory. Likewise, use the ANONYMOUSHFSINFO statement to point to a set of messages displayed when an anonymous user changes working directory to a particular z/OS UNIX directory.

## Using magic cookies to represent information

The content of all the informational messages may include a predefined set of magic cookies, which are substituted by the FTP server before the data is sent to the FTP client. The following magic cookies are supported:

- %T — Local time
- %C — Current working directory
- %E — The email address of the FTP server administrator
- %R — Remote host name
- %L — Local host name
- %U — Username (logged in user)

If %R is used, a long delay in login processing might occur as the FTP server will issue a DNS query to resolve the remote host IP address. In order to use %E, the ADMINEMAILADDR keyword must be specified in the server FTP.DATA configuration file.

## Configuring the FTP server to log session (user ID) activity

You can configure the FTP server to write log messages for trace activity related to individual sessions by coding the FTPLOGGING or ANONYMOUSFTPLOGGING statements in FTP.DATA. If you have configured syslogd for FTP, the log messages appear in syslog.

Table 35 on page 744 shows the FTP log message written for various activities. You can identify an FTP log message by the ID=*sessionID* parameter in the message. Each login session is assigned a session ID that can be used to identify all log messages related to that session. For more information about [EZYFxxxx messages](#), see [z/OS Communications Server: IP Messages Volume 3 \(EZY\)](#).

| Table 35. EZYFxxxx messages  |                                                                                              |
|------------------------------|----------------------------------------------------------------------------------------------|
| FTP log message              | Activity                                                                                     |
| EZYFS50I                     | A client connected to the FTP daemon.                                                        |
| EZYFS51I                     | A client connection to the FTP daemon failed.                                                |
| EZYFS52I                     | An FTP session ended.                                                                        |
| EZYFS54I                     | The server accepted the security mechanism. The connection with the client is now protected. |
| EZYFS55I                     | The server rejected the security mechanism. The connection with the client is not protected. |
| EZYFS56I                     | A client logged into the server.                                                             |
| EZYFS57I                     | A client login to the server failed.                                                         |
| EZYFS58I                     | The server denied the client access to an MVS data set.                                      |
| EZYFS59I                     | The server denied the client access to a z/OS UNIX file.                                     |
| EZYFS60I, EZYFS61I, EZYFS62I | The server successfully allocated an MVS data set.                                           |
| EZYFS63I, EZYFS64I, EZYFS65I | The server could not allocate an MVS data set.                                               |
| EZYFS67I                     | The server successfully allocated an MVS data set.                                           |
| EZYFS68I, EZYFS69I           | The server could not allocate a z/OS UNIX file.                                              |
| EZYFS70I, EZYFS74I, EZYFS75I | The server deallocated an MVS data set.                                                      |
| EZYFS71I, EZYFS72I, EZYFS73I | The server detected an error while deallocating an MVS data set.                             |

| Table 35. EZYFxxxx messages (continued) |                                                                                                    |
|-----------------------------------------|----------------------------------------------------------------------------------------------------|
| FTP log message                         | Activity                                                                                           |
| EZYFS77I                                | The server deallocated a z/OS UNIX file.                                                           |
| EZYFS78I, EZYFS79I                      | The server detected an error while deallocating a z/OS UNIX file.                                  |
| EZYFS80I                                | The server sent a reply to the client after data transfer.                                         |
| EZYFS81I                                | The server finished processing an MVS data set transfer.                                           |
| EZYFS82I                                | The server finished processing a z/OS UNIX data set transfer.                                      |
| EZYFS83I                                | The server stored a data set or file into its file system.                                         |
| EZYFS84I                                | The server sent a data set or file to the client (or to a server in the case of a proxy transfer). |
| EZYFS85I                                | The server finished returning job output to the client.                                            |
| EZYFS86I                                | The server assigned a confidence of success level to the completed data transfer.                  |
| EZYFS91I                                | The server submitted a job for the client.                                                         |

| EZYFS95I                                | An abend occurred while the server was transferring data.                                          |

## Configuring to send detailed login failure replies to an FTP client (optional)

The FTP server returns minimal information to the client when the PASS command fails. However, you can configure the FTP server to send additional information by coding ACCESSERRORMSGs TRUE in FTP.DATA. This directs the server to reply to the client with detailed login failure data. The reply might report server errors, such as failing function calls with diagnostic return codes. It might report user errors, such as an expired or incorrect password or password phrase, an unknown user ID, or a revoked user ID. You should not code ACCESSERRORMSGs TRUE in FTP.DATA if you do not want to share this type of information with users logging in to FTP.

You can capture the same information in syslog by coding FTPLOGGING TRUE and ANONYMOUSFTPLOGGING TRUE in FTP.DATA. You can also turn on the DEBUG option called ACC to log the error messages in the syslog. For more information on coding FTP.DATA statements, see [z/OS Communications Server: IP Configuration Reference](#).

## Install the SQL query function (optional) and access the Db2 modules

To use FTP to perform SQL queries, bind a plan that allows FTP to invoke the package EZAFTPMQ in collection EZAFTPMQ, and grant execution privileges for that plan to PUBLIC. You can specify the name of the plan using the DB2PLAN keyword in FTP.DATA, or the default is EZAFTPMQ. This FTP facility performs only SELECT operations on the Db2 tables; it does not perform UPDATE, INSERT, or DELETE operations.

**Requirement:** If secondary authorization for SQL queries is required, you must modify the DSN3SATH sample exit shipped by Db2. The exit returns the primary AUTHID for requests that originate from the FTP server.

The following sample job is provided in the FTOEBIND member of the SEZAINST data set; you can use it to enable the FTP server and client to perform SQL queries.

```
//FTPSETUP JOB FTPSETUP,
```

```

// CLASS=A,
// NOTIFY=&SYSUID
//*****
//*
//* File name: tcpip.SEZAINST(FTOEbind)
//* SMP/E distribution name: EZAFTPMQ
//*
//* Licensed Materials - Property of IBM
//* This product contains "Restricted Materials of IBM"
//* 5647-A01 Copyright IBM Corp. 1997, 2011
//* All rights reserved.
//* US Government Users Restricted Rights -
//* Use, duplication or disclosure restricted by GSA ADP Schedule
//* Contract with IBM Corp.
//* See IBM Copyright Instructions.
//*
//* This JCL binds a plan that allows the application to ability the
//* invoke the package EZAFTPMQ in collection EZAFTPMQ.
//* The JCL allows execution of the plan EZAFTPMQ by PUBLIC.
//*
//* The FTP server and client use this plan. (See
//* Usage note #7)
//*
//* Usage notes:
//*
//* 1. You must execute this job from a user ID that has
//* the authority to bind the EZAFTPMQ plan.
//*
//* 2. Change the STEPLIB DD statement in the FTPBIND and
//* FTPGRANT steps to reflect the DB2 DSNLOAD data set.
//*
//* 3. Change the DB2 subsystem name in the FTPBIND and
//* FTPGRANT steps from SYSTEM(xxx) to the
//* installation defined DB2 subsystem name.
//*
//* 4. Change the library parameter in the FTPBIND step from
//* TCPIP.SEZADBRM to the installation defined TCPIP
//* SEZADBRM library.
//*
//* 5. Change the plan name in the FTPGRANT step from
//* DSNTIAYY to reflect the plan associated with the
//* program DSNTIAD.
//*
//* 6. Change the library parameter in the FTPGRANT step
//* from xxxxxx.RUNLIB.LOAD to reflect the library
//* where the DSNTIAD program resides.
//*
//* 7. You can bind the DBRM to a package and a plan name
//* other than EZAFTPMQ by changing the plan specified
//* in the FTPBIND and FTPGRANT steps.
//*
//*****
//FTPBIND EXEC PGM=IKJEFT01,DYNAMNBR=20

```

## Accessing Db2 modules

The FTP server or client loads 3 Db2 modules into storage to perform an SQL query. These modules are:

- DSNALI
- DSNHLI2
- DSNTIAR

The modules are usually found in the Db2 load library with the suffix DSNLOAD. The Db2 administrator or system programmer should add the DSNLOAD library to the LINKLIST to ensure FTP has access to this library.

Another way to ensure access is to add the DSNLOAD library to the FTP STEPLIB. For the FTP server this means the JCL used to start the FTP server has a STEPLIB DD statement referring to the DSNLOAD library or, if the FTP daemon is started from the z/OS shell, the STEPLIB environment variable is set. For the FTP client, this means a TSO CLIST must allocate the DSNLOAD library as the STEPLIB.

If the FTP client is to be run from a batch job to perform SQL queries, the DSNLOAD library must be added to the STEPLIB DD statement for the batch job.

### Usage notes:

To allow FTP access to multiple levels of Db2, link to the libraries that contain the lowest level of Db2 to be accessed.

## FTP.DATA updates for SQL query function

To obtain FTP.DATA updates for the SQL query function, follow these steps:

1. Set the FTP.DATA DB2 statement to specify the name of the Db2 subsystem.
2. Set DB2PLAN to specify the Db2 plan to be used by the FTP server.
3. Set the SPREAD statement to specify whether SQL output is in spreadsheet format.
4. Set SQLCOL to specify the column headings of the output data.

## Verifying the FTP server

If FTP is in the autolog list and the TCP/IP address space is restarted, FTP should start automatically. For other cases, it should be started manually. To do this, go to the MVS console and enter the following command:

```
S FTPD
```

**Note:** This command assumes the FTP procedure name is FTPD.

If the FTP server startup is complete, the following message should be seen on the MVS console:

```
EZY2702I Server-FTP: Initialization completed at 17:37:29 on 12/17/99.
```

If the message is not seen, a message explaining why FTP did not start up will appear in SYSLOG. Even if the above message is issued, it would be beneficial to inspect SYSLOG for warning messages issued during FTP initialization. EZY2700I displays the port FTP uses as the control port, the port it listens to for incoming connections from clients. In this example, FTP is listening to standard port 21.

The file syslog uses is defined in /etc/syslog.conf. The statement daemon.info /tmp/daemon.log directs SYSLOGD to save all the daemon messages in /tmp/daemon.log. Below is an example of output error messages.

```
EZYFT18I Using catalog '/usr/lib/nls/msg/C/ftpdmsg.cat' for FTP messages.
EZY2697I IBM FTP CS V1R10 21:04:56 on 04/17/08
EZY2640I Using dd:SYSFTPD=USER1.FTP.DATA for local site configuration parameters
EZYFT46E Error in dd:SYSFTPD file: line 4 near column 9.
EZY2636E SMFLOGN value not specified.
EZYFT46E Error in dd:SYSFTPD file: line 5 near column 8.
EZY2636E SMFREN value not specified.
EZYFT47I dd:SYSFTPD file, line 21: Ignoring keyword "EXTENSIONS REST_STREAM".
EZYFT47I dd:SYSFTPD file, line 29: Ignoring keyword "CTRLCONN".
EZYFT21I Using catalog '/usr/lib/nls/msg/C/ftpdprly.cat' for FTP replies.
EZYFT26I Using 7-bit conversion derived from 'ISO8859-1' and 'IBM-1047' for the control connection.
EZYFT33I Unable to open DDNAME 'SYSFTSX' for the data connection: EDC5129I No such file or directory.
EZYFT31I Using '//TPOUSER.STANDARD.TCPXLBIN' for FTP translation tables for the data connection.
EZYFT09I system information for VIC135: z/OS version 1 release 10 (2094)
EZY2700I Using port FTP control (21)
EZY2701I Inactivity time is 0
EZY2702I Server-FTP: Initialization completed at 21:05:57 on 04/17/08.
EZYFT41I Server-FTP: process id 16777255, server job name FTPD11
```

## Verifying the FTP client

To verify that the FTP client works correctly, log onto TSO and issue the NETSTAT HOME command, or issue NETSTAT -h from the z/OS UNIX shell. These commands will show the interface addresses that are known to the system. Below is an example of the output from NETSTAT HOME:

```
MVS TCP/IP NETSTAT CS V1R9 TCPIP Name: TCPCS 14:22:17
Home address list:
LinkName: OSAQDI06L
 Address: 9.67.115.13
 Flags: Primary
LinkName: LSAMEH
 Address: 9.1.1.1
 Flags:
LinkName: LOOPBACK
 Address: 127.0.0.1
 Flags:
Address: fe80::9:6b00:671a:586
 Type: Link_Local
 Flags: Autoconfigured
IntfName: V6SAMEH
 Address: 1::8
 Type: Global
 Flags:
IntfName: V6VIRT
Address: 2::55
 Type: Global
 Flags:
IntfName: LOOPBACK6
 Address: 3::1
 Type: Global
 Flags:
Address: ::1
 Type: Loopback
 Flags:
```

To invoke the FTP client, use any address shown on the NETSTAT HOME address list. The first example below shows how you could log in to the FTP server at 9.67.115.13 using a batch job (the output of the batch job is not shown). The second example shows logging in to the FTP server at 9.67.113.37 from the TSO environment.

```
//FTPBATCH JOB FTPUSER,
// USER=USER1,PASSWORD=TCPSUP
//BATCH EXEC PGM=FTP
//OUTPUT DD SYSOUT=*
//INPUT DD *
9.67.115.13
```

```

USER10 tcpusr
SITE FILE=SEQ
QUIT
//*

```

```

Using 'USER1.FTP.DATA' for local site configuration parameters.
IBM FTP CS V1R9
FTP: using TCP/CS

## Verifying FTP.DATA statements

You can verify many FTP.DATA statements by using the FTP client STATUS and LOCSTAT subcommands. The output from the STATUS and LOCSTAT subcommands depends on the client and server copy of FTP.DATA at each installation. The following sample shows the output of one system:

```

stat
EZA1701I >>> STAT
211-Server FTP talking to host ::ffff:10.1.2.3, port 1026
211-User: USER1 Working directory: USER1.

## Verifying anonymous, banner, and other optional configuration information

Depending on your installation's choices for anonymous level, banner support chosen, exits, and so on, verification of support output will differ. To verify anonymous configuration at a particular installation, log in as anonymous and verify the behavior is as expected. For example, if EMAILADDRCHECK FAIL is specified in FTP.DATA, try to log in as anonymous using an incorrect email address as password. To verify banner support, login and verify the banners are displayed as expected. Below is a sample of FTP.DATA and FTP client output for one such installation.

```

; BANNER STUFF
EMAILADDRCHECK FAIL
BANNER USER1.TEST1
ADMINEMAILADDR FTPADMIN@MYSYSTEM.COM
; ANONYMOUS STUFF
ANONYMOUSLEVEL 3
STARTDIRECTORY HFS

```

```

```

## Verifying the FTP-JES interface (optional)

As with the other optional configuration information, FTP-JES support can best be verified by logging in and confirming the FTP.DATA parameters chosen. To verify JES support, a simple batch job can be created if the JESINTERFACELEVEL is set to the security requirements of an installation. Below is the batch job and FTP client output for JESINTERFACELEVEL 2.

```

EDIT USER1.FTP.JCL.TEST

## Chapter 13. The resolver

The resolver acts on behalf of programs as a client to perform the following functions:

- Access name servers to provide name-to-address or address-to-name resolution
- Allocate and read the TCPIP.DATA file
- Establish TCP/IP stack affinity for certain socket APIs
- Provide protocol and services information

To resolve the query for the requesting program, the resolver uses information that it obtains from the following sources:

- Available name servers
- The DNS response information that has been cached locally (when system-wide caching is enabled)
- Local definitions, such as `/etc/hosts`, `/etc/ipnodes`, `HOSTS.SITEINFO`, `HOSTS.ADDRINFO`, and `ETC.IPNODES`

The TCPIP.DATA statements control how (and if) the resolver uses name servers. For detailed information about TCPIP.DATA configuration statements, see [z/OS Communications Server: IP Configuration Reference](#).

**Requirement:** The resolver address space must be started before any application or TCP/IP stack resolver calls can occur.

---

### DNS overview

While TCP/IP applications refer to host computers by their IP addresses, it is easier to use host names. To enable the use of host names in a network, the Domain Name System (DNS) translates host names to IP addresses. Mapping must be consistent across the network to ensure interoperability. DNS provides the host name-to-IP address mapping through network server hosts called *domain name servers*. For detailed information about name servers, see “Domain name servers” on page 754. DNS can also provide other information about server hosts and networks such as the TCP/IP services available at a server host and the location of domain name servers in a network.

DNS organizes the hosts in a network into domains. A *domain* is a group of hosts that share the same name space in the domain hierarchy and are usually controlled within the same organization. Domains are arranged in a hierarchy. A special domain known as the *root domain* exists at the top of the hierarchy. The root domain servers store information about server hosts in the root domain and the name servers in the delegated, *top-level* domains, such as `com` (commercial), `edu` (education), and `mil` (military). The name servers in the top-level domain, in turn, store the names of name servers for their delegated domains, and so on.

The complete name of a host, also known as the *fully qualified domain name* (FQDN), is a series of labels separated by dots or periods. Each label represents an increasingly higher domain level within a network. The complete name of a host connected to one of the larger networks generally has more than one subdomain, as shown in the following examples:

```
host1.subdomain2a.subdomain2.rootdomain
user4720.eng.mit.edu
```

A domain name server requires the FQDN. The client resolver combines the host name with the domain name to create the FQDN before sending the name resolution request to the domain name server.

DNS also provides IP address-to-host name mapping. The DNS defines a special domain called `in-addr.arpa` to translate IPv4 addresses to host names, and the `ip6.int` and `ip6.arpa` domains for IPv6 address-to-host name translation. This kind of mapping is useful for producing output (host names) that is easy to read. An `in-addr.arpa` name is composed of the reverse octet order of an IP address concatenated with the `in-addr.arpa` string. For example, a host named `Host1` has

9.67.43.100 as an IP address. The in-addr.arpa domain translates the Host1 IP address 9.67.43.100 to 100.43.67.9.in-addr.arpa.

A system administrator can name the host systems and domains in the local, private network with any name you want, but to link with name servers in a public network like the Internet, you need to determine which domain you want to be in (which parent domain) and then contact the registrar in that domain to register the names and IP addresses of your name servers. This ensures that queries from outside the domain being defined can be answered by this name server if need be.

**Note:** Contact the InterNetwork Information Center (InterNIC) for more information about Internet registration. You can contact InterNIC by pointing your web browser at <http://www.internic.net>.

## Domain names

The DNS uses a hierarchical naming convention for naming hosts. Each host name is composed of domain labels separated by periods. Local network administrators have the authority to name local domains within an intranet. Each label represents an increasingly higher domain level within an intranet. The fully qualified domain name of a host connected to one of the larger intranets generally has one or more subdomains:

- *host.subdomain.subdomain.rootdomain*
- *host.subdomain.rootdomain*

Domain names often reflect the hierarchy level used by network administrators to assign domain names. For example, the domain name eng.mit.edu is the fully qualified domain name, where eng is the host, mit is the subdomain, and edu is the highest level domain (root domain).

Figure 106 on page 754 is an example of the DNS used in the hierarchy naming structure across an intranet.

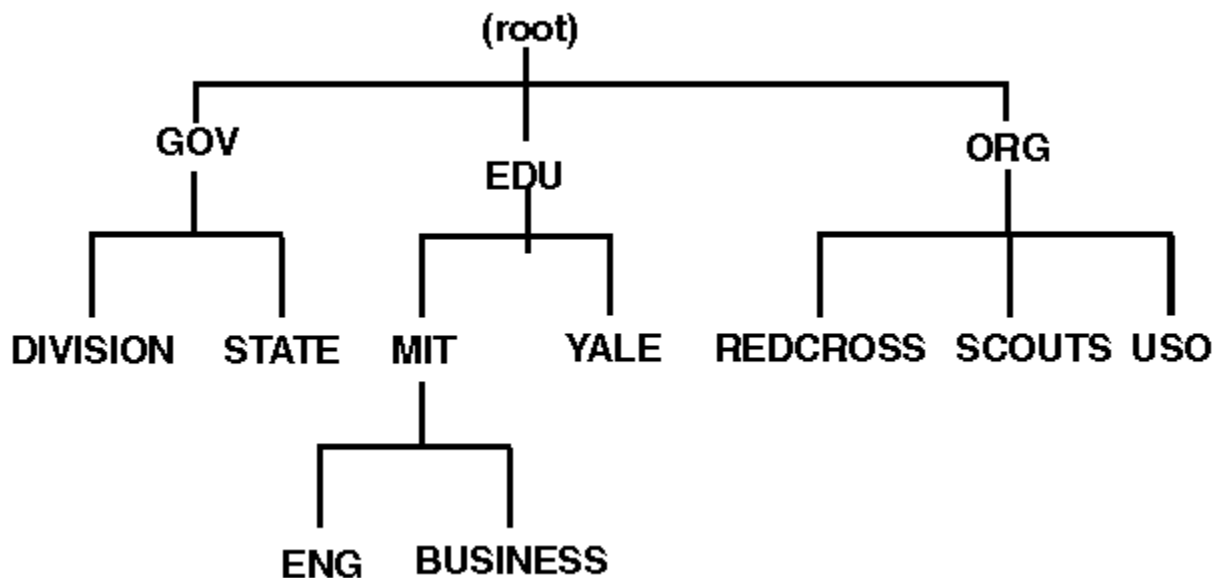

Figure 106. Hierarchical naming tree

You can refer to hosts in your domain by host name only; however, a name server requires a fully qualified domain name. The local resolver appends the domain name before sending the query to the Domain Name Server for address resolution.

## Domain name servers

Domain name servers are designated network nodes that maintain a database of information about all nodes in some part of the domain name space, called a *zone*. A name server is said to be *authoritative* for

its zone. A zone consists of the resources within a single domain (for example, commercial or .com) or subdomain (for example, raleigh.ibm.com). Typically, a zone is administered by a single organization or individual. The complete database is not kept by any one name server on a network. A name server is authoritative only within its zone of authority.

All host systems in a given zone share the same higher level domain name (for example, host1.raleigh.ibm.com, host2.raleigh.ibm.com, host3.raleigh.ibm.com, and so on). As system administrator, you create a zone of authority by listing all the host systems in your zone in the database file of the name server that is authoritative for the zone.

If a domain name server receives a query about a host for which it has information in its database or in its cache, it performs the name resolution and returns all the address records associated with the host to the client. Some hosts (for example, routers or gateways between two or more networks) might have more than one IP address.

Alternatively, the name server can query other name servers for information. This process is called *iterative resolution*. The local name server successively queries other name servers, each of which responds by referring the local name server to a remote name server that is closer to the name server authoritative for the target domain. Finally, the local name server queries the authoritative name server and gets an answer. If the information about a requested host name does not exist or if a name server does not know where to go for the information, it sends a negative response back to the client.

There are multiple name server modes in the DNS:

- Authoritative
  - Master (primary)
  - Secondary
- Caching-only servers
- Forwarders
- Stealth

A single server can perform multiple functions. For example, it can be a primary server and a secondary server for different zones. The purpose of having these different kinds of servers is to provide redundancy (in case of system failure), to distribute the workload among multiple servers, to speed up the name-resolution process, and to provide flexibility in network design. In addition to being an authoritative or caching-only server, a name server can be defined to contact only a specific set of name servers if queries cannot be resolved locally (through the use of forwarders).

The following subtopics discuss authoritative servers, caching-only servers, and forwarding.

## Authoritative servers

An authoritative server is the authority for its zone. It queries and is queried by other name servers in the DNS. The data it receives in response from other name servers is cached. Authoritative servers are not authoritative for cached data.

There are two types of authoritative servers: master (primary) and secondary. Each zone must have only one master name server, and it should have at least one secondary name server for backup purposes to minimize dependency on a particular node. Calling a particular name server a master or secondary server is misleading. Any given name server can take on either or both roles, as defined by the conf file.

The zone data updates and maintenance are reflected in the master name server and the changes are then reflected in secondary name servers. Both master and secondary name servers are authoritative for a zone.

The zones of authority are arranged in a hierarchy based on the domain origin components. A special zone known as the *root* exists at the top of the domain name hierarchy in a network. The root zone contains a list of all the root servers. For example (see [Figure 106 on page 754](#)), in the Internet, the root name servers store information about nodes in the root domain, and information about the delegated domains, such as com (commercial), edu (education), and mil (military). The root name servers store the names

of name servers for each of these domains, which in turn store the names of name servers for their delegated subdomains.

TCP/IP applications contact a name server whenever it is necessary to translate a domain name into an IP address, or when information is required about a domain. The name server performs the translation if it has the necessary information. If it does not have the necessary information, the name server can contact other name servers, which in turn can contact other name servers. This process is called a *recursive query*. Alternatively, a name server can return the address of another name server that might hold the requested information. This is called a *referral response* to a query. Name server implementations must support referrals, but are not required to perform recursive queries. See [“Resolvers” on page 757](#) for more information about query responses.

### **Master name servers**

A master name server maintains all the data for its zone. Static resources are kept in database files called *domain data files*. Master name servers can also receive zone updates dynamically.

### **Secondary name servers**

A secondary name server acts as an alternate to the master name server if the master name server becomes unavailable or overloaded. The secondary name server receives zone data directly from the master name server in a process called *zone transfer*. Zone transfers occur only when data changes. Some name servers support zone change notification, which results in the zone transfer happening quickly after the data changes. Other name servers poll for changed data based on the refresh interval in the Start of Authority (SOA) resource record. For a description of the SOA resource record, see [z/OS Communications Server: IP Configuration Reference](#). A secondary name server, like a master name server, is authoritative for a zone.

### **Caching-only servers**

All name servers cache (store) the data they receive in response to a query. A caching-only server, however, is not authoritative for any domain. Responses derived from cached information are flagged in the response. When a caching-only server receives a query, it checks its cache for the requested information. If it does not have the information, it queries a local name server or a root name server, passes the information to the client, and caches the answer for future queries. The names and addresses of the root name servers are acquired from the servers listed in the hints file, the name and file path of which are specified in the name server's configuration file.

You can manually configure a name server to create a large cache of responses to queries that are frequently requested and reduce the number of queries made to master servers. The name server that you configure as a caching-only server stores data for a period of time determined by the time-to-live (ttl) value, and the cached information is lost if the name server is restarted.

**Tip:** As an alternative to manually configuring a caching-only server, you can use the cache that the resolver creates. The resolver cache is enabled by default and typically provides better system performance than using a caching-only name server that you have configured manually. For more information about using, configuring, and managing the resolver cache, see [“Resolver caching” on page 774](#).

### **Forwarders**

Normally, name servers answer queries from cached data or, if that does not succeed, they attempt to contact other name servers identified in their data files as authoritative for certain domains. However, name servers can also be configured to contact special servers called *forwarders* before contacting the name servers listed in their data files. If a forwarder cannot process the query and if the local name server is not a forward-only name server, the local name server contacts the name servers in its data files. A forward-only name server relies completely on its forwarders. It does not try to contact other servers to find out information if the forwarders do not give it an answer.

The forwarding function is useful for reducing the number of queries to servers on the Internet and for creating a large cache of information on forwarders. It is also a useful function for providing Internet access for local servers that, for one reason or another, do not have access themselves.

## Stealth server

A *stealth server* is a server that answers authoritatively for a zone, but is not listed in that zone's NS records. Stealth servers can be used as a way to centralize distribution of a zone, without having to edit the zone on a remote name server. When the master file for a zone is on a stealth server in this way, it is often referred to as a *hidden primary* configuration. Stealth servers can also be a way to keep a local copy of a zone for rapid access to the zone's records, even if all official name servers for the zone are inaccessible.

## Resolvers

Programs that query a name server are called *resolvers*. Because many TCP/IP applications need to query the name server, a set of routines is usually provided for application programmers to perform queries. On z/OS, these routines are available in the resolver provided by z/OS Communications Server.

z/OS Communications Server provides programs for interactively querying a name server:

- NSLOOKUP (TSO)
- **onslookup/nslookup** (z/OS UNIX)
- DIG (TSO)
- **dig** (z/OS UNIX)
- **host**

**Restriction:** For IBM z/OS Container Platform environments, onslookup/nslookup and host are supported in a z/OS Container Platform environment.

**Note:** The **nsupdate** program also makes queries to name servers as part of its operations.

For information on these programs, see [z/OS Communications Server: IP System Administrator's Commands](#).

The **onslookup** command and the **dig** command use the resolver initialization facilities of the resolver provided by z/OS Communications Server, but use their own resolver for any additional resolver facilities needed.

## Resolver directives for nslookup

The onslookup program uses the following resolver directives (TCPIP.DATA statements):

- domain/domainorigin
- search
- nameserver/nsinteraddr
- options debug/options ndots

## Resolver directives for dig

The dig program uses the following resolver directives (TCPIP.DATA statements):

- domain/domainorigin
- search
- nameserver/nsinteraddr
- options ndots

## Query Packets

Resolvers operate by sending query packets to a name server. A query packet contains the following fields:

- Domain name
- Query type
- A query class

RFC 1035 defines the query types and query classes. The name server attempts to match the three fields of the query packet to its database. For flexibility, the following wildcard query types are defined:

| Type | Description |
|------|-------------|
|------|-------------|

|            |                                                |
|------------|------------------------------------------------|
| <b>ANY</b> | Indicates any record type for the domain name. |
|------------|------------------------------------------------|

|             |                                                                                                                                                             |
|-------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>AXFR</b> | Indicates the query type used by secondary name servers to transfer all records in the zone. (The query class is set to IN when using the AXFR query type.) |
|-------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------|

|              |                                                    |
|--------------|----------------------------------------------------|
| <b>MAILB</b> | Indicates any mailbox records for the domain name. |
|--------------|----------------------------------------------------|

The name server can return the following query responses:

| Response | Description |
|----------|-------------|
|----------|-------------|

|                      |                                                                                                                                                    |
|----------------------|----------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Authoritative</b> | Is returned from a primary or secondary name server. The name server contains all the domain data used to define the zone for the specified query. |
|----------------------|----------------------------------------------------------------------------------------------------------------------------------------------------|

|                |                                                                                       |
|----------------|---------------------------------------------------------------------------------------|
| <b>BADVERS</b> | The name server received a request that contained a EDNS0 version that was not valid. |
|----------------|---------------------------------------------------------------------------------------|

|                         |                                                                                                                                             |
|-------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Nonauthoritative</b> | Is returned from a cache kept by a name server. The cache does not contain the domain data used to define the zone for the specified query. |
|-------------------------|---------------------------------------------------------------------------------------------------------------------------------------------|

|                     |                                                                          |
|---------------------|--------------------------------------------------------------------------|
| <b>Format Error</b> | The name server found an error in the query packet sent by the resolver. |
|---------------------|--------------------------------------------------------------------------|

|                   |                                                                                            |
|-------------------|--------------------------------------------------------------------------------------------|
| <b>Name Error</b> | No resource records of any type (including wildcards) exist for the domain name specified. |
|-------------------|--------------------------------------------------------------------------------------------|

|                            |                                                                            |
|----------------------------|----------------------------------------------------------------------------|
| <b>NXDOMAIN (negative)</b> | No records of the requested type were found for the domain name specified. |
|----------------------------|----------------------------------------------------------------------------|

|                        |                                                               |
|------------------------|---------------------------------------------------------------|
| <b>Not-implemented</b> | The name server does not support the type of query requested. |
|------------------------|---------------------------------------------------------------|

|                |                                                    |
|----------------|----------------------------------------------------|
| <b>NOTAUTH</b> | The name server is not authoritative for the zone. |
|----------------|----------------------------------------------------|

|                |                                                                                                |
|----------------|------------------------------------------------------------------------------------------------|
| <b>NOTZONE</b> | A dynamic update failed because the name to be updated is not contained within the given zone. |
|----------------|------------------------------------------------------------------------------------------------|

|                |                                                                                                                                                   |
|----------------|---------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>NXRRSET</b> | A dynamic update failed because the prerequisites were not satisfied. The Resource Record set existed when the prerequisite stated it should not. |
|----------------|---------------------------------------------------------------------------------------------------------------------------------------------------|

|                 |                                                                                                                                                                                                                                     |
|-----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Referral</b> | Contains the addresses of other name servers that might be able to answer the query. A referral response is returned when a recursive query is not supported, not requested, or cannot be answered because of network connectivity. |
|-----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

**Refused**

The name server refuses to perform the specified operation. For example, some root name servers limit zone transfers to a set number of IP addresses.

**YXDOMAIN**

DNAME mapping failed because the new name was too long.

**YXRRSET**

A dynamic update failed because the prerequisites were not satisfied. The Resource Record set did not exist when the prerequisite stated it should.

## Resource Records

Data from a name server is stored and distributed in a format known as a resource record. Each response from a name server can contain several resource records, which can contain a variety of information. The format of a response is defined in RFC 1035. It includes the following sections:

- A question section, echoing the query for which the response is returned.
- An answer section, containing resource records matching the query.
- An additional section, containing resource records that do not match the query, but might provide useful information for the client. For example, the response to a query for the host name of a name server for a specific zone includes the IP address of that name server in the additional section.
- An authority section, containing information specific to the type of response made to the query. If a referral is returned, this section contains the domain names of name servers that could provide an authoritative answer. If a negative response is returned indicating the name does not exist, this section contains a Start Of Authority (SOA) record defining the zone of authority of the responding name server.

## Querying name servers

This topic describes how to use the `nslookup` command to query the name server. `onslookup` is an alias of `nslookup` in the z/OS UNIX environment.

**Notes:**

1. The z/OS UNIX `nslookup` command runs only from the z/OS shell. The `nslookup` command can query the name server from TSO or the z/OS shell. However, only the legacy TSO version of `NSLOOKUP` is available from TSO. See [z/OS Communications Server: IP System Administrator's Commands](#) for detailed information.
2. The **host** and **dig** commands are another way to query name servers from the z/OS shell. For information on the `host` and `dig` commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

## nslookup command

The z/OS UNIX `nslookup` and TSO `NSLOOKUP` commands can be used to query the name server to perform the following tasks:

- Identifying the location of name servers
- Examining the contents of a name server database
- Establishing the accessibility of name servers

**Note:** `sortlist` is not supported by `nslookup`

The z/OS UNIX `nslookup` and TSO `NSLOOKUP` commands have two modes of operation: interactive mode and command mode. The address of the default name server comes from the resolver configuration

data. In the sample data below, the default domain is `raleigh.ibm.com`, and the default name server is at `9.37.34.149`. If that name server fails to respond, the one at `9.37.34.7` is used.

```
domain raleigh.ibm.com
nameserver 9.37.34.149
nameserver 9.37.34.7
```

## ***Entering the interactive mode***

Interactive mode can be used to repetitively query one or more name servers for information about various hosts and domains, to display that information on the console, and, in some cases, to write response data to a file.

You can enter the interactive mode under the following conditions only:

- No arguments are supplied on command invocation or the `-v` option is specified; the default name server is used.
- The first argument is a hyphen, and the second argument is the host name or Internet address of a name server.

For a complete description of the z/OS UNIX and TSO `nslookup` interactive modes, see [z/OS Communications Server: IP System Administrator's Commands](#).

## ***Entering the command line mode***

The command line mode displays or stores the output from the query supplied as part of the invocation string and then exits.

To enter the command line mode, provide a complete query with the z/OS UNIX `nslookup` command invocation string.

For a complete description of the z/OS UNIX and TSO `nslookup` command line modes, see [z/OS Communications Server: IP System Administrator's Commands](#).

## ***nslookup configuration***

There are only two places to specify **nslookup** options: as command options, or from the resolver configuration data set. Only a few of the options may be set in the resolver configuration data set. The command options always have precedence over any option configured in the resolver configuration data set.

Only the following options can be specified in the resolver configuration data set for v9 **nslookup**:

- `nameserver/nsinteraddr`
- `options ndots: n`
- `search`
- `domain/domainorigin`

The z/OS UNIX **nslookup** command uses a private resolver that is different from the resolver used by other z/OS UNIX socket programs. The z/OS UNIX **nslookup** command has the following functional differences:

- z/OS UNIX **nslookup** does not use SiteTables (for example, `/etc/hosts`) for host name resolution.
- Only the built-in translation table is used for **nslookup**.

For a complete discussion of resolver configuration files, see [Chapter 2, “IP configuration overview,” on page 11](#).

## **Recommended reading**

The latest edition of *DNS and BIND* by Paul Albitz and Cricket Liu (O'Reilly & Associates, Inc.) gives a comprehensive description of DNS and BIND.

You can subscribe to a BIND users mailing list at <http://lists.isc.org/mailman/listinfo>.

DNS protocols are described in various Request for Comments (RFC) papers and Internet drafts. RFCs outline existing protocols, suggest new protocols, and establish standards for the Internet protocol suite. Internet drafts are proposals, techniques, and mechanisms that document Internet Engineering Task Force (IETF) work-in-progress.

For information about obtaining RFCs, see [Appendix G, “Related protocol specifications,”](#) on page 1439.

## Resolver API calls

---

Application programs invoke resolver functions by using resolver API calls such as `gethostbyname()` and `getaddrinfo()`. The z/OS resolver supports a number of IBM APIs, although not all APIs support all possible resolver API calls. The z/OS resolver is invoked by the following resolver API calls:

- Application programs that use the `gethostbyaddr()` and `gethostbyname()` resolver calls from the following IBM APIs:
  - [Library functions in z/OS C/C++ Runtime Library Reference](#)
  - [Callable services descriptions in z/OS UNIX System Services Programming: Assembler Callable Services Reference](#)
  - [z/OS Communications Server C/C++ API, z/OS Communications Server Callable and Macro API, z/OS Communications Server REXX API, and z/OS Communications Server PASCAL API in z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference](#)
- Application programs that use the `getaddrinfo()`, `getnameinfo()`, and `freeaddrinfo()` resolver calls from the following IBM APIs:
  - [Library functions in z/OS C/C++ Runtime Library Reference](#)
  - [Callable services descriptions in z/OS UNIX System Services Programming: Assembler Callable Services Reference](#)
  - [z/OS Communications Server Callable and Macro API and z/OS Communications Server REXX API in z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference](#)
- Application programs that use the `sethostent()`, `gethostent()`, and `endhostent()` resolver calls from the following IBM APIs:
  - [Library functions in z/OS C/C++ Runtime Library Reference](#)
  - [z/OS Communications Server C/C++ API in z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference](#)

The **dig**, **nslookup**, and **nsupdate** z/OS UNIX commands provide their own unique resolver services. When their resolver initializes, it uses the appropriate TCPIP.DATA information, including information from the global TCPIP.DATA file, if one is specified. For more information, see [“The resolver and the global TCPIP.DATA file”](#) on page 766.

## Starting the resolver

---

Prior to starting the resolver, you must have a user ID defined for the resolver started procedure that includes an OMVS segment, so that the resolver can use z/OS UNIX services. For information about defining and assigning a user ID for [Using started procedures](#), see [z/OS Security Server RACF Security Administrator's Guide](#).

**Requirement:** If the resolver user ID does not have an OMVS segment and you are not using the automatic assignment of unique UNIX identities support to automatically generate OMVS segments, you must explicitly configure an OMVS segment for the resolver user ID. For more information about [RACF and z/OS UNIX](#), see [z/OS Security Server RACF Security Administrator's Guide](#).

**Guideline:** The HOME directory in the OMVS segment for the resolver user ID must be accessible when the resolver is started. Specify the root directory [HOME(/)] to avoid problems.

There are two ways that the resolver can be started:

- Use z/OS UNIX to start the resolver

The resolver is started when z/OS UNIX is initialized. This method of starting the resolver ensures that applications that require resolver services are not started before the resolver starts. If you use z/OS UNIX to start the resolver, you can use the default resolver settings (see [“The default resolver settings”](#) on page 762), or you can optionally create a start procedure and define the address space (see [“Customizing the resolver”](#) on page 762).

- Use automation tools to start the resolver

The resolver is started by issuing the MVS START operator command. You must customize the resolver to use this starting method; see [“Customizing the resolver”](#) on page 762 for more information. If you use this method of starting the resolver, then it is possible that an application that needs resolver services (such as INETD) is started before the resolver address space is initialized. In this case, you might need to remove the starting of INETD from the z/OS UNIX /etc/rc file and start INETD with automation after the resolver has initialized.

If you are using z/OS UNIX to start the resolver, then the following actions occur when z/OS UNIX is initialized:

- z/OS UNIX uses SUB=MSTR to start the resolver (the resolver does not require JES); for information about SUB=MSTR, see [z/OS MVS JCL Reference](#)
- z/OS UNIX issues an informational message that contains the name of the procedure that it is starting:

BPXF224I THE RESOLVER\_PROC, *procname*, IS BEING STARTED

**Rule:** If the RESOLVER\_PROC statement is not present or is specified with the procedure name DEFAULT, the *procname* value is RESOLVER, even though a start procedure was not used. For more information about the RESOLVER\_PROC statement, see [z/OS MVS Initialization and Tuning Reference](#).

- If the start procedure is not found or if it contains a JCL error, then error messages for the z/OS START command are issued and the resolver address space does not initialize.
- If the resolver address space cannot be started, z/OS UNIX initialization continues.

## The default resolver settings

---

You do not have to perform any customization steps to use the resolver. The default resolver starts automatically when z/OS UNIX is initialized; you cannot use automation tools to start the resolver unless you customize it. z/OS UNIX starts a resolver address space, which uses the assigned name RESOLVER, using the system default procedure IEESYSAS. The resolver uses the applicable native MVS or z/OS UNIX search order to find TCPIP.DATA statements, without a GLOBALTCPIPDATA or a DEFAULTTCPIPDATA specification.

The following resolver functions are active by default:

- System-wide caching, which uses the default maximum cache size, the default maximum time-to-live (TTL) value, and the default setting for the cache reordering function. See [“Resolver caching”](#) on page 774.

**Restriction:** Resolver caching is disabled by default for IBM z/OS Container Platform environments and cannot be configured.

- Network operator notification of unresponsive Domain Name System (DNS) servers, using the default threshold setting. See [“Monitoring the responsiveness of Domain Name System name servers”](#) on page 786.

The Extension Mechanisms for DNS (EDNS0) standards function is always active. For more information, see [“Extension Mechanisms for DNS standards and the resolver”](#) on page 795.

## Customizing the resolver

---

You can customize resolver functions, or enable or disable certain resolver functions, by using resolver configuration statements in a resolver setup file. For example, you can control which resolver statements

are used by all applications or TCP/IP stacks for name resolution by specifying the GLOBALTCPIPDATA statement (see [“The resolver setup file”](#) on page 763 for more information about the statements that are supported by the resolver setup file). If you want to customize resolver functions, you must create a resolver setup file and define the resolver address space.

**Note:** For IBM z/OS Container Platform environments, the resolver configuration information is obtained from the z/OS UNIX files `/etc/resolv.conf` and `/etc/nsswitch.conf` in the container’s filesystem namespace.

**Restriction:** For IBM z/OS Container Platform environments, the CACHE, COMMONSEARCH, DEFAULTIPNODES, DEFAULTTCPIPDATA, GLOBALIPNODES, GLOBALTCPIPDATA, and AUTOQUIESCE statements are ignored.

## The resolver setup file

The resolver setup file is an optional file (either an MVS data set or a z/OS UNIX file) that contains resolver configuration statements that you can use to customize resolver functions.

If the resolver setup file is an MVS data set, the file must have the following characteristics:

- Use sequential (PS) or partitioned (PO) organization
- Use fixed (F) or fixed block (FB) format
- Contain a logical record length (LRECL) that is 80 - 256 bytes in length
- Contain any valid blocksize (BLKSIZE) for a fixed block
- If you think you will need to modify the setup file, use a member of an MVS partitioned data set

If the resolver setup file is a z/OS UNIX file, the file can be located in any directory. The maximum line length that is supported is 256 characters. If a line is longer than 256 characters, then the line is truncated to 256 characters before it is processed.

If you do not use a resolver setup file, the resolver uses the applicable native MVS or z/OS UNIX search order without any additional information and performs the following functions using the default settings:

- Enables system-wide caching (using the default maximum cache size and the default time-to-live [TTL] value)
- Monitors Domain Name System (DNS) name server responsiveness (using the default threshold setting)

The following statements are supported by the resolver setup file:

- Comments (; or #)
- CACHE

Enables system-wide caching of DNS queries that have been resolved. System-wide caching is enabled by default, but you can explicitly enable it using this statement. For more information about caching, see [“Resolver caching”](#) on page 774.

- CACHEREORDER

Enables system-wide reordering of a cached list of IP addresses in response to resolver API queries for the associated host name. If you do not specify this statement, system-wide reordering of a cached list is disabled by default.

- CACHESIZE

Defines the amount of storage that can be allocated by the resolver to manage cached records.

- COMMONSEARCH

Indicates that the same search order for local host files is used for both IPv4 and IPv6 name queries.

- DEFAULTIPNODES

Identifies the default local host file.

- DEFAULTTCPIPDATA

Identifies a default TCPIP.DATA file. The file that is specified by the DEFAULTTCPIPDATA statement becomes the last file that is searched by the resolver for resolver configuration information. If you do not specify the DEFAULTTCPIPDATA statement, the default file is TCPIP.TCPIP.DATA. For more information, see [“The resolver and the global TCPIP.DATA file” on page 766.](#)

- GLOBALIPNODES

Identifies a local host file that contains hard-coded IP addresses and host names that can be used globally.

- GLOBALTCPIPDATA

Identifies the file that is the first file that is searched by the resolver for resolver configuration information. Parameters that you specify in the file that is identified by the GLOBALTCPIPDATA statement become the global settings for the entire MVS image and for all TCP/IP stacks. For more information, see [“The resolver and the global TCPIP.DATA file” on page 766.](#)

**Restriction:** You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCPIP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the [UNRESPONSIVETHRESHOLD statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

- MAXNEGTTL

Defines the maximum amount of time that the resolver can use negative cache resource information that it receives from a Domain Name System (DNS) name server.

- MAXTTL

Defines the amount of time that the resolver can use resource information that it receives from a Domain Name System (DNS) name server.

- NOCACHE

Disables system-wide caching of DNS response data. If you do not specify this statement, system-wide caching is enabled by default.

- NOCACHEREORDER

Disables system-wide reordering of a cached list of IP addresses in response to resolver API queries for the associated host name. System-wide reordering of a cached list of IP addresses is disabled by default, but you can explicitly disable it by using this statement.

- NOCOMMONSEARCH

Indicates that a different search order for local host files is used for IPv4 and IPv6 name queries.

- UNRESPONSIVETHRESHOLD

Identifies the threshold value that determines when the resolver declares a DNS name server to be unresponsive. If the percentage of query failures to a name server during a fixed interval is greater than or equal to this threshold value, the resolver considers the name server to be unresponsive. The resolver might stop sending DNS queries that are generated by an application to unresponsive name servers, depending on the values that are coded on this statement. For more information, see [“Monitoring the responsiveness of Domain Name System name servers” on page 786.](#)

**Restriction:** You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCPIP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the [UNRESPONSIVETHRESHOLD statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

For more information about [resolver setup statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

**Note:** The name of the resolver setup file most recently used to configure the resolver is displayed as part of the MODIFY RESOLVER command output. See [z/OS Communications Server: IP System Administrator's Commands](#) for more details.

## Resolver processing of the setup file when the resolver is started

During resolver address space initialization, the resolver parses the entire resolver setup file using the following rules:

- When a setup statement has a syntax error, the resolver generates a warning message to the console and the setup statement is skipped.
- When the resolver does not recognize a setup statement, the resolver generates a warning message to the console and the setup statement is skipped.
- When the resolver parses multiple instances of the same setup statement that have no syntax errors, the resolver uses the setting on the last instance that is parsed.
- When the resolver completes parsing of the resolver setup file and did not parse any instances of a resolver setup statement that are syntactically correct, the resolver takes the default value for that setup statement
- When a resolver setup statement (for instance, GLOBALTCPIPDATA) specifies an MVS data set name or a z/OS UNIX file name that the resolver cannot open or access, the resolver considers that to be a syntax error.
- When there are multiple instances of a setup statement that have no syntax errors and that specify an MVS data set name or z/OS UNIX file name, the resolver attempts to open or access the data set or file specified on only the last instance that is parsed. If the resolver cannot open or access this data set or file, the resolver proceeds as if this setup statement had not been specified.
- When the resolver cannot open the resolver setup file, the resolver uses all the default settings for the configuration.
- When the resolver setup file is the wrong format, the resolver uses all the default settings for the configuration.
- If the resolver generates any warning messages due to syntax errors or unrecognized statements during resolver address space initialization, the resolver issues message EZD2038I at the conclusion of resolver address space initialization.
- If the resolver does not generate any warning messages during resolver address space initialization, the resolver issues message EZZ9291I when the address space is initialized.

### Results:

- Consider a resolver setup file that contains the following statements:

```
CACHE
NOCACHE
CACH
```

The resolver issues a warning message for the line specifying the value CACH and ignores the value. Because NOCACHE was parsed after the valid statement CACHE, the resolver uses the NOCACHE setup statement and caching is disabled for this system.

- Consider a resolver setup file that contains the following statements:

```
GLOBALTCPIPDATA(/etc/tcpip.data)
GLOBALTCPIPDATA(/etc/newer.tcpip.data)
DEFAULTTCPIPDATA(/etc/default.tcpip.data)
```

Each of these statements is syntactically correct, so the resolver uses the value coded on the last GLOBALTCPIPDATA statement as the name of the global TCPIP.DATA file. The resolver attempts to access the files /etc/newer.tcpip.data and /etc/default.tcpip.data. If the file /etc/newer.tcpip.data does not exist, the resolver generates a warning message and proceeds as if no global file were specified; the resolver does not attempt to use /etc/tcpip.data as the global TCPIP.DATA file. If /etc/default.tcpip.data

does not exist, the resolver generates a warning message and proceeds as if no default file were specified.

## The resolver and the global TCPIP.DATA file

The optional GLOBALTCPIPDATA statement identifies a global TCPIP.DATA file, in which you can specify global settings. If you specify a global TCPIP.DATA file, you can control which resolver statements are used for name resolution and you do not need to merge resolver statements from multiple files. TCPIP.DATA statements in this file are the first that are searched, regardless of which socket API library you are using.

If you use a global TCPIP.DATA file, you can specify the following resolver statements, or you can use the default values. These statements are required by the resolver to process queries.

- DomainOrigin or Domain
- NSInterAddr or NameServer
- NSPortAddr
- ResolveVia
- ResolverTimeOut
- ResolverUDPRetries
- Search
- SortList

If you specify any of these statements in the global TCPIP.DATA file, those settings become the global settings for this MVS image and for all users of resolver services, across the entire system. If you do not specify one of these statements in the global TCPIP.DATA file, the resolver uses the default values. The search continues beyond the global TCPIP.DATA file, but any of these resolver statements that are specified in files that are located lower in the search order are ignored.

If you do not identify a global TCPIP.DATA file, then the resolver uses the regular search order until it finds a local TCPIP.DATA file.

**Restriction:** You must code the GLOBALTCPIPDATA statement if you want to use the autonomic quiescing of unresponsive name servers function. For more information, see [“Monitoring the responsiveness of Domain Name System name servers” on page 786](#).

If you do not specify one of these statements in this local TCPIP.DATA file, the resolver uses the default values. The setting that the resolver uses applies only to this application, not to all users of resolver services. In any case, the search order depends on whether the native MVS or z/OS UNIX application environment is in use. The search order for the local hosts table (HOSTS.xxxxINFO, ETC.IPNODES, /etc/hosts, or /etc/ipnodes) remains the same.

You can specify other statements in the global TCPIP.DATA file (for information about configuration statements in TCPIP.DATA, see [z/OS Communications Server: IP Configuration Reference](#)). There are some statements, like Trace Resolver, for which you likely do not want a global setting. If you do not specify one or more of these other statements in the global file, the resolver uses the regular search order until it finds a local TCPIP.DATA file. If you do not specify these other statements in the local TCPIP.DATA file, the resolver uses the default values. You can implement these global settings gradually, in case there are private TCPIP.DATA files that are in use on your system about which you are unaware.

You can identify a global TCPIP.DATA file in a CINET (common INET) environment. You specify in the global TCPIP.DATA file all the resolver statements for which you want to set a global value, and the resolver conducts its searches in the same way as in a non-CINET environment. However, if you do use a global TCPIP.DATA file in a CINET environment, all the resolver statements must be usable by all stacks. For example, the IP addresses that are specified by the NameServer statement must be accessible from all stacks. If the IP addresses are not accessible, then you should not use a global TCPIP.DATA file; use multiple TCPIP.DATA data sets instead. If you use multiple TCPIP.DATA data sets, you should not code the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement in the resolver setup file.

You can use the DEFAULTTCPIPDATA setup statement to specify a TCPIP.DATA file as the last TCPIP.DATA file that is searched, instead of TCPIP.TCPIP.DATA. You can specify any file as the default file.

## Steps for creating a resolver setup file

The SETUP DD statement in the start procedure for the resolver points to the resolver setup file. The setup file can be an MVS data set or a z/OS UNIX file.

### Procedure

Perform the following steps to create a resolver setup file:

1. Use an MVS data set or a z/OS UNIX file for your setup file, depending on your requirements.
2. Customize the search order that the resolver uses to resolve queries by specifying one or more of the following statements:

- Specify the GLOBALTCPIPDATA statement to identify the global TCPIP.DATA file that becomes the first file that is searched. Parameters that you specify in this file become the global settings for the entire MVS image and for all users of resolver services, across the entire system.

**Restriction:** You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCPIP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the UNRESPONSIVETHRESHOLD statement, see [z/OS Communications Server: IP Configuration Reference](#).

- Specify the DEFAULTTCPIPDATA statement to identify a default TCPIP.DATA file. The file specified by the DEFAULTTCPIPDATA statement becomes the last file that can be searched. If you do not specify the DEFAULTTCPIPDATA statement, the default file is TCPIP.TCPIP.DATA.
- Specify either the GLOBALIPNODES statement or the DEFAULTIPNODES statement to identify a local host file. The GLOBALIPNODES statement identifies a local host file that contains hard-coded IP addresses and host names that can be used globally. The DEFAULTIPNODES statement identifies the default local host file.

**Result:** You can specify both the GLOBALIPNODES statement and the DEFAULTIPNODES statement, but the resolver search order for local host files ensures that only the global IPNODES file is used. For more information, see [“Search orders used in the z/OS UNIX environment”](#) on page 803 and [“Search orders used in the native MVS environment”](#) on page 808.

- Specify the COMMONSEARCH statement or the NOCOMMONSEARCH statement. The COMMONSEARCH statement indicates that the same search order for local host files is used for both IPv4 and IPv6 name queries, and for MVS and UNIX searches. The NOCOMMONSEARCH statement indicates that different search orders for local host files are used for IPv4 and IPv6 name queries, and for MVS and UNIX searches. For more information, see [“Search orders used in the z/OS UNIX environment”](#) on page 803 and [“Search orders used in the native MVS environment”](#) on page 808.
- Specify the CACHE statement or the NOCACHE statement. The CACHE statement enables system-wide caching of Domain Name System (DNS) queries that have been resolved. System-wide caching is enabled by default, but you can explicitly enable it using this statement. See [“Resolver caching”](#) on page 774 for more information about caching. The NOCACHE statement indicates that you do not want to cache DNS response data.
  - If you are using system-wide caching, specify the CACHESIZE statement to define the amount of storage that can be allocated by the resolver to manage cached records. If you specify this statement and the NOCACHE statement, the CACHESIZE statement is ignored.
  - If you are using system-wide caching, specify the MAXNEGTTTL statement to define the amount of time that the resolver can use negative cache resource information that it receives from a Domain Name System (DNS) name server. Negative cache information represents DNS resource lookups that result in NXDOMAIN responses, and indicate that the resource name (hostname or IP address) or the DNS zone does not exist. If you specify this statement and the NOCACHE statement, the MAXNEGTTTL statement is ignored.

- If you are using system-wide caching, specify the MAXTTL statement to define the amount of time that the resolver can use resource information that it receives from a name server. If you specify this statement and the NOCACHE statement, the MAXTTL statement is ignored.
- If you are using system-wide caching, you can enable the resolver to reorder the cached list of IP addresses when the resolver responds to a host name resolution request.
  - To enable reordering of a list of cached IP addresses in a round-robin manner, specify the CACHEREORDER statement.
  - To disable reordering of a list of cached IP addresses, specify the NOCACHEREORDER statement.

If you specify the NOCACHE statement, the CACHEREORDER and NOCACHEREORDER statements are ignored.

- Specify the UNRESPONSIVETHRESHOLD statement to define the threshold value that is used by the resolver to declare that a DNS name server is unresponsive. The monitoring of unresponsive name servers is enabled by default, but you can explicitly enable it using the UNRESPONSIVETHRESHOLD statement. In addition to specifying the threshold value, use the UNRESPONSIVETHRESHOLD statement to indicate how you want the resolver to react when an unresponsive name server is detected:
  - Specify only the threshold value on the UNRESPONSIVETHRESHOLD statement to indicate that the resolver should only alert the operator that a name server is unresponsive. The resolver will continue to send DNS queries that are generated by an application to the name server.
  - Specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement to indicate that the resolver should stop sending DNS queries that are generated by an application to unresponsive name servers.

**Restriction:** You must code the GLOBALTCPIPDATA statement if the AUTOQUIESCE operand is coded on the UNRESPONSIVETHRESHOLD statement. If you cannot ensure that all DNS IP addresses are accessible from all your TCPIP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file. For more information about the [UNRESPONSIVETHRESHOLD statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

If you do not want the resolver to maintain awareness of unresponsive name servers, you can use the UNRESPONSIVETHRESHOLD statement to disable resolver monitoring of name server responsiveness to DNS queries.

## Results

The following example setup file is located in SEZAINST as member EZBRECNF (alias RESSETUP):

```
;
; IBM Communications Server for z/OS
; SMP/E distribution name: EZBRECNF
;
; 5694-A01 Copyright IBM Corp. 2002, 2019,
; Licensed Materials - Property of IBM
;
; Function: Sample Resolver setup file
;
;
; The following statement defines the final search location for
; TCPIP.DATA statements. It will replace TCPIP.TCPIP.DATA
; It may be an MVS data set or HFS file.
;
DEFAULTTCPIPDATA('TCPIP.TCPIP.DATA')
;
The following statement defines the first search location for
TCPIP.DATA statements. It may be an MVS data set or HFS file.
;
; Update with the correct data set or HFS file name
;
; GLOBALTCPIPDATA('TCPCS.SYS.TCPPARMS(GLOBAL)')

UNRESPONSIVETHRESHOLD(25)
;
; UNRESPONSIVETHRESHOLD(100,AUTOQUIESCE)

```

## The resolver address space

The resolver address space must be started before any application or TCP/IP stack resolver calls can occur. When the address space starts, it reads an optional resolver setup data set that is pointed to

by the SETUP DD card in the resolver JCL procedure. To use the functions that are provided by the GLOBALTCIPDATA statement and other statements, you must define a resolver address space. You use a BPXPRMxx statement, RESOLVER\_PROC, to specify the procedure name, if any, to be used by z/OS UNIX to start the resolver address space. If the RESOLVER\_PROC statement is not in the BPXPRMxx parmlib member or is specified with the procedure name DEFAULT, z/OS UNIX starts a resolver address space that has the assigned name RESOLVER.

## Steps for defining the resolver address space

You must define the resolver address space to use the functions provided by the GLOBALTCIPDATA statement and other statements.

### Before you begin

You must have already created a resolver setup file, if you are using one.

### Procedure

Perform the following steps to define the resolver address space:

1. Create a start procedure.

The start procedure has the following requirements:

- The procedure must not contain any DD cards that specify SYSOUT=\*
- The procedure must be in a data set that is specified by the IEFPSI DD card specification of the MSTJCLxx PARMLIB member. If the procedure is not in this location, the resolver will not start. For information about MSTJCL, see [z/OS MVS Initialization and Tuning Reference](#).

To process its definitions, the resolver might need to allocate data sets or files. For those definitions, such as GLOBALTCIPDATA, DEFAULTTCIPDATA, /etc/hosts, HOSTS.SITEINFO, and HOSTS.ADDRINFO, allocation messages appear in the JES joblog. For long-running applications that heavily use resolver services, such as IBM Tivoli NetView for z/OS, consider using a started job that specifies MSGLEVEL=(1,0) to eliminate all allocation messages. This specification could also eliminate allocation messages that might be useful for problem analysis. For information about started jobs and the MSGLEVEL parameter, see [z/OS MVS JCL Reference](#).

See [the example resolver startup procedure](#).

2. In the SETUP DD JCL statement, specify the location of the setup file.

3. Grant read access (using RACF or other security program) to the following files for the user ID that is assigned to the resolver address space:

- SYS1.PARMLIB
- The resolver setup file
- The file specified by the GLOBALTCIPDATA statement, if you are using one
- The file specified by the DEFAULTTCIPDATA statement, if you are using one
- The file specified by the GLOBALIPNODES statement, if you are using one
- The file specified by the DEFAULTIPNODES statement, if you are using one

4. If you are using any of the following files, grant read access to the files for the user IDs or jobs that are using TCP/IP facilities:

- The file specified by the GLOBALTCIPDATA statement
- The file specified by the DEFAULTTCIPDATA statement
- The file specified by the GLOBALIPNODES statement
- The file specified by the DEFAULTIPNODES statement
- /etc/hosts
- /etc/ipnodes
- /etc/services

- HOSTS.SITEINFO
- HOSTS.ADDRINFO
- ETC.IPNODES

If you do not specify the correct permission bit settings for a file to allow that file to be read, error message IEC141I 013-C0 is issued. Other error messages might also be issued that indicate that a file cannot be read.

5. (Optional) If you want z/OS UNIX to start the resolver (rather than using automation to start the resolver with the MVS START operator command), specify the resolver start procedure name as the *procname* value in the RESOLVER\_PROC(*procname*) statement of the BPXPRMxx parmlib member. See [“Starting the resolver” on page 761](#) for information about starting the resolver.

**Guideline:** The default procedure name is RESOLVER. If you want to specify a procedure that uses the name RESOLVER, then specify RESOLVER for the *procname* value.

If you do not specify the RESOLVER\_PROC statement or if you specify DEFAULT, then z/OS UNIX starts a resolver address space using the system default procedure IEESYSAS with the assigned name RESOLVER. If you do not want to use z/OS UNIX to start the resolver, you must use the MVS START command to start the resolver address space.

6. If you use automation to start the resolver, consider looking for message EZD2038I and taking corrective action based on the warning messages that are generated by the resolver.

The resolver issues messages during resolver address space initialization identifying the errors that exist in the resolver setup file. If the resolver issues message EZD2038I at the end of resolver address space initialization, there were setup statements with syntax errors or setup statements that were not recognized in the setup file. The errors might include errors accessing or opening one or more of the files specified on resolver setup statements, such as the GLOBALTCPIPDATA statement.

## Results

The following example resolver start procedure is located in SEZAINST as member EZBREPRC (alias RESOPROC).

```
//RESOLVER PROC PARMS='CTRACE(CTIRES00)'
//*
//* IBM Communications Server for z/OS
//* SMP/E distribution name: EZBREPRC
//*
//* 5694-A01 Copyright IBM Corp. 2001, 2010.
//* Licensed Materials - Property of IBM
//*
//* Function: Start Resolver
//*
//EZBREINI EXEC PGM=EZBREINI,REGION=0M,TIME=1440,PARM=&PARMS
//*
//* When the Resolver is started by UNIX System Services it is
//* started with SUB=MSTR.
//* This means that JES services are not available to the Resolver
//* address space. Therefore, no DD cards with SYSOUT can be used.
//* See the MVS JCL Reference manual for SUB=MSTR considerations in
//* section "Running a Started Task Under the Master Subsystem".
//* This Resolver start procedure will need to reside in a data
//* set that is specified by the MSTJCLxx PARMLIB member's
//* IEFPDSI DD card specification. If not, the procedure will
//* not be found and the Resolver will not start.
//* See the MVS Initialization and Tuning Reference manual for
//* MSTJCL considerations in section "Understanding the Master
//* Scheduler Job Control Language"
//*
//* SETUP contains Resolver setup parameters.
//* See the chapter "The resolver" in the
//* IP Configuration Guide for more information. A sample of
//* Resolver setup parameters is included in member RESSETUP
//* of the SEZAINST data set.
//*
//*SETUP DD DSN=TCPIP.TCPPARMS(SETUPRES),DISP=SHR,FREE=CLOSE
```

```
//*SETUP DD DSN=TCPIP.SETUP.RESOLVER,DISP=SHR,FREE=CLOSE
//*SETUP DD PATH='/etc/setup.resolver',PATHOPTS=(ORDONLY)
```

## Managing the resolver address space

The resolver start procedure name is used with the following MVS system commands to manage the resolver address space:

- Start (S)
- Stop (P)

You should stop and restart the resolver only when a new level of the resolver code has been installed.

- Force
- Modify (F)

Use the MODIFY command to dynamically change resolver setup statements, to update the use of TCPIP.DATA statements, or to update the use of local host and services tables.

You can also use the MODIFY command to delete the information that the resolver has acquired about name server capabilities, and to restart the monitoring of unresponsive DNS name servers function after the resolver has stopped monitoring because of a system error.

You can use the MODIFY FLUSH command to delete all the resolver cache data.

**Guideline:** If you use the MODIFY command to dynamically change resolver setup statements and the resolver detects unrecognized setup statements or setup statements with syntax errors in the setup file specified on the MODIFY command, the resolver does not process the MODIFY command.

See [z/OS Communications Server: IP System Administrator's Commands](#) for more information about these commands.

You can use the following MVS system commands to control and display the status of the resolver CTRACE facilities:

- Trace CT
- Display Trace

See [z/OS Communications Server: IP Diagnosis Guide](#) for information about using CTRACE.

## Steps for manually restarting the resolver

If the resolver is stopped for any reason, manually restart the resolver.

### Before you begin

When you start the resolver, specify REUSASID=YES on the START command to ensure that a reusable ASID is used. If the resolver address space is stopped enough times and you do not specify REUSASID=YES, when you restart the resolver, all available ASIDs might be exhausted, which prevents the creation of a new address space on the system. If a new address space is not created on the system, an IPL is required. For more information about tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in [z/OS MVS Initialization and Tuning Reference](#).

### Procedure

Perform one of the following steps to restart the resolver:

- If you have not customized the resolver (you have not created a start procedure and you have not defined the address space), then issue the following system operator command:

```
START IEESYSAS.RESOLVER,PROG=EZBREINI,SUB=MSTR,REUSASID=YES
```

- If you have customized the resolver, issue one of the following system operator commands, where *procname* is the name of the PROCLIB member that you created:

```
START procname,REUSASID=YES
START procname,SUB=MSTR,REUSASID=YES
```

## Steps for applying an interim fix to the resolver

To apply IBM-supplied interim fixes to the resolver, you do not need to stop and restart the TCPIP started task or any application programs.

### Before you begin

For the short duration of time that the resolver is not running, all resolver requests will fail.

### Procedure

Perform the following steps to apply an interim fix to the resolver:

1. Use SMP/E to apply the interim fix.
2. If LLA (library lookaside) is running, refresh it by issuing the following operator command:

```
MODIFY LLA,REFRESH
```

3. Stop the resolver by performing one of the following steps:

- If you have not customized the resolver (you have not created a start procedure), issue the following system operator command:

```
STOP RESOLVER
```

- If you have customized the resolver, issue the following system operator command, where *procname* is the name of the PROCLIB member that you created:

```
STOP procname
```

4. Restart the resolver by performing one of the following steps:

- If you have not customized the resolver (you have not created a start procedure), issue the following system operator command:

```
START IEESYSAS.RESOLVER,PROG=EZBREINI,SUB=MSTR,REUSASID=YES
```

- If you have customized the resolver, issue one of the following system operator commands, where *procname* is the name of the PROCLIB member that you created:

```
START procname,REUSASID=YES
START procname,SUB=MSTR,REUSASID=YES
```

**Rule:** When you manually stop and then restart the resolver, specify REUSASID=YES on the START command to ensure that a reusable ASID is used. If the resolver address space is stopped enough times and you do not specify REUSASID=YES then when you restart the resolver, all available ASIDs might be exhausted, which would prevent the creation of a new address space on the system. If a new address space is not created on the system, an IPL is required. For more information on tuning parameters for the maximum number of ASIDs on a system, see the MAXUSER parameter in [z/OS MVS Initialization and Tuning Reference](#).

## IPv6 name servers and the resolver

The z/OS resolver can communicate to a Domain Name System (DNS) name server using either IPv4 or IPv6 communications. When the resolver is operating on an IPv6-capable system, the resolver opens either an IPv6 socket or an IPv4 socket to connect to the target DNS name server, depending on the IP addresses of the potential target name servers. If both IPv6 and IPv4 addresses are specified as IP addresses for the target name servers, the resolver opens an IPv6 socket and relies on TCP/IP stack processing of IPv4-mapped IPv6 addresses to provide the appropriate communication with the name

server. When the resolver is operating on an IPv4-only system, any IPv6 address specified as a target name server is ignored.

The list of name servers to be searched, as defined using the NSINTERADDR or NAMESERVER configuration statements in the TCPIP.DATA file, is stored in the res\_state control block structure. Depending on the API used, applications can obtain the res\_state control block, and can examine or even modify the contents of the res\_state list of name servers (nsaddr\_list). The nsaddr\_list structure is not designed to accommodate IPv6 addresses, and changing the structure to accommodate IPv6 addresses would adversely affect existing applications. Therefore, resolver does not save IPv6 addresses into the nsaddr\_list array, and returns only the IPv4 addresses coded on the NSINTERADDR or NAMESERVER configuration statements. If only IPv6 addresses are specified for name server addresses, the nsaddr\_list array returns as an empty list in res\_state. If your application examines the contents of the res\_state control block, in particular the nsaddr\_list information, and requires that at least one name server IP address be present in the list, you need to specify at least one IPv4 address on a NSINTERADDR or NAMESERVER statement in the TCPIP.DATA file used by the application. Although nsaddr\_list does not reflect the IPv6 addresses specified in the TCPIP.DATA file, resolver maintains the full list internally and uses the entire list for searching and caching purposes, unless the application modifies nsaddr\_list for its own purposes.

The following z/OS function do not use the resolver's ability to communicate to a name server using IPv6:

- The TSO DIG and TSO NSLOOKUP commands do not support specification of an IPv6 address as the target server IP address, either explicitly on the command or as an entry in the TCPIP.DATA file.

If you choose to use IPv6 name servers, ensure that the setting for the MAXSOCKETS parameter on the BPXPRMxx AF\_INET6 NETWORK statement is sufficiently large enough to include the number of IPv6 sockets being opened by resolver. Use the following rough calculations to determine whether the MAXSOCKETS value is large enough:

1. Determine how many concurrent resolver calls typically occur on your system. Each resolver call that involves communication with a DNS name server opens 1 or 2 sockets depending on the actual resolver API being used.
2. Determine the largest number of IPv6 sockets you have open on your system at any one point in time.
3. Add (number of concurrent resolver calls \* 2) and the largest number of IPv6 sockets together. Compare this number against the setting of MAXSOCKETS on the appropriate BPXPRMxx AF\_INET6 NETWORK statement.
  - If the MAXSOCKETS setting is the larger value, then the setting is acceptable.
  - If the MAXSOCKETS setting is the lesser value, update the MAXSOCKETS setting to the larger number.

## Resolver functions

---

To use the resolver functions efficiently in your environment, you need to be familiar with the following resolver functions that are active, by default, when the resolver is started:

- Resolver caching
- Monitoring responsiveness of Domain Name System name servers
- Extension Mechanisms for DNS standards

## Resolver caching

In the context of resolvers, *caching* is defined as saving and storing information from resolved DNS queries so that the information can be reused. A *cache* is the area of memory where the information is kept. The primary advantage of caching is the improved performance that is obtained by the elimination of repetitive queries to the name servers.

For example, in the configuration shown in [Figure 107 on page 775](#), a local caching-only DNS name server is defined to provide some level of resource caching.

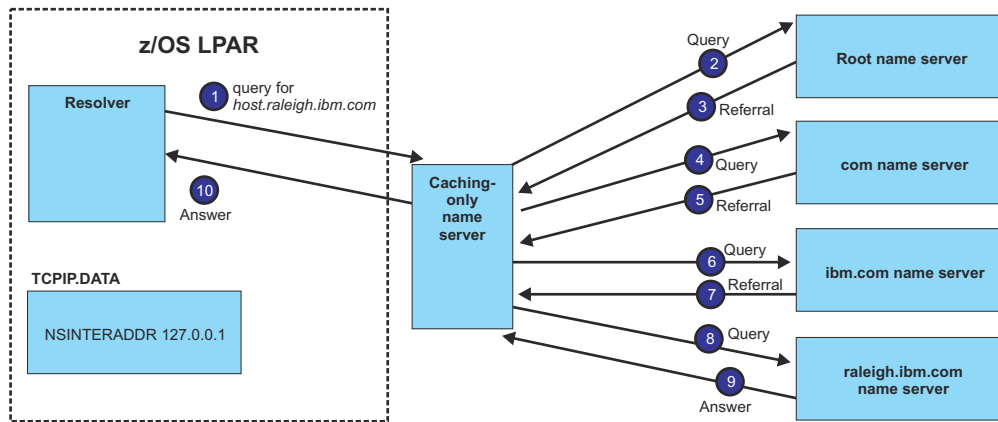

Figure 107. Local caching-only name server example

In the caching-only name server model depicted in Figure 107 on page 775, when a request for host.raleigh.ibm.com is received, the resolver contacts the local name server (see arrow 1). The local name server then must perform standard name-server processing to locate the resource, which might include contacting one or more name servers (see arrows 2 through 9). When the name server that can provide an authoritative response for the queried host name is found and the response is returned to the local name server, the local name server caches the information and forwards it back to the resolver (arrow 10).

However, in the caching-only name server model depicted in Figure 107 on page 775, subsequent requests to the resolver for information about host.raleigh.ibm.com still require that a DNS query be created and forwarded to the local name server to obtain the cached results. This DNS query can be eliminated if the resolver itself caches the information, as shown in Figure 108 on page 775.

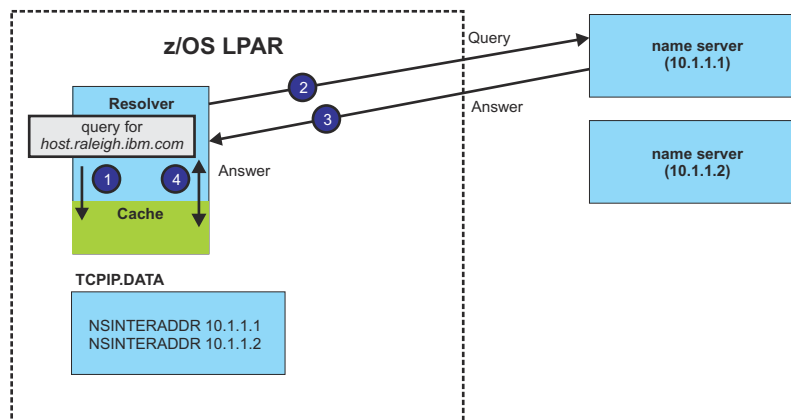

Figure 108. Resolver caching example

In the resolver caching model, when the initial query of the resolver cache (arrow 1) does not return any host name information, the DNS query is sent to the network name server (arrow 2), which might or might not already have information cached about host.raleigh.ibm.com. When the response is received (arrow 3), the information is cached by the resolver (arrow 4), and subsequent requests for host.raleigh.ibm.com can be satisfied without a DNS query (arrow 4).

Resolver caching is advantageous for the following reasons:

- You do not need to take any steps to enable resolver caching; it is automatically enabled. As shown in Figure 107 on page 775 and in Figure 108 on page 775, this eliminates the need to manually configure a local name server to cache the DNS responses.
- The cached information can be used by all applications that are running in the z/OS logical partition (LPAR), which provides the performance benefits of caching across the entire system for the cost of one DNS query.
- Resolver caching provides high performance because it reduces the network traffic to name servers.

- The resolver automatically regulates your storage use.
- Cached IP addresses can be returned and reordered in a round-robin manner, which provides a balanced way of using cached resources.

If you have been using a caching-only name server and you want to use resolver caching, see [“Migrating from a local caching-only name server to resolver caching”](#) on page 786.

You can disable resolver caching for selected applications; for more information, see [“Steps for disabling caching for selected applications”](#) on page 783.

**Restriction:** Resolver caching is disabled by default for IBM z/OS Container Platform environments and is ignored.

## Information that is cached by the resolver

Table 36 on page 776 shows the application programming interfaces (APIs) that use resolver caching.

| Table 36. APIs that use resolver caching |                                                                                        |
|------------------------------------------|----------------------------------------------------------------------------------------|
| API                                      | Usage                                                                                  |
| getaddrinfo()                            | Resolves host name to one or more IP addresses. Supports both IPv4 and IPv6 addresses. |
| gethostbyaddr()                          | Resolves an IP address to a host name. Supports only IPv4 addresses.                   |
| gethostbyname()                          | Resolves a host name to one or more IP addresses. Supports only IPv4 addresses.        |
| getnameinfo()                            | Resolves an IP address to a host name. Supports both IPv4 and IPv6 addresses.          |

The resolver caches the following DNS response information generated by the APIs in [Table 36 on page 776](#):

- Forward lookup information (IP addresses as A or AAAA records)

*Forward lookups* are host-name-to-IP-address resolution requests. This includes IPv4 (A records) and IPv6 (AAAA records) addressing records from getaddrinfo() and gethostbyname() API calls.

- Reverse lookup information (domain name pointers as PTR records)

*Reverse lookups* are IP-address-to-host-name resolution requests. This includes records from getnameinfo() and gethostbyaddr() API calls.

- Negative caching (NX) information

*Negative caching* is the storage of the knowledge that a record does not exist, or that a request for a specific resource cannot or does not give an answer. The negative cache represents the received NXDOMAIN (nonexistent domain) responses from the server. The negative cache also represents the received NOERROR responses that did not include answer records of the requested type, such as a request for IPv6 addresses when the resource has only IPv4 addresses defined. Negative cache entries represent resources that are known to not exist and they include both reverse and forward entries.

### Notes:

- IP addresses cached by getaddrinfo() and gethostbyname() API calls can be returned in a round-robin manner if CACHEREORDER is enabled.
- Sorting algorithms, such as the SORTLIST statement, might affect the results of the cache reordering logic. See [“Interactions of address sorting and cache reordering”](#) on page 781 for more information.

There is an upper limit on the amount of storage that can be used for negative caching information. The upper limit is 20 percent of the maximum amount of cache storage that the resolver is permitted to use. The resolver does not set aside this amount of storage for exclusive use by negative cache entries; rather, the resolver never exceeds this amount of storage to hold negative cache entries. When the upper limit is reached, no subsequent negative cache entries are saved until some existing entries are deleted and the

negative cache entry storage use drops below the 20 percent upper limit. For information about setting the maximum amount of cache storage available to the resolver, see [“Steps for configuring resolver caching \(optional\)”](#) on page 782.

The resolver does not cache information retrieved from local host files, such as `/etc/hosts` and `/etc/ipnodes`; that type of information is already cached at a process level. The resolver also does not cache information retrieved using an API not listed in [Table 36](#) on page 776.

The length of time that cache entries, including negative entries, are valid depends on the time-to-live (TTL) value that is returned by each domain name server. This is consistent with the behavior when using a caching-only name server or an intermediate name server to resolve a query.

In the following situations, cached entries are not saved up to the TTL value that is returned by the name server:

- When you flush the cache using the `MODIFY RESOLVER,FLUSH,ALL` command to delete all cached entries (for more information, see [“Step for deleting cache entries”](#) on page 785)
- When the maximum allocated storage for the cache is exhausted (for more information, see [“Managing the cache size and cache storage”](#) on page 784)
- When you limit the duration of time that any individual cache record can be saved using the `MAXTTL` resolver setup statement (for more information about the `MAXTTL` statement, see [z/OS Communications Server: IP Configuration Reference](#))
- When you limit the duration of time that any individual negative cache record can be saved using the `MAXNEGTTT` resolver setup statement. For more information about the `MAXNEGTTT` statement, see [z/OS Communications Server: IP Configuration Reference](#)).

## The organization of the cached data

The cache is contained in one physical location that has separate logical structures for forward and reverse lookup information. The cache data is organized by DNS name server, which permits different name servers to provide different values for a given host name or IP address.

For example, consider the installation shown in [Figure 109](#) on page 778. There are two TCP stacks; one TCP stack is used for the core production processing, and a second TCP stack is used for test purposes only. The stacks use different name servers to isolate test resources from the production environment. Each name server can potentially have different IPv4 (A record) definitions for the same host name, as is the case for `host.ibm.com`. If the test application issues a query for `host.ibm.com`, the test TCP stack directs the request to the test name server, and IP address 10.45.5.5 is obtained. If the production application issues the same query, a different IP address (10.145.5.5) is obtained. The resolver caches both responses but remembers which response was received from which name server, so that a subsequent request from the test application for `host.ibm.com` returns the correct test IP address, and not the production IP address.

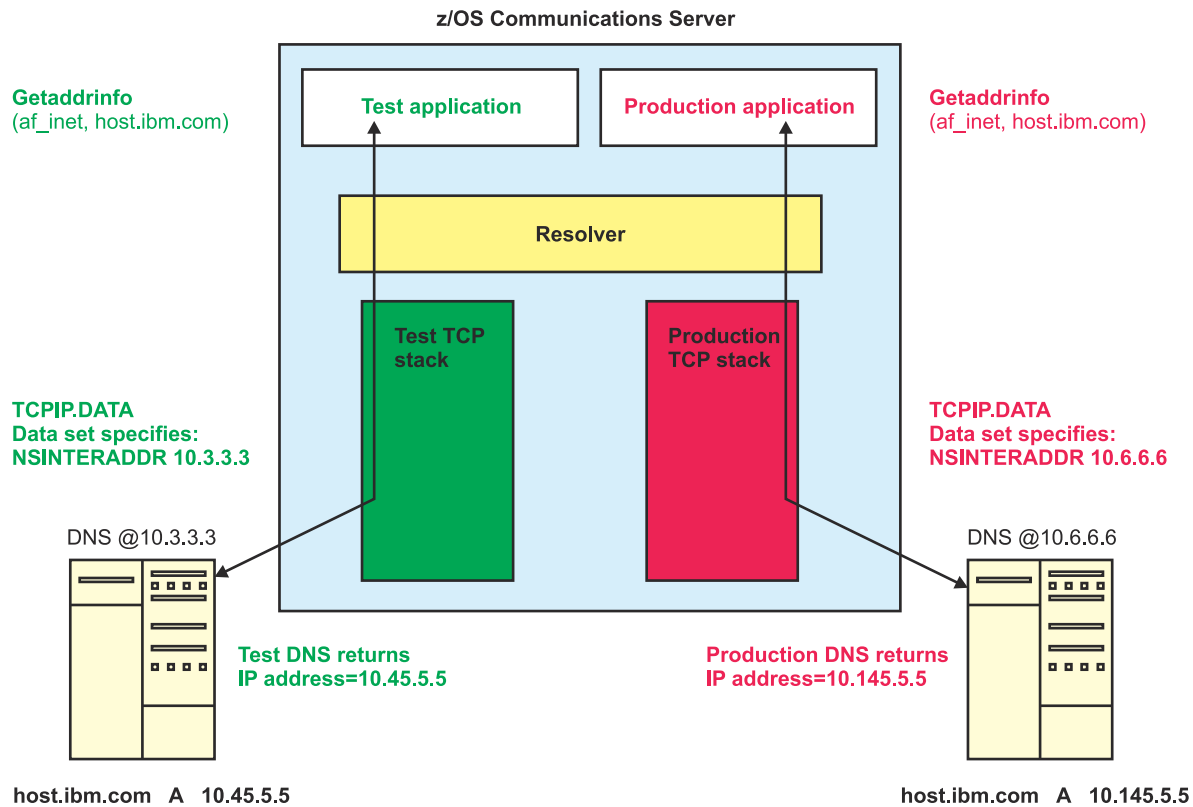

Figure 109. Resolver caching process; each stack specifies one NSINTERADDR value

The resolver performs cache lookups using the NSINTERADDR search order list in the TCPIP.DATA data set. In Figure 109 on page 778, each stack specifies a single NSINTERADDR value. More likely, in reality, multiple NSINTERADDR definitions are provided, as shown in Figure 110 on page 779. In this example installation, if the primary name server is unavailable, a secondary name server is used instead. The resolver considers a cache entry that is associated with any name server in the NSINTERADDR list as a match for the target host name; the name resolution is complete and no DNS queries are sent to any of the name servers. The resolver searches the cache in the order that the name servers appear in the NSINTERADDR list; if multiple entries exist for the same target host name (one from each of the name servers in the NSINTERADDR list), the information provided by the first name server in the list is used. In Figure 110 on page 779, if the test application issues a query for host.ibm.com, IP address 10.145.5.5 is obtained because the first name server IP address in the list is now the production name server (10.6.6.6). If the production application issues the same query, the same IP address, 10.145.5.5 is obtained because there is no entry in the cache for host.ibm.com from the first name server in the list, but there is cache information from the second name server (which is, again, 10.6.6.6).

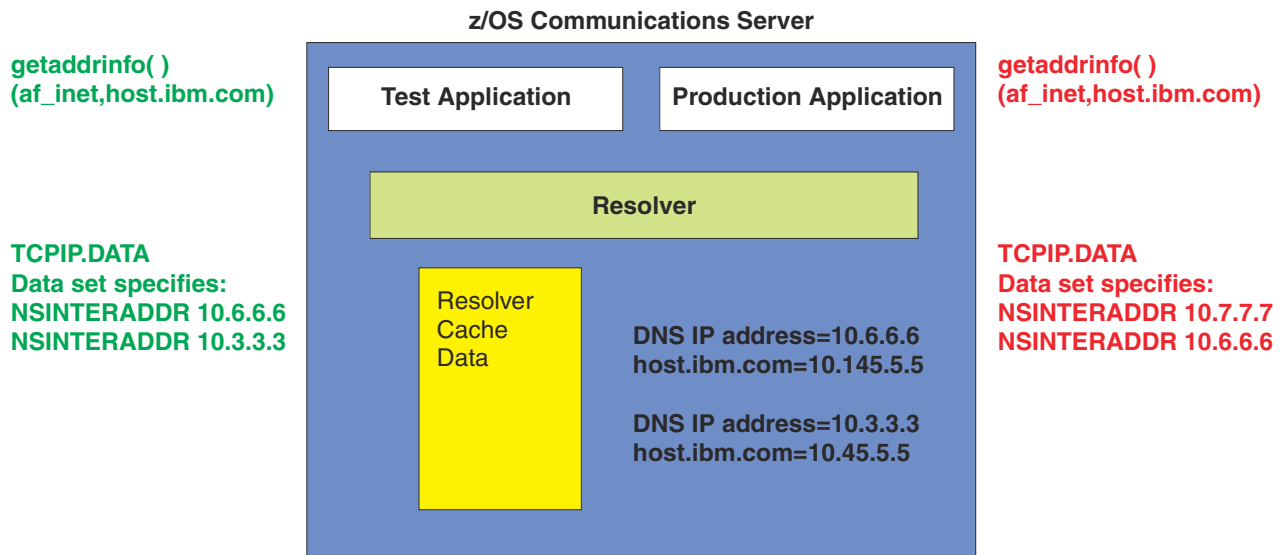

Figure 110. Resolver caching process; each stack specifies multiple NSINTERADDR values

IPv4 information and IPv6 information are cached as separate entries. A maximum of 35 IP addresses is saved per host name for each name server that provides data for that host name.

## Cache reordering

DNS servers can be configured to use a round-robin manner for ordering the IP addresses that are returned in response to forward lookup requests. The load balancing that this reordering provides is lost if the resolver does not also reorder its cached list of IP addresses in a round-robin manner. If the resolver does not perform cache reordering, the list of IP addresses is always returned in the same order that the information was received from the DNS server, as long as the cache information remains valid.

Starting in z/OS Communications Server V2R2, you can control whether the resolver reorders the list of cached IP addresses before the resolver returns the list in response to forward lookup resolution requests.

- Use the CACHEREORDER resolver setup statement to enable system-wide cache reordering.
- Use the NOCACHEREORDER resolver setup statement to disable system-wide cache reordering.

You can also disable cache reordering for an individual application by specifying NOCACHEREORDER in the TCPIP.DATA file that the application uses.

### Rules:

- If both IPv6 and IPv4 addresses are cached for a host name, the two lists of addresses are managed and reordered independently of each other.
- The list of IP addresses is reordered independently of which applications issue the forward lookup requests.
- The list of IP addresses is reordered independently of the type of forward request that the application issues. The forward request can be `getaddrinfo()` or `gethostbyname()`.
- If system-wide cache reordering is enabled, forward lookup requests from applications that have locally disabled cache reordering have no effect on the round-robin processing.
- If you dynamically change either system-wide or local setting of cache reordering to NOCACHEREORDER, the resolver, on subsequent forward lookup requests, returns the list of IP addresses in the order that the list was cached.
- The resolver performs the cache reordering function before any address sorting is performed. See [“Interactions of address sorting and cache reordering” on page 781](#) for more information.
- Cache reordering has no effect on reverse lookup requests.

## Example

Consider host name **reorder.domain** that has three IPv6 and four IPv4 addresses that were cached in the following order:

```
IPv6 addresses 2001::10:9:1:1
 2001::10:9:1:2
 2001::10:9:1:3
IPv4 addresses 10.9.1.1
 10.9.1.2
 10.9.1.3
 10.9.1.4
```

If system-wide cache reordering is in effect, the resolver reorders the lists as follows for this sequence of forward lookup requests for **reorder.domain**:

1. Application APPLA issues a `getaddrinfo()` request for IPv4 addresses:

```
IPv4 addresses 10.9.1.2
 10.9.1.3
 10.9.1.4
 10.9.1.1
```

2. Application APPLD issues a `getaddrinfo()` request for both IPv4 and IPv6 addresses:

```
IPv6 addresses 2001::10:9:1:2
 2001::10:9:1:3
 2001::10:9:1:1
IPv4 addresses 10.9.1.3
 10.9.1.4
 10.9.1.1
 10.9.1.2
```

3. Application APPLNOCR, which has `NOCACHEREORDER` specified in its `TCPIP.DATA` file, issues a `getaddrinfo()` request for both IPv4 and IPv6 addresses:

```
IPv6 addresses 2001::10:9:1:1
 2001::10:9:1:2
 2001::10:9:1:3
IPv4 addresses 10.9.1.1
 10.9.1.2
 10.9.1.3
 10.9.1.4
```

4. Application APPLB issues a `gethostbyname()` request for IPv4 addresses:

```
IPv4 addresses 10.9.1.4
 10.9.1.1
 10.9.1.2
 10.9.1.3
```

5. Application APPLC issues a `getaddrinfo()` request for IPv6 addresses:

```
IPv6 addresses 2001::10:9:1:3
 2001::10:9:1:1
 2001::10:9:1:2
```

6. Application APPLB issues a `getaddrinfo()` request for both IPv4 and IPv6 addresses:

```
IPv6 addresses 2001::10:9:1:1
 2001::10:9:1:2
 2001::10:9:1:3
IPv4 addresses 10.9.1.1
 10.9.1.2
 10.9.1.3
 10.9.1.4
```

7. Application APPLB issues a `gethostbyname()` request for IPv4 addresses:

```
IPv4 addresses 10.9.1.2
 10.9.1.3
```

```
10.9.1.4
10.9.1.1
```

8. Application APPLD issues a `getaddrinfo()` request for both IPv4 and IPv6 addresses:

```
IPv6 addresses 2001::10:9:1:2
 2001::10:9:1:3
 2001::10:9:1:1
IPv4 addresses 10.9.1.3
 10.9.1.4
 10.9.1.1
 10.9.1.2
```

#### Notes:

- Because cache reordering does not consider which applications issue the forward lookup requests, an individual application might get results that suggest that cache reordering is not being performed even though it is being performed. For example, the two requests from APPLD result in the same lists even though requests from other applications result in lists with different orders.
- Because `NOCACHEREORDER` is specified in its `TCPIP.DATA` file, the resolver returns the list of IP addresses in the same order for every request `APPLNOCR` issues. The requests from `APPLNOCR` have no effect on the other results where cache reorder is performed.

### *Interactions of address sorting and cache reordering*

The resolver can perform the following types of IP address sorting after the resolver obtains the list of IP addresses for a forward lookup request:

- IPv4 addresses are sorted based on the values that are defined on the `SORTLIST` statement in the application's `TCPIP.DATA` file. To prevent this kind of sorting, do not specify a `SORTLIST` statement.
- As part of `getaddrinfo()` processing, IPv4 and IPv6 addresses are sorted based on the default address selection algorithm. You cannot prevent this sorting from being performed. However, to influence the algorithm, you can define a policy table by using the `DEFADDRTABLE` statement in the TCP/IP profile. See [DEFADDRTABLE statement](#) in *z/OS Communications Server: IP Configuration Reference* for more information.

When both cache reordering and address sorting are performed, the resolver first reorders the list of IP addresses. The appropriate sorting algorithm is then performed on the reordered list of IP addresses. Depending on the sorting algorithm and the IP addresses in the list, the outcome of the sorting algorithm might cause the resolver to return the list of IP addresses in the same order for every forward lookup request.

For example, if host name **sorted.domain** resolves to IPv4 addresses 10.9.1.1 and 20.10.8.7, the following results might occur:

- If no `SORTLIST` statement is coded, half of the resolution requests for **sorted.domain** have IP address 10.9.1.1 listed first, and half of the requests have IP address 20.10.8.7 listed first.
- If a `SORTLIST` statement is coded, the results depend on how the sorting algorithm applies to these addresses:
  - If the sorting values on the `SORTLIST` statement favor one address over the other, the chosen address is always displayed first in the returned list, regardless of cache reordering. For example, if 10.9.1/24 is coded on the `SORTLIST` statement, IP address 10.9.1.1 is favored and is always first in the sorted list.
  - If the sorting values on the `SORTLIST` statement do not favor any address, the results are similar to when no `SORTLIST` statement is defined. For example, if 55.1/16 is coded on the `SORTLIST` statement, no IP address is favored. Half of the requests have IP address 10.9.1.1 listed first and half have IP address 20.10.8.7 listed first.

## Steps for configuring resolver caching (optional)

Resolver caching is automatically enabled and you do not need to make parmlib or JCL changes. Unless you choose to do so, you do not have to configure the cache; however, you can explicitly configure resolver caching.

**Restriction:** Resolver caching is disabled by default for IBM z/OS Container Platform environments and is ignored.

### Before you begin

You must have already created a resolver setup file; see [“The resolver setup file” on page 763](#) for more information.

### Procedure

Perform the following steps to configure resolver caching:

1. Specify the CACHE statement to enable system-wide caching of Domain Name System (DNS) queries that have been resolved.

System-wide caching is enabled by default, but you can explicitly enable it by specifying this statement.

2. Specify the CACHESIZE(*cachesize*M) statement to define the amount of storage, in megabytes, that can be allocated by the resolver to manage cached records.

The default value is 200 megabytes.

**Guideline:** If you set a CACHESIZE value that is too low, the resolver might repeatedly take action to reduce cache usage. You should set the CACHESIZE value to be at least 50 percent higher than your expected usage.

If you specify this statement and the NOCACHE statement, the CACHESIZE statement is ignored. For more information about cache size, see [“Managing the cache size and cache storage” on page 784](#).

3. Specify the MAXTTL statement to define the maximum amount of time, in seconds, that cache entries are considered to be valid by the resolver.

The default value is the maximum time-to-live (TTL) value that is provided by the DNS name server for this resource. If you specify this statement and the NOCACHE statement, the MAXTTL statement is ignored.

4. Specify the MAXNEGTTT statement to define the maximum amount of time, in seconds, that negative cache entries are considered to be valid by the resolver. The default value is the setting for MAXTTL if it is specified, otherwise the default is the maximum TTL value that is provided by the DNS name server for the resource. If you specify this statement and the NOCACHE statement, the MAXNEGTTT statement is ignored.

5. Specify whether cache reordering is used on a system-wide basis.

- Specify CACHEREORDER to enable system-wide cache reordering.
- Specify NOCACHEREORDER to disable system-wide cache reordering.

The default setting is to disable system-wide cache reordering. If you specify the NOCACHE statement, the CACHEREORDER and NOCACHEREORDER statements are ignored. See [“Cache reordering” on page 779](#) for more information.

6. Perform one of the following steps:

- If the resolver is not active, start the resolver.
- If the resolver is currently active, issue the MODIFY RESOLVER,REFRESH,SETUP=*setup\_file\_name* command to cause the resolver to use the new settings.

### Results

You complete the task when the correct values for the CACHE, CACHEREORDER or NOCACHEREORDER, CACHESIZE(*cachesize*M), MAXTTL and MAXNEGTTT statements are displayed after you issue the START command or in the MODIFY RESOLVER,REFRESH command output.

For more information about [resolver setup statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

For more information about the [MODIFY RESOLVER,REFRESH](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

## Steps for disabling caching for selected applications

You can disable resolver caching for applications in your environment that do not need to use it.

### Before you begin

Some applications might not need to use resolver caching. For example, as shown in [Figure 109](#) on [page 778](#), you might have a production network and a test network in your environment. Users of the test network might require specialized host name resolution using a unique set of DNS servers that are not used in the production network. Because the test network is isolated and is likely to affect only a small number of users, using resolver caching for the test network could waste cache storage, and could complicate operation of the production network by adding information that is not pertinent to the production network. You can disable resolver caching for applications using the test network, while continuing to use resolver caching for the production network.

### Procedure

Perform the following steps to disable caching for some applications:

1. Identify or create the TCPIP.DATA data set associated with the application for which you want to disable resolver caching.
2. Turn off the resolver caching function by specifying the NOCACHE statement in that TCPIP.DATA data set.
3. Issue the MODIFY RESOLVER,REFRESH command to cause the resolver to refresh the settings for the application.
4. Activate the Trace Resolver facility to determine which TCPIP.DATA values are being used by the resolver and where they are being read from.
5. When the trace is active, issue the Netstat HOME/-h command to display the values.

### Results

The task is completed when the value NOCACHE is displayed in the Trace Resolver output that is generated by the Netstat HOME/-h command.

For more information about [configuration statements in TCPIP.DATA](#), see [z/OS Communications Server: IP Configuration Reference](#). For more information about the [MODIFY RESOLVER,REFRESH](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

## Steps for disabling cache reordering for selected applications

You can disable cache reordering for applications in your environment if you do not need to use it.

### Before you begin

Some applications might not need cache reordering. For example, applications that do not have load balancing requirements or that have a well-defined algorithm might require the resolver to return the cached addresses in the same order all the time. Determine which applications do not require cache reordering and disable cache reordering for these specialized applications.

### Procedure

Perform the following steps to disable cache reordering for the selected applications:

1. Identify or create the TCPIP.DATA data set that is associated with the application for which you want to disable cache reordering.

2. Turn off the cache reordering function by specifying the NOCACHEREORDER statement in the TCPIP.DATA data set.
3. Issue the MODIFY RESOLVER,REFRESH command to refresh the settings for the application.
4. Activate the trace resolver facility to determine the TCPIP.DATA values that the resolver is using and where the values are read from.
5. When the trace resolver is active, issue the Netstat HOME/-h command to display the values.

## Results

Cache reordering is disabled when the value NOCACHEREORDER is displayed in the trace resolver output that the Netstat HOME/-h command generates.

For more information about configuration statements in the TCPIP.DATA data set, see [z/OS Communications Server: IP Configuration Reference](#). For more information about the MODIFY command for the resolver address space, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Managing the cache size and cache storage

Resolver cache information is maintained in 64-bit private storage in the resolver address space, which is also referred to as the storage above the 2 GB bar. This means that caching does not impact common storage.

The default maximum size of the cache is 200 megabytes. The size is allocated incrementally, as the cache increases. For planning purposes, assume that 1 megabyte of storage holds between 400 and 450 cache entries. The actual number of cache entries depends on the amount of storage used for cache infrastructure control blocks, which varies depending on the number of name servers and the number of entries. If you want to control the maximum size of the cache instead of using the 200 megabyte default, you can use the CACHESIZE resolver setup statement. The CACHESIZE statement specifies the maximum amount of storage, in megabytes, that can be allocated by the resolver to manage cached records. The CACHESIZE statement is also used to determine the upper limit of storage that can be used for negative cache entries. If you use the default CACHESIZE value of 200M, then no more than 40 megabytes of that storage will be used for negative cache entries.

The resolver does not automatically delete expired records (those records whose TTL value has been exceeded). Regardless of the amount of cache storage that is in use, the resolver deletes expired records if a new request is received for the expired resource. The resolver also deletes expired records when your cache storage usage has reached the following levels, and takes additional actions to reduce your storage usage.

- When cache storage is less than 75 percent full, the resolver deletes all expired records approximately every 10 minutes, without waiting for a new request to be processed.
- When cache storage is 75 - 97 percent full, the resolver deletes all expired records approximately every minute, without waiting for a new request to be processed.
- When cache storage is 98 percent or more full, the resolver deletes all expired records approximately every 30 seconds, without waiting for a new request to be processed. The resolver does not add new records to the cache while usage is greater than 99 percent. Message EZZ9307E is displayed until usage is less than 90 percent, you increase the CACHESIZE value, or you delete the contents of the cache; see [“Step for deleting cache entries” on page 785](#) for more information.

## ***Steps for manually managing the storage capacity of the resolver cache***

You can increase the size of the cache, decrease the length of time that cache records are saved in the cache, and delete all cache entries.

## Before you begin

You must have already created a resolver setup file; see [“The resolver setup file” on page 763](#) for more information.

## Procedure

Perform one of the following steps to manage the storage capacity of the resolver cache:

- On the CACHESIZE statement in the resolver setup file, increase the CACHESIZE value and issue the `MODIFY RESOLVER,REFRESH,SETUP=resetup_filename` command.
- On the MAXTTL statement in the resolver setup file, decrease the MAXTTL value to decrease the length of time that cache records are saved in the cache and issue the `MODIFY RESOLVER,REFRESH,SETUP=resetup_filename` command. The new MAXTTL value affects only new cache records as they are created; there is no effect on existing cache records.
- On the MAXNEGTTT statement in the resolver setup file, or if you had previously been taking the value of MAXTTL for the default for MAXNEGTTT, decrease or specify a smaller MAXNEGTTT value to decrease the length of time that negative cache records are saved in the cache. Issue the `MODIFY RESOLVER,REFRESH,SETUP=resetup_filename` command. The new MAXNEGTTT value affects only new negative cache records as they are created; there is no effect on existing cache records.

**Note:** You can completely disable caching of negative cache records by specifying a value of 0 for MAXNEGTTT.

- Issue the `MODIFY RESOLVER,FLUSH,ALL` command to delete all cache entries.

## Results

You know you are done when message EZZ9307E is no longer displayed on the operator console.

## Step for deleting cache entries

You might want to delete the contents of the cache when an IP address has changed for a given host name or when your cache storage is exhausted.

## Procedure

Perform the following step to delete the contents of the cache:

- Issue the `MODIFY RESOLVER,FLUSH,ALL` command to delete all cache entries.  
For more information about the `MODIFY RESOLVER,REFRESH`, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Results

If you have deleted cache entries because your cache storage was exhausted, you know you are done when message [EZZ9307E](#) no longer appears on the screen.

## Step for displaying the contents of the cache

## Procedure

Perform the following step to display the contents of the resolver cache:

- Issue the `Netstat RESCache/-q` command to display the RESCache/-q report.  
The Netstat RESCache/-q report displays the contents of the resolver cache data. You can display statistical data, both overall and by name server. You can also create a report that shows all the cache entries, or you can use filters to produce a report that shows subsets of cache entries.

## What to do next

For details about access control considerations for the Netstat RESCache/-q report, see “Netstat access control” on page 167. For Netstat command syntax and sample report output, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Migrating from a local caching-only name server to resolver caching

If you have been using a local caching-only name server, you should consider using resolver caching. You can compare the contents of your local caching-only name server with the contents of the resolver cache by performing these steps.

### Before you begin

Resolver caching must be enabled and active. If resolver caching is not enabled (the NOCACHE statement is coded in the resolver setup statement), see [“Steps for configuring resolver caching \(optional\)”](#) on page 782.

### Procedure

Perform the following steps to migrate from a local caching-only name server to resolver caching:

1. Display the contents of your caching-only name server and of the resolver cache at specific intervals.
  - For your caching-only name server, you can dump the contents of the DNS cache. For DNS servers running BIND 9, use the **rndc dumpdb** command.
  - For the resolver cache, use the Netstat RESCache/-q report. For more information, see [“Step for displaying the contents of the cache”](#) on page 785.
2. Compare the contents of the caching-only name server and the resolver cache, and determine whether to use only resolver caching or resolver caching with the local caching-only name server, using the following criteria:
  - If the contents are similar, and consist primarily of A, AAAA, and PTR DNS records, then you would benefit the most by using only resolver caching. This situation is the most common.
  - If the contents are dissimilar, but the caching-only name server has primarily A, AAAA, and PTR DNS records, then the dissimilar contents are most likely the result of differences in how the resolver cache and the caching-only name server delete expired records. In this situation, you are still most likely to benefit from using only resolver caching.
  - If the contents are dissimilar, and the caching-only name server has many DNS records that are not A, AAAA, or PTR records, you will probably benefit the most by using both resolver caching and the caching-only name server. This situation is not common.
3. Calculate the amount of resolver cache storage that you think you need.

You can use the default amount of storage (200 megabytes) or you can use the CACHESIZE resolver setup statement to specify a maximum amount of storage. For calculation purposes, 1 megabyte of storage holds roughly 400 - 450 cache entries.
4. If you are not going to use the local caching-only name server, stop that server.

**Guideline:** If the local caching-only name server is the only name server in the NSINTERADDR list of name servers to be contacted, replace the caching-only name server entry with one or more name server IP addresses to be contacted. If there is already more than one name server in the NSINTERADDR list of name servers, delete the IP address of the local caching-only name server.

### Results

For more information about [resolver setup statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Monitoring the responsiveness of Domain Name System name servers

The resolver monitors the responsiveness level of Domain Name System (DNS) name servers that are in the network. The resolver provides two levels of name server monitoring:

- [“Network operator notification”](#) on page 788

The resolver alerts the network operator about name servers that fail to respond to a significant percentage of resolver queries, but continues to send DNS queries that are generated by an application

to the unresponsive name server. You can use these alerts to better manage the list of name servers that the system uses and to avoid unnecessary delays when a host name or IP address is being resolved.

- [“Autonomic quiescing of unresponsive name servers” on page 789](#)

The resolver alerts the network operator about name servers that fail to respond to a significant percentage of resolver queries, and does not send additional DNS queries that are generated by an application to the unresponsive name server. While the name server remains unresponsive, the resolver periodically sends DNS polling queries to the name server. When the name server is responsive to the resolver's DNS polling queries, the resolver resumes sending DNS queries that are generated by an application to the name server.

To determine name server responsiveness, the resolver collects statistics about name server responsiveness at 30-second or 1-minute intervals, depending on the monitoring function that is being performed. During a given monitoring interval, the resolver keeps system-wide statistics about the total number of resolver queries that are sent to a name server and about the number of those resolver queries that were not responded to by the name server. At the end of the monitoring interval, the resolver calculates a percentage of the total number of queries that were not responded to by the name server over the course of the last interval, or the last five intervals, depending on the monitoring function being performed. This percentage is compared to the setting on the `UNRESPONSIVETHRESHOLD` resolver setup statement. If the percentage of failures equals or exceeds the threshold value, the resolver considers the name server to be unresponsive. For information about the `UNRESPONSIVETHRESHOLD` statement and how to set its value, see [z/OS Communications Server: IP Configuration Reference](#) and [“Optimizing the UNRESPONSIVETHRESHOLD value for your network” on page 793](#).

The phrase *resolver queries* does not mean the same thing as *resolver API calls* in the context of name server responsiveness. A single resolver API call, such as `getaddrinfo()` or `gethostbyname()`, can generate multiple resolver queries to one or more DNS name servers, based on retry counts, domain names to append to a search, or the type of information that is being requested by the API. Conversely, a resolver API call might not generate any resolver queries to any DNS name servers, if the resource is already in the resolver cache. See [“Examples of resolver monitoring of DNS name servers” on page 792](#) for examples of how different `TCPIP.DATA` file settings can influence name server responsiveness statistics.

**Restriction:** The resolver can monitor a maximum of 32 name servers for responsiveness.

The resolver considers the following failures to be indicative of an unresponsive name server:

- The resolver sends a UDP or TCP query to a name server and never receives a response.
- The resolver sends a UDP query to a name server and receives a response after the `RESOLVETIMEOUT` value has expired.
- The resolver attempts to send data to a name server using UDP, but the data cannot be sent to the target IP address (for example, because of an error in the route configuration).
- The resolver attempts to connect to a name server using TCP, but the connection attempt times out.
- In some situations, the BIND 9 DNS utilities (for example, `dig` or `nsupdate`) issue `getaddrinfo()` API calls to resolve a host name that represents a remote DNS name server, and those API calls invoke z/OS resolver processing. If any of the previously mentioned failures occur during these BIND 9 resolver calls, the failures are included in the name-server statistics.

The resolver does not consider the following failures to be indicative of an unresponsive name server:

- The resolver cannot open a socket (UDP or TCP) to send a request to a name server, including instances in which the system is IPv4-only capable and an IPv6 name server IP address is coded on the `NSINTERADDR` statement.
- The resolver sends a UDP query to a name server to determine whether the name server is EDNS0-capable, but does not receive a response to that UDP query; see [“Extension Mechanisms for DNS standards and the resolver” on page 795](#) for more information about EDNS0 processing.
- The resolver sends a UDP query to a name server and the name server responds with a DNS return code (such as `SERVFAIL` or `NOTIMPL`) that indicates that the name server is active and responding but is unable to process the request that was sent.

- Timeouts or failures occur during BIND 9 DNS utility processing that does not involve getaddrinfo() calls (that processing uses BIND 9 resolver services to send queries to a name server).

## Network operator notification

You can specify only a failure threshold percentage using the UNRESPONSIVETHRESHOLD resolver setup statement, or you can use the default value, which is 25%. In either case, the resolver reacts to unresponsive name servers by notifying the network operator of the condition and continues to send DNS queries to the unresponsive name server. The network operator notification function collects name-server statistics at 1-minute intervals, but makes decisions based on the last five monitoring intervals. These intervals are called sliding 5-minute windows.

### *Messages generated by the resolver for the network operator notification function*

If the resolver detects that a name server is not being responsive, a series of network operator messages is issued that relate to that name server. For example, if a name server is operating at IP address 10.42.35.200 and the UNRESPONSIVETHRESHOLD value is 25, then the following sequence of messages might be generated by the resolver:

1. At the end of a 5-minute monitoring interval, the resolver determines that the name server failed to respond to 35% of 6000 queries that were attempted by the resolver. The resolver considers the name server to be unresponsive and issues the following messages:

```
EZZ9308E UNRESPONSIVE NAME SERVER DETECTED AT IP ADDRESS 10.42.35.200
EZZ9310I NAME SERVER 10.42.35.200
 TOTAL NUMBER OF QUERIES SENT 6000
 TOTAL NUMBER OF FAILURES 2100
 PERCENTAGE 35%
```

2. At the end of the next 5-minute interval, the resolver determines that the name server failed to respond to 55% of the 3000 queries that it attempted during that interval. The name server is still considered to be unresponsive, and the following message is issued:

```
EZZ9310I NAME SERVER 10.42.35.200
 TOTAL NUMBER OF QUERIES SENT 3000
 TOTAL NUMBER OF FAILURES 1650
 PERCENTAGE 55%
```

This message and the statistical information for the name server are issued at 5-minute intervals for as long as the resolver considers the name server to be unresponsive.

3. At the end of a subsequent monitoring interval, the resolver determines that the name server failed to respond to 15% of the 4500 queries that the resolver attempted during the latest sliding 5-minute interval. This percentage is under the threshold value, so the resolver considers this name server to be responsive again. The resolver clears message EZZ9308E from the operator console and issues the following messages:

```
EZZ9309I NAME SERVER IS NOW RESPONSIVE AT IP ADDRESS 10.42.35.200
EZZ9310I NAME SERVER 10.42.35.200
 TOTAL NUMBER OF QUERIES SENT 4500
 TOTAL NUMBER OF FAILURES 675
 PERCENTAGE 15%
```

4. The resolver also clears message EZZ9308E from the operator console if any of the following situations occur:
  - The network operator disables the monitoring function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see [“Steps for modifying the UNRESPONSIVETHRESHOLD value”](#) on page 794.
  - The network operator enables the autonomic quiescing of unresponsive name servers function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see [“Steps for modifying the UNRESPONSIVETHRESHOLD value”](#) on page 794.
  - No resolver queries are sent to the name server during the current 5-minute monitoring interval.
  - The network operator notification function abnormally terminates due to system error.

- The resolver is stopped.

The resolver issues individual messages for each name server that it considers to be unresponsive at the end of a given monitoring interval. Because the resolver calculates the responsiveness of a name server by using a sliding 5-minute interval, messages might be issued for different name servers at different times, rather than notifications about all unresponsive name servers being issued at the same time.

### ***Diagnosing problems with unresponsive name servers***

Use the statistics supplied in message EZZ9310I to determine the severity of the problem that the resolver is reporting. For example, if the unresponsive name server is the primary server for the network, and it is failing to respond to over half of a large number of queries that are directed to it, that situation might be more serious than a secondary name server that is not responding to 25% of a small number of queries. You can also use the statistics that are displayed when message EZZ9309I is issued to determine whether the name server is fully responsive again, is likely to become unresponsive again because the failure rate is still close to the threshold value, or is just not being used in your environment.

**Guideline:** The resolver does not require that there be a certain number of failed queries to a particular name server before it declares that server to be unresponsive. For example, if only one query is received by a particular name server during a monitoring interval, and that query fails to obtain a response, then the resolver considers that name server to be 100% unresponsive.

### **Autonomic quiescing of unresponsive name servers**

In addition to specifying a failure threshold percentage on the UNRESPONSIVETHRESHOLD resolver setup statement, you can also specify the AUTOQUIESCE operand. If you specify the AUTOQUIESCE operand, in addition to network operator notification, the resolver stops sending DNS queries that are generated by an application to the unresponsive name server. While a name server is considered to be unresponsive, the resolver sends DNS polling queries to the name server every 6 seconds. When the name server is responsive to the resolver's DNS polling queries, the resolver resumes sending DNS queries that are generated by an application to the name server. The autonomic quiescing of unresponsive name servers function collects name-server statistics in intervals of 30 seconds, but makes decisions based on no more than two monitoring intervals.

**Guideline:** If all name servers specified on the TCPIP.DATA NSINTERADDR statements are unresponsive, the resolver sends DNS queries that are generated by an application to those name servers; the resolver does not fail the application queries immediately.

**Restriction:** If you specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement, you must also specify the GLOBALTCPIPDATA statement. If you do not specify the GLOBALTCPIPDATA statement, the resolver issues message EZZ2036I and ignores the AUTOQUIESCE operand. The resolver operates as if you requested the network operator notification function. For more information about the UNRESPONSIVETHRESHOLD statement, see [z/OS Communications Server: IP Configuration Reference](#).

#### **Restrictions:**

- If you specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement, you must also specify the GLOBALTCPIPDATA statement. If you do not specify the GLOBALTCPIPDATA statement, the resolver issues message EZZ2036I and ignores the AUTOQUIESCE operand. The resolver operates as if you requested the network operator notification function. For more information about the UNRESPONSIVETHRESHOLD statement, see [z/OS Communications Server: IP Configuration Reference](#).
- The AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement is ignored for IBM z/OS Container Platform environments.

If you use multiple TCP/IP stacks in a common INET (CINET) environment, you must ensure that the IP addresses of the name servers that are specified in the global TCPIP.DATA file are accessible from all TCP/IP stacks. If a name server IP address is accessible only from a specific TCP/IP stack, the autonomic quiescing function could mistakenly consider that name server as unresponsive to DNS queries. For example, consider two TCP/IP stacks, TCPIP1 and TCPIP2, where the IP address for DNS1 is accessible using only TCPIP1 and the IP address for DNS2 is accessible using only TCPIP2. If the NSINTERADDR statement in the global TCPIP.DATA specifies DNS1 and DNS2, in that order, any application DNS queries

with stack affinity to TCPIP2 results in DNS query failures to DNS1 because the IP address for DNS1 is not accessible using TCPIP2. If there is a sufficient volume of these queries with stack affinity to TCPIP2, or the UNRESPONSIVETHRESHOLD value is very small, the resolver might decide that DNS1 is unresponsive and stop using it temporarily, resulting in unnecessary failures for application DNS queries that use TCPIP1.

**Guideline:** If you cannot ensure that all DNS IP addresses are accessible from all your TCP/IP stacks, you should not use a global TCPIP.DATA file, and you should not code AUTOQUIESCE on the UNRESPONSIVETHRESHOLD setup statement in your resolver setup file.

### ***Messages generated by the resolver for the autonomic quiescing of unresponsive name servers function***

If the resolver detects that a name server is not being responsive, a series of network operator messages is issued that relate to that name server. For example, if a name server is operating at IP address 10.42.35.200 and the UNRESPONSIVETHRESHOLD value is 100, then the following sequence of messages might be generated by the resolver:

1. At the end of a 30-second monitoring interval, the resolver determines that the name server failed to respond to 100% of the 500 queries that were attempted by the resolver. The resolver considers the name server to be unresponsive and issues the following messages:

```
EZZ9311E STOPPED USING NAME SERVER AT IP ADDRESS 10.42.35.200
EZZ9313I NAME SERVER 10.42.35.200
TOTAL NUMBER OF QUERIES SENT 500
TOTAL NUMBER OF FAILURES 500
TOTAL NUMBER OF RESOLVER POLLS SENT 0
TOTAL NUMBER OF POLL FAILURES 0
PERCENTAGE 100%
```

After issuing this message, the resolver sends only DNS polling queries to the unresponsive name server.

2. At the end of a subsequent monitoring interval, the resolver determines that the name server failed to respond to 10% of the 10 or more DNS polling queries during the last two monitoring intervals. This percentage is below the 100% threshold value, so the resolver considers this name server to be responsive again. The resolver clears message EZZ9311E from the operator console and issues the following message:

```
EZZ9312I RESUMED USING NAME SERVER AT IP ADDRESS 10.42.35.200
```

3. After the resolver issues message EZZ9312I, it resumes sending DNS queries that are generated by an application to the name server.
4. The resolver also clears message EZZ9311E from the operator console if any of the following events occur:
  - The network operator disables the monitoring function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see [“Steps for modifying the UNRESPONSIVETHRESHOLD value” on page 794](#).
  - The network operator enables the network operator notification function using the MODIFY RESOLVER,REFRESH,SETUP command. For more information, see [“Steps for modifying the UNRESPONSIVETHRESHOLD value” on page 794](#).
  - The autonomic quiescing of unresponsive name servers function abnormally terminates because of a system error.
  - The resolver is stopped.

The resolver issues individual messages for each name server that it considers to be unresponsive at the end of a given monitoring interval. Because the resolver calculates the responsiveness of a name server at every interval, messages might be issued for different name servers at different times, rather than notifications being issued about all unresponsive name servers at the same time. The resolver does not periodically reissue message EZZ9313I for each name server, but the status and current failure rate for each name server specified on an NSINTERADDR statement in the global TCPIP.DATA file is included

in the MODIFY RESOLVER,DISPLAY command output when the autonomic quiescing function is active. The failure rate that is displayed is the percentage calculated by the resolver for the individual name server at the end of the last 30-second monitoring interval. For more information about the [MODIFY RESOLVER,REFRESH](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

**Guideline:** In most cases, the resolver requires a sample size of at least 10 DNS queries before it declares a name server to be either unresponsive or responsive. For example, if only one query is received by a particular name server during a 30-second monitoring interval, and that query fails to obtain a response, then the resolver does not consider that name server to be unresponsive, even though the failure rate is 100% and exceeds the UNRESPONSIVETHRESHOLD value. The resolver sends DNS polling queries to this name server to collect a sufficient sample size of responses. In subsequent intervals, the resolver uses the results from DNS queries that are generated by an application and from DNS polling queries to calculate the overall failure rate for the name server.

### ***How the resolver polls unresponsive name servers***

The resolver sends DNS polling queries to unresponsive name servers every 6 seconds. The resolver uses the value specified on the RESOLVERTIMEOUT statement in the global TCPIP.DATA file to determine how long to wait for a response to a given DNS polling query. If the RESOLVERTIMEOUT value is greater than 6, multiple DNS polling queries can be outstanding to a given name server.

**Rule:** If you change the value of the RESOLVERTIMEOUT statement, only the timeout value of subsequent DNS polling queries is affected. For more information about the [RESOLVERTIMEOUT statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

The resolver continues to poll unresponsive name servers until one of the following events occur:

- The name server responds to all DNS queries generated by an application and to all DNS polling queries.

If a name server is unresponsive, the only queries that the resolver sends to the name server are DNS polling queries. The resolver sends DNS queries generated by an application to the name server as soon as the name server is responsive to DNS polling queries, but the resolver continues polling a name server as long as some DNS queries result in failures. The resolver considers a name server to be responsive to DNS polling queries if one of the following situations occur:

- If the name server had responded to DNS queries that are generated by an application prior to becoming 100% unresponsive to these queries, a single positive response to a DNS polling query is sufficient for the name server to be considered responsive.
- In all other cases, the name server must respond to a sufficient percentage of DNS polling queries to ensure that the following conditions are true:
  - At least 10 DNS polling queries received positive responses or timed out within the last 60 seconds
  - The failure rate for this name server in terms of responding to DNS polling queries is less than the UNRESPONSIVETHRESHOLD percentage.

Any response from the name server to a DNS polling query is considered to be a positive response, including responses that specify NXDOMAIN, SERVFAIL, or similar responses.

- The autonomic quiescing of unresponsive name servers is stopped with a MODIFY REFRESH,SETUP command. For more information about the [MODIFY RESOLVER,REFRESH](#), see [z/OS Communications Server: IP System Administrator's Commands](#).
- The name server is removed from the list of name servers that is specified on the NSINTERADDR statements in the global TCPIP.DATA file. The resolver stops polling this name server whether the server was explicitly removed from the list by the network operator using a MODIFY REFRESH command or implicitly removed as a result of a DNS query generated by an application. For more information about the [MODIFY RESOLVER,REFRESH](#), see [z/OS Communications Server: IP System Administrator's Commands](#).
- The resolver is stopped.

## Examples of resolver monitoring of DNS name servers

Values in the TCPIP.DATA file can affect the statistics that the resolver collects when it monitors DNS name servers. For example, consider the following settings from TCPIP.DATA:

```
NAMESERVER 10.43.25.200 10.43.125.203 10.43.25.200
RESOLVERUDPRETRIES 2
RESOLVERTIMEOUT 0.075
RESOLVEVIA UDP
```

In this example, one name server (10.43.25.200) appears twice in the list of name servers that the resolver will search. The resolver should try that list of name servers again one time before it considers the name servers to be unresponsive. Assume that the resolver generates a query to resolve the address user.ibm.com as part of gethostbyname processing. The following example sequence occurs:

1. The resolver sends the query to name server 10.43.25.200, which times out after 75 milliseconds (based on the RESOLVERTIMEOUT value).
2. The resolver forwards the request to name server 10.43.125.203, which also times out.
3. The request goes to name server 10.43.25.200 a second time (as the last name server in the list), which times out again.

The first retry of the list name servers is complete.

4. The resolver begins at the top of the list again and sends the request to name server 10.43.25.200 for a third time. A response arrives from this name server, possibly as the result of name server delays.
5. The resolver stops searching for the resource.

Based on the search that the resolver performed, the system-wide total request count for name server 10.43.25.200 is incremented by 3, and the total failure count is incremented by 2. If the searches that are shown in this example are all the activity for this name server over the course of a 5-minute sliding window or the 30-second monitoring interval, the failure rate for this name server is 66%; the system-wide total request count and the total failure count for name server 10.43.124.203 are both incremented by 1. If the resolver does not send any more queries to this name server during the 5-minute sliding window or the 30-second monitoring interval, the failure rate for name server 10.43.124.203 is 100%.

If you are using the network operator notification and the threshold percentage is less than 66%, the resolver reports both of these name servers as unresponsive, but continues to send DNS queries to both name servers.

If you are automatically quiescing unresponsive name servers, the resolver does not consider either of these name servers to be unresponsive because less than 10 queries were directed to the name server during the 30-second interval. The name servers are not considered unresponsive regardless of the setting of the UNRESPONSIVETHRESHOLD value.

Consider these different TCPIP.DATA file settings:

```
NAMESERVER 10.43.25.200
SEARCH raleigh.ibm.com
RESOLVERTIMEOUT 0.075
RESOLVEVIA UDP
```

In this example, only one name server is coded, and only one domain name can be appended to the input host name as an additional search attempt. Assume that an application issues getaddrinfo() for host name user, and that ai\_family=AF\_UNSPEC is specified. The following example sequence occurs:

1. The resolver searches for domain name user.raleigh.ibm.com and requests AAAA records.
2. One of the following actions occurs:
  - If the resolver obtains resource information, the search ends.
  - If the resolver does not obtain resource information, the resolver continues to request AAAA records, but searches the next domain in the sequence, which is user.
3. One of the following actions occurs:

- If the resolver obtains resource information, the search ends.
- If the resolver does not obtain resource information, the resolver searches for domain name `user.raleigh.ibm.com` and requests A records.

4. One of the following actions occurs:

- If the resolver obtains resource information, the search ends.
- If the resolver does not obtain resource information, the resolver continues to request A records, but searches the next domain in the sequence, which is `user`.

If the name server at 10.43.25.200 fails to respond to all of the queries, the system-wide total request count and the total failure count for this name server are incremented by 4. The network operator notification function would consider this name server to be unresponsive (because it experienced a 100% failure rate), but the autonomic quiescing of unresponsive name servers function would not (because less than 10 requests were directed to the name server). If this query were repeated three times within the 30-second monitoring interval and the total request count and total failure count for this name server was 12 and not 4, then the autonomic quiescing of unresponsive name servers function would consider this name server to be unresponsive because more than 10 queries were directed to the name server.

## Optimizing the UNRESPONSIVETHRESHOLD value for your network

Once every monitoring interval, the resolver calculates the percentage of queries to a name server that failed in the previous 30-seconds or 5 minutes, and then compares this percentage to the threshold value that you set in the UNRESPONSIVETHRESHOLD statement to determine whether that DNS name server is unresponsive. If the resolver sends a query to a name server multiple times and the name server does not respond to multiple queries, each query is considered to be a unique failure to respond. When you specify the UNRESPONSIVETHRESHOLD value, consider the following factors that have an impact on the effectiveness of your setting:

- If you specify a small percentage for this value, an excessive number of operator notifications might occur. Short network disruptions that occur during the 30-second or 5-minute monitoring interval might result in some undeliverable resolver queries or name server responses, and a low threshold value might cause the resolver to alert the operator, and possibly stop using the name server, unnecessarily.
- If you specify a large percentage for this value, persistent issues with the network or the name server might be undetected even though a significant portion of resolver queries are not being processed by the name server.
- The setting on the RESOLVERTIMEOUT statement in the TCPIP.DATA file also affects the value that you should specify for the UNRESPONSIVETHRESHOLD setting. If you set a very short timeout value, even slight network disruptions might cause name server responses to be delayed longer than the amount of time specified by the RESOLVERTIMEOUT value. These delays are considered to be non-responses from the name server, which might cause unnecessary messages to be generated for this name server. A less aggressive (higher) percentage setting for the UNRESPONSIVETHRESHOLD value might be warranted in such a situation.
- The settings of the RESOLVERUDPRETRIES, SEARCH, and NAMESERVER statements in the TCPIP.DATA file can also contribute to high numbers of apparent failures on the part of the name server. See [“Examples of resolver monitoring of DNS name servers” on page 792](#) for information about how these settings can influence the statistics that are collected by the resolver.

**Guideline:** When you set the optimal threshold by determining the error rate for a given name server, determine the error rate before you activate the autonomic quiescing of unresponsive name servers function.

One strategy that you can use to select the most optimal threshold value is to start with the default setting, which is 25%, and determine how many network operator messages are issued, if any, during normal operation of the network.

- If your network is operating in an acceptable manner (for example, no performance issues are detected and no host name or IP address resolutions delays are detected), examine the number of network operator alerts that are generated by the resolver:

- If the number of network operator messages is zero or insignificant, leave the setting at the default value, or even decrease the threshold value slightly.
- If the number of network operator messages is excessive, which suggests that a lot of false negative conditions were detected by the resolver, increase the threshold setting until the number of messages that is generated is appropriate for your network.
- If the name server is now responsive, but the failure rate is just slightly below the threshold value, the name server will probably become unresponsive again with a minor disruption in the network. If your network is currently operating in a satisfactory manner, consider increasing the threshold setting so that the resolver issues EZZ9308E messages only when your network conditions change significantly. Use the statistics that are displayed when message EZZ9309I is issued to modify the threshold setting to a more optimal value.
- If your network is experiencing performance issues that resolver delays might be contributing to (for example, unexplained application delays), consider decreasing the responsiveness threshold setting to determine whether issues with the name servers are being detected by the resolver but are not being reported as unresponsive. If this lower threshold value causes the resolver to generate network operator messages that identify name servers that are unresponsive and that are impacting network operations, consider using this lower value for normal operations to provide more timely identification of name server issues.

A second strategy that you can use to select the most optimal threshold value is to start with the lowest threshold setting, which is 1%. If your name servers are failing to respond to a small percentage of the overall resolver queries that are being sent, the resolver generates EZZ9308E messages. At 5-minute intervals, the resolver also generates EZZ9310I messages, which indicate the percentage of failures for the most recent 5-minute sliding window. Use the EZZ9310I messages to determine the highest failure rate during normal operation of the network, and then set the threshold value to that rate, or to a value slightly above that rate. For example, if the highest failure percentage displayed on the EZZ9310I messages is 4%, set the threshold value to 5% for your network. This value ensures that the resolver considers name servers to be unresponsive only when they experience a failure rate that is greater than the rate that typically occurs in your network.

## Steps for modifying the UNRESPONSIVETHRESHOLD value

You can modify your threshold value and restart or refresh the resolver.

### Before you begin

You must have already created a resolver setup file; see [“Steps for creating a resolver setup file” on page 767](#) for instructions.

### Procedure

Perform the following steps to modify the UNRESPONSIVETHRESHOLD value.

1. Specify the UNRESPONSIVETHRESHOLD value that you want to use in the resolver setup file:
  - To disable the monitoring function, specify UNRESPONSIVETHRESHOLD(0).
  - To notify the network operator, specify UNRESPONSIVETHRESHOLD(*percentage*), where *percentage* is a value in the range 1 - 100. Do not specify the AUTOQUIESCE operand on the UNRESPONSIVETHRESHOLD statement.
  - To automatically quiesce unresponsive name servers, specify UNRESPONSIVETHRESHOLD(*percentage*,AUTOQUIESCE), where *percentage* is a value in the range 1 - 100.

**Rule:** If you do not specify the UNRESPONSIVETHRESHOLD statement in the resolver setup file, the resolver notifies the network operator using the default value, which is 25%.
2. Perform one of the following steps:
  - If the resolver is not active, start the resolver.

- If the resolver is currently active, issue the `MODIFY RESOLVER,REFRESH,SETUP=setup_file_name` command to cause the resolver to use the new threshold setting.

If you did not specify the `AUTOQUIESCE` operand on the `UNRESPONSIVETHRESHOLD` statement, the new *percentage* value is used at the end of the next sliding 5-minute interval to determine name server responsiveness.

If you specified the `AUTOQUIESCE` operand on the `UNRESPONSIVETHRESHOLD` statement, the new *percentage* value is used at the end of the next 30-second interval to determine name server responsiveness.

## Results

You know you are done when the correct `UNRESPONSIVETHRESHOLD` value and `AUTOQUIESCE` values are displayed after you issue the `START` command or the correct values are displayed in the `MODIFY RESOLVER,REFRESH` command output.

## Extension Mechanisms for DNS standards and the resolver

The resolver can use UDP protocols to more efficiently obtain resource information when it uses the Extension Mechanisms for DNS (EDNS0) standards. Before these standards existed, UDP responses from a name server were limited to 512 bytes. If a large number of resource records appear on a DNS response message, more than 512 bytes might be required to return all the response data to the resolver. IPv6 resource records are larger than IPv4 resource records, so fewer IPv6 resource records are needed to reach the 512 byte limitation, but the limitation can be reached even with just IPv4 resource records. EDNS0 support permits the resolver to accept DNS messages, using UDP protocols, of greater than 512 bytes, if the name server that is providing the response message also supports EDNS0.

- If the name server does not support EDNS0, these larger responses are truncated to fit within 512 bytes of UDP packet data, and the resolver resends the request using TCP protocols to acquire the entire response message.
- If the name server does support EDNS0, the resolver accepts up to 3072 bytes of DNS response message data in a single UDP packet.

You do not need to configure support for EDNS0 standards. If the resolver is not certain of the EDNS0 capability of a name server, the resolver does not use EDNS0 for that name server and does not indicate on any query that it sends to the name server that it supports EDNS0 processing. After the resolver dynamically determines that a name server supports EDNS0 processing, the resolver modifies the DNS requests that are sent to the name server to use EDNS0.

The resolver dynamically attempts to determine the EDNS0 capabilities of a name server the first time that the resolver receives a truncated UDP response from the name server; the resolver sends the same query to the name server and includes an indication that it supports EDNS0 processing, which is called an EDNS0 probe. The resolver determines whether the name server supports EDNS0 based on the following possible results from the EDNS0 probe:

- If the name server response to the EDNS0 probe indicates that the name server also supports EDNS0, the resolver uses EDNS0 on all subsequent queries to that name server.
- If the name server response to the EDNS0 probe indicates that the name server does not support EDNS0, the resolver does not use EDNS0 on subsequent queries to that name server.
- If the resolver does not receive a response before the timeout period expires, it does not use EDNS0 on subsequent queries to that name server.

No response can indicate any of the following conditions:

- The `RESOLVETIMEOUT` value was too small for the larger UDP packet to be received in time
- The name server ignored the EDNS0 probe query
- A network router along the path from the name server to the resolver is discarding UDP packets greater than 512 bytes even though the name server and the resolver both support EDNS0

Because the resolver cannot determine why a timeout occurs, it does not use EDNS0 to that name server for a minimum five-minute interval. At the end of that interval, if appropriate, the resolver sends another EDNS0 probe query to determine whether the name server now supports EDNS0. To fully gain EDNS0 performance benefits, you should choose a resolver timeout value that is long enough to allow larger UDP packets to arrive.

The resolver periodically verifies that the name server does not support EDNS0, even if the response to the EDNS0 probe explicitly indicated that the name server does not support EDNS0. The periodic EDNS0 probe processing allows the resolver to dynamically discover that the capabilities of the name server have changed, although the rediscovery period might take some time. You can use the `MODIFY RESOLVER,REFRESH` command to cause the resolver to rediscover the capabilities of the name servers more quickly. For more information about the `MODIFY RESOLVER,REFRESH` command, see [z/OS Communications Server: IP System Administrator's Commands](#).

To verify whether a name server supports EDNS0, use the **dig** command with the `+bufsize=` option to force **dig** to send an OPT RR record on the request. If the name server supports EDNS0, it responds with its own OPT RR record on the response.

If you have upgraded a name server to support EDNS0, you can issue the `MODIFY RESOLVER,REFRESH` command to force the resolver to dynamically determine name server capability. The resolver can then use EDNS0 support to accept DNS messages of greater than 512 bytes, using the less costly UDP protocol, which results in improved DNS and resolver performance.

## Resolver configuration files

---

Understanding the resolver search orders used in native MVS and z/OS UNIX environments is key to setting up your system properly.

The resolver can use available name servers, local definitions, or a combination of both, to process API resolver requests. [Figure 111 on page 797](#) shows how local definitions can be specified and searched for when needed.

Use the Trace Resolver facility to determine what TCPIP.DATA values are being used by the resolver and where they were read from. For information about dynamically starting the trace or using the Resolver CTRACE function to collect Trace Resolver output, see [z/OS Communications Server: IP Diagnosis Guide](#). After the trace is active, issue the `Netstat HOME/-h` command to display the values. You can issue a Ping of a host name from TSO and from the z/OS UNIX shell to show the activity to the resolver cache and to any DNS servers that might be configured.

Figure 111. Resolver related configuration files in z/OS UNIX and native MVS environments

Table 37 on page 798 shows the complete set of local definition possibilities available to the resolver.

Table 37. Local definitions available to resolver

| File type description             | APIs affected                                                                                                                                                                                                                                             | Candidate files                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |

The actual search order of the candidate files varies depending on the type of API that is used and the resolver setup. The search orders are explained in more detail in [“Search orders used in the z/OS UNIX environment”](#) on page 803 and [“Search orders used in the native MVS environment”](#) on page 808. Because the resolver runs in the address space of the application, the resolver accesses the candidate files from the application address space.

Use the Trace Resolver facility to obtain information about an application's search order. Trace Resolver output provides a caller API value that determines which search order is used. For information about dynamically starting the trace or using the Resolver CTRACE function to collect Trace Resolver output, see [z/OS Communications Server: IP Diagnosis Guide](#).

The following caller API values indicate the z/OS UNIX environment search order is used:

- Language Environment C Sockets
- UNIX System Services [z/OS UNIX System Services (z/OS UNIX) callable services]

The following caller API values indicate the native MVS environment search order is used:

- TCP/IP C Sockets
- TCP/IP Pascal Sockets
- TCP/IP Rexx Sockets
- TCP/IP Sockets Extended

The following commands are some examples of Communications Server TSO commands that use the native MVS search order:

- DIG
- FTP (batch only)

**Rule:** Batch FTP jobs use //SYSTCPD if it is specified. If //SYSTCPD is not specified, then the z/OS UNIX search order is used.

- LPR
- NETSTAT
- NSLOOKUP
- PING
- REXEC
- RPCINFO
- RSH
- TRACERTE

The following commands are some examples of Communications Server UNIX commands that use the z/OS UNIX search order:

- **dig**
- **dnsdomainname**
- **domainname**
- **ftp**

**Rule:** The TSO FTP command also uses the z/OS UNIX search order.

- **host**
- **hostname**
- **netstat**
- **nslookup**
- **ping**
- **rexec**
- **rpcinfo**
- **snmp**
- **traceroute**

The following applications are some examples of Communications Server applications that use the native MVS search order:

- CICS Listener
- LPD
- Miscellaneous server
- PORTMAP
- RSHD
- TN3270E Telnet server

The following applications are some examples of Communications Server applications that use the z/OS UNIX search order:

- CSSMTP
- FTP
- SNMP agent
- z/OS UNIX OPORTMAP
- z/OS UNIX OREXECD
- z/OS UNIX ORSHD

## z/OS XL C/C++ environment variables for configuration files

A z/OS XL C/C++ environment variable is an identifier used like a variable in a program. In [Table 37 on page 798](#), the following environment variables appear:

### HOSTALIASES

The host aliases data set, file, or ddname.

### RESOLVER\_CONFIG

The resolver configuration data set, file, or ddname. The RESOLVER\_CONFIG environment variable is used by TCP/IP to include the name of an MVS data set or z/OS UNIX file in the search order for TCPIP.DATA.

### RESOLVER\_IPNODES

The IPNODES data set, file, or ddname.

### X\_SITE and X\_ADDR

The HOSTS.SITEINFO and HOSTS.ADDRINFO data sets or ddnames created by the MAKESITE TSO command. The X\_SITE environment variable influences how `gethostbyname()` resolves the network address of the specified host name. The X\_ADDR environment variable is used by some TCP/IP functions, such as `getnetbyaddr()`, to include the name of an MVS data set or z/OS UNIX file in the search order for the HOSTS.ADDRINFO data set.

### X\_XLATE

The ASCII-EBCDIC translate table data set or ddname created by the CONVXLAT TSO command. The X\_XLATE environment variable is used by TCP/IP to include the name of an MVS data set or z/OS UNIX file in the search order for the STANDARD.TCPXLBIN data set.

Other environment variables that can be explicitly set by the resolver include the following variables:

### LOCALDOMAIN

Defines the domain origin. When this environment variable is set, it overrides any setting for DOMAIN, DOMAINORIGIN, or SEARCH found in TCPIP.DATA

### RESOLVER\_TRACE

Defines the data set, file, or ddname into which the resolver trace output is written.

### MESSAGECASE

Determines whether messages are translated to all uppercase characters before being sent to the console.

**Restriction:** For IBM z/OS Container Platform environments, RESOLVER\_TRACE is the only valid environment variable. All other environment variables are ignored.

## Setting z/OS XL C/C++ environment variables

The method that you use to set z/OS XL C/C++ environment variables so that a z/OS XL C/C++ UNIX application is able to retrieve the value depends on whether you start the application from the z/OS shell or from JCL. The following general methods apply to all environmental variables; the examples are specific to the RESOLVER\_CONFIG environmental variable.

### Setting z/OS XL C/C++ environment variables from the z/OS shell

If you are starting the z/OS XL C/C++ UNIX application from the z/OS shell, you must set the environment variables using the **export** shell command. You can specify either the file name or the data set name, as shown in the following two examples for setting the RESOLVER\_CONFIG environment variable:

- To set the value of the RESOLVER\_CONFIG environment variable to the file name `/etc/tpca.data`, specify the following **export** command:

```
export RESOLVER_CONFIG=/etc/tpca.data
```

- To set the RESOLVER\_CONFIG environment variable to the data set TCPA.MYFILE(TCPDATA), specify the following **export** command.

```
export RESOLVER_CONFIG="//'TCPA.MYFILE(TCPDATA)'"
```

**Rule:** You must put single quotation marks around the data set name. If you do not, your user ID will be added as a prefix to the data set name when the resolver tries to open the file.

### Setting z/OS XL C/C++ environment variables from JCL

If you are starting the z/OS XL C/C++ UNIX application from JCL, you must code the environment variable as a parameter in the JCL of the application, as shown in the following examples:

- This example shows setting the RESOLVER\_CONFIG environment variable to a z/OS UNIX file:

```
//OSNMPD PROC
//*
//* Procedure for running the SNMP agent
//*
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("RESOLVER_CONFIG=/etc/tcpa.data")/-d 0')
:
```

- This example shows setting the RESOLVER\_CONFIG environment variable to an MVS partitioned data set:

```
//OSNMPD PROC
//*
//* Procedure for running the SNMP agent
//*
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("RESOLVER_CONFIG="//'TCPA.MYFILE(TCPDATA)'"")/-d 0')
:
```

- This example shows setting the RESOLVER\_CONFIG environment variable to a DD card:

```
//OSNMPD PROC
//*
//* Procedure for running the SNMP agent
//*
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("RESOLVER_CONFIG=DD:TCPDATA")/-d 0')
//TCPDATA DD DSN=TCPA.MYFILE(TCPDATA),DISP=SHR
:
```

**Tip:** You can also specify a ddname as //DD:ddname, as shown in the following example:

```
:
// 'ENVAR("RESOLVER_CONFIG="//DD:TCPDATA")/-d 0')
```

For more information about specifying a ddname, see [z/OS XL C/C++ Programming Guide](#).

- This example shows how you can set environment variables using the STDENV DD statement. The environment variables will be read from the location specified by the STDENV DD statement. The advantage of using STDENV is that it eliminates any concern about the maximum number of characters that can be specified on the PARM= parameter of the EXEC JCL statement. Perform the following steps to set environment variables using the STDENV DD statement:

1. Create the MVS data set that will contain the environment variables with a variable length record format (RECFM=V/VB).

This example uses an MVS data set TCPA.ENVAR(OSNMPD).

**Rule:** Do not use fixed length record format (RECFM=F/FB) to allocate the MVS data set because fixed length pads the environment variables with blanks.

2. Edit the MVS data set so that it contains the environment variables.

The following example shows setting the RESOLVER\_CONFIG environment variable to a file:

```
RESOLVER_CONFIG=/etc/tcpa.data
```

The following example shows setting the RESOLVER\_CONFIG environment variable to an MVS data set:

```
RESOLVER_CONFIG=// 'TCPA.MYFILE(TCPDATA) '
```

3. Update the application's JCL to pick up the TCPIP.DATA information from the specified RESOLVER\_CONFIG environment variable.

```
//OSNMPD PROC
// *
// * Procedure for running the SNMP agent
// *
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,
// PARM=('POSIX(ON) ALL31(ON) ',
// 'ENVAR("_CEE_ENVFILE=DD:STDENV")/-d 0')
//STDENV DD DSN=TCPA.ENVAR(OSNMPD),DISP=SHR
```

For more information about specifying a list of environment variables using the \_CEE\_ENVFILE environment variable, see [z/OS XL C/C++ Programming Guide](#).

## Search orders used in the z/OS UNIX environment

This information describes the search orders used in the z/OS UNIX environment for the different file types shown in Table 37 on [page 798](#). The z/OS UNIX socket functions use various types of TCP/IP data sets and files. They include:

- Base resolver configuration files
- Translate tables
- Local host tables
- Protocol information
- Services information
- Host alias table

The particular file or table chosen can be either an MVS data set or z/OS UNIX file, depending on the resolver configuration settings and the presence of given files on the system.

**Note:** A program's first resolver service request initializes the resolver definitions that will be used for all resolver requests. For long running programs, the definitions can be modified by use of the MODIFY REFRESH operator command. For command usage and syntax, see [z/OS Communications Server: IP System Administrator's Commands](#).

### Base resolver configuration files

The base resolver configuration file contains TCPIP.DATA statements. In addition to resolver directives, it is referenced to determine, among other things, the data set prefix (DATASETPREFIX statement's value) to be used when trying to access some of the configuration files.

The search order used to access the base resolver configuration file is as follows:

1. GLOBALTCPIPDATA

If defined, the resolver GLOBALTCPIPDATA setup statement value is used. For a description of the GLOBALTCPIPDATA statement, see [“The resolver and the global TCPIP.DATA file” on page 766](#).

The search continues for an additional configuration file. The search ends with the next file found.

2. The value of the environment variable RESOLVER\_CONFIG

The value of the environment variable is used. This search will fail if the file does not exist or is allocated exclusively elsewhere.

3. /etc/resolv.conf

4. //SYSTCPD DD card

The data set allocated to the ddname SYSTCPD is used. In the z/OS UNIX environment, a child process does not have access to the SYSTCPD DD. This is because the SYSTCPD allocation is not inherited from the parent process over the fork() or exec function calls.

5. *userid*.TCPIP.DATA

*userid* is the user ID that is associated with the current security environment (address space or task/thread)

6. SYS1.TCPPARMS(TCPDATA)

7. DEFAULTTCPIPDATA

If defined, the resolver DEFAULTTCPIPDATA setup statement value is used. For a description of the DEFAULTTCPIPDATA statement, see [“The resolver and the global TCPIP.DATA file” on page 766](#).

8. TCPIP.TCPIP.DATA

Any TCPIP.DATA statements that have not been found will have their default values, if any, assigned.

**Restriction:** For IBM z/OS Container Platform environments, the search order to find the resolver configuration file is ignored. The z/OS UNIX files '/etc/resolv.conf' and '/etc/nsswitch.conf' in the container's filesystem namespace are used.

## Translate tables

The translate tables (EBCDIC-to-ASCII and ASCII-to-EBCDIC) are referenced to determine the translate data sets to be used.

**Restriction:** For IBM z/OS Container Platform environments, the search order to find the translation tables is ignored. The hardcoded default table that is identical to the STANDARD member in the SEZATCPX data set is used.

The search order that is used to access this configuration file is as follows. The search order ends at the first file found:

1. The value of the environment variable X\_XLATE

The value of the environment variable is the name of the translate table that is produced by the CONVXLAT TSO command.

2. *userid*.STANDARD.TCPXLBIN

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

3. *hlq*.STANDARD.TCPXLBIN

*hlq* represents the value of the DATASETPREFIX statement that is specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

4. If no table is found, the resolver uses a hardcoded default table that is identical to the STANDARD member in the SEZATCPX data set.

**Tip:** You can use a JCL DD statement to preallocate the STANDARD.TCPXLBIN data set and prevent the resolver from dynamically allocating it. The name on the DD statement can be any valid ddname. Preallocation prevents the dynamic allocation messages (for example, IEF237I and IEF285I) from being written to the job output log.

## Local host tables

By default, resolver first attempts to use any configured domain name servers for resolution requests. If the resolution request cannot be satisfied, local host tables are used. Resolver behavior is controlled by the following factors:

- TCPIP.DATA statements

The TCPIP.DATA resolver statements define if and how domain name servers are to be used. The LOOKUP TCPIP.DATA statement can also be used to control how domain name servers and local host tables are used. For more information on TCPIP.DATA statements, see [z/OS Communications Server: IP Configuration Reference](#).

**Note:** For IBM z/OS Container Platform environments, the HOSTS statement in the z/OS UNIX file ‘/etc/nsswitch.conf’ in the z/OS Container’s filesystem namespace can be used to control how domain name servers and local host tables are used.

- How your application is written and compiled

If your application program uses the TCP/IP-provided C/C++ API and the XL C/C++ RESOLVE\_VIA\_LOOKUP symbol was defined, only local host tables will be used. For information on the use of the RESOLVE\_VIA\_LOOKUP symbol, see [z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference](#) and [z/OS XL C/C++ Programming Guide](#).

The local host table supplies sitename information for, as one example, resolving hostnames to host or network addresses. The local host table can also supply address information, for example, for resolving addresses to hostname or network names. There are different search orders used for selecting the local host table for these different purposes. The search order to use is based on certain resolver setup statements, the type of API invocation, and possibly the type of host address (IPv4 versus IPv6) being requested or being resolved.

### ***IPv4-unique search order for sitename information***

The resolver uses the IPv4-unique search order for sitename information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the:

- getaddrinfo API is attempting to locate an IPv4 address.
- gethostbyname, sethostent, gethostent, or endhostent API is invoked.

If the COMMONSEARCH statement is specified, see [“IPv6/common search order” on page 806](#), where the resolver can use IPNODES to locate sitenames.

The resolver uses the IPv4-unique search order for sitename information unconditionally for getnetbyname API calls.

The IPv4-unique search order for sitename information is as follows. The search ends at the first file found:

1. The value of the environment variable X\_SITE

The value of the environment variable is the name of the MVS data set that contains the sitename information. This data set is created by the TSO MAKESITE command.

2. /etc/hosts

3. *userid*.HOSTS.SITEINFO

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

4. *hlq*.HOSTS.SITEINFO

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

### ***IPv4-unique search order for address information***

The resolver uses the IPv4-unique search order for address information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the getnameinfo API is attempting to resolve an IPv4 address or the gethostbyaddr API is invoked. If the COMMONSEARCH statement is specified, see [“IPv6/common search order” on page 806](#), where the resolver can use IPNODES to locate IPv4 and IPv6 addresses.

The resolver uses the IPv4-unique search order for address information unconditionally for the setnetent, getnetent, endnetent, or getnetbyaddr APIs.

The IPv4-unique search order for address information is as follows. The search ends at the first file found:

1. The value of the environment variable `X_ADDR`

The value of the environment variable is the name of the MVS data set that contains the address information. This data set is created by the TSO MAKESITE command.

2. `/etc/hosts`

3. `userid.HOSTS.ADDRINFO`

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

4. `hlq.HOSTS.ADDRINFO`

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

### **IPv6/common search order**

The resolver uses the IPv6/common search order when it determines that any of the following conditions exist:

- The resolver setup statement COMMONSEARCH is specified (to have the resolver use IPNODES to locate IPv4 addresses, IPv6 addresses, and sitenames), and the `getaddrinfo`, `gethostbyname`, `getnameinfo`, `gethostbyaddr`, `sethostent`, `gethostent`, or `endhostent` APIs are invoked.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the `getaddrinfo` API is attempting to locate an IPv6 address.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the `getnameinfo` API is attempting to resolve an IPv6 address.

**Note:** The IPv6/common search order is never used for the following API socket calls:

- `getnetbyname`
- `getnetbyaddr`
- `setnetent`
- `getnetent`
- `endnetent`

The IPv6/common search order is as follows. The search ends at the first file found:

1. GLOBALIPNODES value

If defined, the resolver GLOBALIPNODES setup statement value is used. For a description of the GLOBALIPNODES statement, see [“The resolver setup file” on page 763](#).

2. The value of the environment variable `RESOLVER_IPNODES`

3. `userid.ETC.IPNODES`

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

4. `hlq.ETC.IPNODES`

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

5. DEFAULTIPNODES

If defined, the resolver DEFAULTIPNODES setup statement value is used. For a description of the DEFAULTIPNODES statement, see [“The resolver setup file” on page 763](#).

6. `/etc/ipnodes`

## ***IPv4 and IPv6 search order for IBM z/OS Container Platform environments***

The resolver uses the z/OS UNIX file ‘/etc/hosts’ in the container’s filesystem namespace to locate IPv4 addresses, IPv6 addresses and hostnames. The search ends if the ‘/etc/hosts’ file is not found in the container’s filesystem.

**Note:** The resolver setup statement NOCOMMONSEARCH/COMMONSEARCH is not used for IBM z/OS Container Platform environments.

This local hosts file is used when the following API socket calls are invoked from within an IBM z/OS Container Platform environment:

- getaddrinfo()
- gethostbyname()
- getnameinfo()
- gethostbyaddr()
- sethostent()
- gethostent()
- endhostent()

This local hosts file is not used when the following API socket calls are invoked from within an IBM z/OS Container Platform environment:

- getnetbyname()
- getnetbyaddr()
- setnetent()
- getnetent()
- endnetent()

## **Protocol information**

The protocol information supplies protocol related information for the socket calls listed in [Table 37 on page 798](#).

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. /etc/protocol
2. *userid*.ETC.PROTO

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

3. *hlq*.ETC.PROTO

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCP/IP by default.

**Restriction:** For IBM z/OS Container Platform environments, the search order to find the resolver configuration file containing the protocol information is ignored. The z/OS UNIX file ‘/etc/protocol’ in the container’s filesystem namespace is used.

## **Services information**

The services information supplies the service information for the socket calls listed in [Table 37 on page 798](#).

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. /etc/services
2. *userid*.ETC.SERVICES

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

### 3. *hlq*.ETC.SERVICES

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCPIP by default.

**Restriction:** For IBM z/OS Container Platform environments, the search order to find the resolver configuration file containing service information is ignored. The z/OS UNIX file '/etc/services' in the container's filesystem namespace is used.

## Host alias table

The host alias table supplies hostname alias information for the socket calls listed in Table 37 on page 798. The format of the alias information is the alias name, followed by a space, followed by the fully qualified domain name that corresponds to the alias name. The domain name is written without a trailing dot, and the alias name cannot contain dots. The search order used to access this configuration file consists only of the value of the environment variable HOSTALIASES.

**Restriction:** For IBM z/OS Container Platform environments, the HOSTALIASES environment variable is ignored.

## Search orders used in the native MVS environment

The native MVS environment socket functions use various type of TCP/IP data sets, including:

- Base resolver configuration files
- Translate tables
- Local host tables
- Protocol information
- Services information

The particular file or table chosen depends on the resolver configuration settings and the presence of given files on the system.

**Note:** A program's first resolver service request initializes the resolver definitions that will be used for all resolver requests. For long running programs, the definitions can be modified by use of the MODIFY REFRESH operator command. For command usage and syntax, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Base resolver configuration files

The base resolver configuration file contains TCPIP.DATA statements. In addition to resolver directives, it is referenced to determine, among other things, the data set prefix (DATASETPREFIX statement's value) to be used when trying to access some of the configuration files.

The search order used to access the base resolver configuration file is as follows:

### 1. GLOBALTCPIPDATA.

If defined, the resolver GLOBALTCPIPDATA setup statement value is used. For a description of the GLOBALTCPIPDATA statement, see [“The resolver and the global TCPIP.DATA file” on page 766](#).

The search continues for an additional configuration file. The search ends with the next file found.

### 2. //SYSTCPD DD card

The data set allocated to the ddname SYSTCPD is used.

**Rule:** Because TCPIP.DATA statements might need to be read and used multiple times by the resolver, the FREE=CLOSE JCL parameter should not be used when allocating SYSTCPD. To allow TCPIP.DATA statements to be changed while still allocated for long running programs, consider using a member of an MVS partitioned data set instead of an MVS sequential data set. For these long running applications,

the resolver MODIFY REFRESH command should then be used to indicate that TCPIP.DATA statements have been changed.

3. *userid/jobname*.TCPIP.DATA

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

*jobname* is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

4. SYS1.TCPPARMS(TCPDATA)

5. DEFAULTTCPIPDATA

If defined, the resolver DEFAULTTCPIPDATA setup statement value is used. For a description of the DEFAULTTCPIPDATA statement, see [“The resolver and the global TCPIP.DATA file” on page 766](#).

6. TCPIP.TCPIP.DATA

## Translate tables

The translate tables are referenced to determine the translate data sets to be used.

The search order that is used to access this configuration file is as follows. The search order ends at the first file found:

1. *userid/jobname*.STANDARD.TCPXLBIN

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

*jobname* is the name that is specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

2. *hlq*.STANDARD.TCPXLBIN

*hlq* represents the value of the DATASETPREFIX statement that is specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

3. If no table is found, the resolver uses a hardcoded default table that is identical to the STANDARD member in the SEZATCPX data set.

**Tip:** You can use a JCL DD statement to preallocate the STANDARD.TCPXLBIN data set and prevent the resolver from dynamically allocating it. The name on the DD statement can be any valid ddname. Preallocation prevents the dynamic allocation messages (for example, IEF237I and IEF285I) from being written to the job output log.

## Local host tables

By default, resolver first attempts to use any configured domain name servers for resolution requests. If the resolution request cannot be satisfied, local host tables are used. Resolver behavior is controlled by the following factors:

- TCPIP.DATA statements

The TCPIP.DATA resolver statements define if and how domain name servers are to be used. The LOOKUP TCPIP.DATA statement can also be used to control how domain name servers and local host tables are used. For more information on TCPIP.DATA statements, see [z/OS Communications Server: IP Configuration Reference](#).

- How your application is written and compiled

If your application program uses the TCP/IP-provided C/C++ API and the RESOLVE\_VIA\_LOOKUP symbol was defined, only local host tables will be used. For information on the use of the RESOLVE\_VIA\_LOOKUP symbol, see [z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference](#).

The local host table supplies sitename information for, as one example, resolving hostnames to host or network addresses. The local host table can also supply address information, for example, for resolving addresses to hostname or network names. There are different search orders used for selecting the local host table for these different purposes. The search order to use is based on certain resolver setup statements, the type of API invocation, and possibly the type of host address (IPv4 versus IPv6) being requested or being resolved.

### ***IPv4-unique search order for sitename information***

The resolver uses the IPv4-unique search order for sitename information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the:

- getaddrinfo API is attempting to locate an IPv4 address.
- gethostbyname, GetHostNumber, GetHostResol, IsLocalHost, Resolve, sethostent, gethostent, or endhostent API is invoked.

If the COMMONSEARCH statement is specified, see [“IPv6/common search order” on page 811](#), where the resolver can use IPNODES to locate sitenames.

The resolver uses the IPv4-unique search order for sitename information unconditionally for getnetbyname API calls.

The IPv4-unique search order for sitename information is as follows. The search ends at the first file found:

1. *userid/jobname*.HOSTS.SITEINFO

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

*jobname* is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

2. *hlq*.HOSTS.SITEINFO

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

### ***IPv4-unique search order for address information***

The resolver uses the IPv4-unique search order for address information when the resolver setup statement NOCOMMONSEARCH is specified (or left to default), and either the getnameinfo API is attempting to resolve an IPv4 address or the gethostbyaddr or GetHostString API is invoked. If the COMMONSEARCH statement is specified, see [“IPv6/common search order” on page 811](#), where the resolver can use IPNODES to locate IPv4 and IPv6 addresses.

The resolver uses the IPv4-unique search order for address information unconditionally for the setnetent, getnetent, endnetent, or getnetbyaddr APIs.

The IPv4-unique search order for address information is as follows. The search ends at the first file found:

1. *userid/jobname*.HOSTS.ADDRINFO

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

*jobname* is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

2. *hlq*.HOSTS.ADDRINFO

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

## IPv6/common search order

The resolver uses the IPv6/common search order when it determines that any of the following conditions exist:

- The resolver setup statement COMMONSEARCH is specified (to have the resolver use IPNODES to locate IPv4 addresses, IPv6 addresses, and sitenames), and the getaddrinfo, gethostbyname, getnameinfo, gethostbyaddr, GetHostNumber, GetHostResol, GetHostString, IsLocalHost, Resolve, sethostent, gethostent, or endhostent APIs are invoked.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getaddrinfo API is attempting to locate an IPv6 address.
- The resolver setup statement NOCOMMONSEARCH is specified (or left to default), and the getnameinfo or Resolve API is attempting to resolve an IPv6 address.

**Note:** The IPv6/common search order is never used for the following API socket calls:

- getnetbyname
- getnetbyaddr
- setnetent
- getnetent
- endnetent

The IPv6/common search order is as follows. The search ends at the first file found:

1. GLOBALIPNODES value

If defined, the resolver GLOBALIPNODES setup statement value is used. For a description of the GLOBALIPNODES statement, see [“The resolver setup file” on page 763](#).

2. *userid/jobname*.ETC.IPNODES

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

*jobname* is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

3. *hlq*.ETC.IPNODES

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); otherwise, *hlq* is TCPIP by default.

4. DEFAULTIPNODES

If defined, the resolver DEFAULTIPNODES setup statement value is used. For a description of the DEFAULTIPNODES statement, see [“The resolver setup file” on page 763](#).

5. /etc/ipnodes

## Protocol information

The protocol information supplies protocol related information for the socket calls listed in [Table 37 on page 798](#).

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. *userid/jobname*.ETC.PROTO

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

*jobname* is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

2. *hlq*.ETC.PROTO

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCP/IP by default.

## Services information

The services information supplies service information for the socket calls listed in [Table 37 on page 798](#).

The search order used to access this configuration file is as follows. The search ends at the first file found:

1. //SERVICES DD card

The data set allocated to the ddname SERVICES is used.

2. *userid/jobname*.ETC.SERVICES

*userid* is the user ID that is associated with the current security environment (address space or task/thread).

*jobname* is the name specified on the JOB JCL statement for batch jobs or the procedure name for a started procedure.

3. *hlq*.ETC.SERVICES

*hlq* represents the value of the DATASETPREFIX statement specified in the base resolver configuration file (if found); Otherwise, *hlq* is TCP/IP by default.

---

## Chapter 14. Policy-based networking

Businesses typically define goals for network behavior in human terms. Network implementations provide a variety of application-transparent controls for priority treatment of traffic, bandwidth management, security, and control of network behavior. The link between the high-level business goals and network implementations is defined as policy-based networking and is provided by policies. Policies are usually defined in a centralized repository and are accessed by nodes that need to make policy decisions (Policy Decision Point, or PDP) or implement such decisions (Policy Enforcement Point, or PEP).

---

### Policy types and infrastructure overview

To implement networking policies for your users, you must use the z/OS Communications Server policy infrastructure. You can use the policy types supported by the Policy Agent for any of the following purposes:

- Policy-based routing (See [“Policy-based routing”](#) on page 377)
- Quality of service (See [Chapter 15, “Quality of service,”](#) on page 857)
- Intrusion detection services (See [Chapter 16, “Intrusion detection services,”](#) on page 877)
- IP filtering, and manual and dynamic virtual private network (VPN) tunnels, collectively referred to as IPSec policies (See [Chapter 17, “IP security,”](#) on page 911)
- Application Transparent Transport Layer Security (AT-TLS, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149)
- zERT policy-based enforcement (ZERT, see [“Defining a zERT enforcement policy”](#) on page 198)

For more information about the policy types, see [“Policy types”](#) on page 827.

Based on the policy types that you want to implement, you must configure and start one or more policy infrastructure components:

- TCP/IP stack

TCP/IP stacks implement most of the policy types. You need to start one or more stacks per logical partition (LPAR).

- Syslog daemon (syslogd)

Syslogd acts as the central message logging facility for z/OS UNIX applications. Syslogd is not specific to the policy infrastructure, but the policy infrastructure depends on syslogd to provide a central logging facility to maintain an audit trail. If you do not start syslogd, messages are lost. You should start one syslog daemon per LPAR.

- Policy Agent

You must start Policy Agent to install and maintain policies in the TCP/IP stacks in an LPAR. You need one Policy Agent per LPAR.

- Traffic regulation management daemon (TRMD)

TRMD formats and sends policy-related messages to your syslog daemon. You need one TRMD per TCP/IP stack in an LPAR.

- Internet Key Exchange daemon (IKED)

IKED is used for negotiating and setting up dynamic VPN tunnels. If you are not using dynamic VPN tunnels, you do not need to start IKED; otherwise, you need one IKED per LPAR.

- Network security services daemon (NSSD)

NSSD can be used as the central certificate and key server for z/OS IKE daemons, or as a network security server for selected non-z/OS platforms. NSSD can be used independently of any z/OS

networking policies, but is an element of the overall z/OS networking policy infrastructure. Typically, you do not need an NSSD on every LPAR; one NSSD per sysplex is more likely.

- Defense Manager daemon (DMD)

DMD provides support for short-term defensive filters. You can use DMD without defining any IPSec filter policies, but typically you use DMD in addition to IPSec filter policy. You need one DMD per LPAR.

- Network service level agreement performance monitor 2 (NSLAPM2)

NSLAPM2 is an SNMP subagent that provides QoS metrics through MIB variables. You need one NSLAPM2 per TCP/IP stack in an LPAR.

For more information about syslogd, see “Configuring the syslog daemon” on page 235. For more information about the other policy infrastructure components, see “Policy infrastructure components” on page 819.

To determine the policy infrastructure components that you need to start based on which policy types you are implementing, see [Table 38 on page 814](#).

| <i>Table 38. Policy components needed per policy type</i> |                                |                       |          |                         |                                               |          |                                          |          |
|-----------------------------------------------------------|--------------------------------|-----------------------|----------|-------------------------|-----------------------------------------------|----------|------------------------------------------|----------|
| Policy type                                               | Component                      |                       |          |                         |                                               |          |                                          |          |
|                                                           | One or more instances per LPAR | One instance per LPAR |          |                         |                                               |          | One instance per TCP/IP stack in an LPAR |          |
|                                                           | TCP/IP stack                   | Policy Agent          | syslogd  | IKED                    | NSSD                                          | DMD      | NSLAPM2                                  | TRMD     |
| QoS                                                       | Required                       | Required              | Required |                         |                                               |          | Optional                                 |          |
| IDS                                                       | Required                       | Required              | Required |                         |                                               |          |                                          | Required |
| AT-TLS                                                    | Required                       | Required              | Required |                         |                                               |          |                                          |          |
| IPSec filters                                             | Required                       | Required              | Required |                         |                                               | Optional |                                          | Required |
| IPSec VPNs                                                | Required                       | Required              | Required | Optional (dynamic VPNs) | Optional (central key and certificate server) |          |                                          | Required |
| Policy-based routing                                      | Required                       | Required              | Required |                         |                                               |          |                                          |          |
| zERT policy-based enforcement                             | Required                       | Required              | Required |                         |                                               |          |                                          | Required |

You can use the IBM Configuration Assistant for z/OS Communications Server for assistance with setting up and configuring security, JCL procedures, and configuration files for the following policy infrastructure components:

- Policy Agent, including policy definition files for QoS, IDS, AT-TLS, IPSec, policy-based routing, and zERT policy-based enforcement
- IKED

- NSSD
- DMD

## Configuration files and policy definition files

To operate correctly, the policy infrastructure depends on various configuration files and policy definitions files.

The IBM Configuration Assistant for z/OS Communications Server enables flat-file configuration of all supported policy types for z/OS. The IBM Configuration Assistant for z/OS Communications Server is an optional GUI-based tool that provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Table 39 on page 815 lists the policy-related configuration and definition files, whether the files can be created using the IBM Configuration Assistant for z/OS Communications Server, and the default location of the configuration files. You can manually edit all files listed in Table 39 on page 815.

| <i>Table 39. Configuration files and policy definition files</i> |                                                                                          |                              |
|------------------------------------------------------------------|------------------------------------------------------------------------------------------|------------------------------|
| <b>Configuration file or policy definition file</b>              | <b>Can be created by the IBM Configuration Assistant for z/OS Communications Server?</b> | <b>Default z/OS location</b> |
| Configuration files                                              |                                                                                          |                              |
| Policy agent                                                     | Yes                                                                                      | /etc/pagent.conf             |
| syslogd                                                          | No                                                                                       | /etc/syslog.conf             |
| DMD                                                              | Yes                                                                                      | /etc/security/dmd.conf       |
| IKED                                                             | Yes                                                                                      | /etc/security/iked.conf      |
| NSSD                                                             | Yes                                                                                      | /etc/security/nssd.conf      |
| Policy definition files                                          |                                                                                          |                              |
| QoS                                                              | Yes                                                                                      | None                         |
| IDS                                                              | Yes                                                                                      | None                         |
| AT-TLS                                                           | Yes                                                                                      | None                         |
| IPSec                                                            | Yes                                                                                      | None                         |
| Policy-based routing                                             | Yes                                                                                      | None                         |
| zERT policy-based enforcement                                    | Yes                                                                                      | None                         |

## Managing changes to configuration files and policy definition files

Typically, you use a change management procedure when you install a set of new or changed policies, or when you modify the configuration files for the Policy Agent or other policy-related applications. A structure for storing and maintaining the configuration files and policy definition files that are related to the general policy infrastructure is provided by the IBM Configuration Assistant for z/OS Communications Server, and you can use it to manually create and edit the configuration files and policy definition files. The structure is based on three location levels:

- Staging

The staging level is the location in which you manually edit your definitions, or into which you upload definitions from the IBM Configuration Assistant for z/OS Communications Server.

- Production

The production level is the location to which you copy your staging definitions when you are ready to put your changes into production. This is the location from which your Policy Agent and other policy infrastructure components read their definitions.

- Backup and recovery

The backup and recovery level is the location to which you copy your existing production definitions before you copy your staging definitions to your production location. If the changes are in error, you can back out the changes by copying your original production definitions from the recovery location to the production location and restarting your policy infrastructure components.

## Storing configuration files and policy definition files

You can store configuration files and policy definition files in the z/OS UNIX file system or in traditional MVS data sets.

Some definitions are shared by all TCP/IP stacks on a z/OS image, and some definitions are specific to individual TCP/IP stacks on a z/OS image.

For example, if you are using the z/OS UNIX file system to store your configuration files and policy definition files, a directory structure for z/OS image SYSA with TCP/IP stacks TCPIP1 and TCPIP2 might look as follows:

- Staging

### **Image-wide**

/etc/tcpip/POLTRANS/SYSA/

### **TCPIP1**

/etc/tcpip/POLTRANS/SYSA/TCPIP1/

### **TCPIP2**

/etc/tcpip/POLTRANS/SYSA/TCPIP2/

- Production

### **Image-wide**

/etc/tcpip/POLPROD/SYSA/

### **TCPIP1**

/etc/tcpip/POLPROD/SYSA/TCPIP1/

### **TCPIP2**

/etc/tcpip/POLPROD/SYSA/TCPIP2/

- Backup and recovery

### **Image-wide**

/etc/tcpip/POLBACK/SYSA/

### **TCPIP1**

/etc/tcpip/POLBACK/SYSA/TCPIP1/

### **TCPIP2**

/etc/tcpip/POLBACK/SYSA/TCPIP2/

Similarly, you can use MVS partitioned data set (PDS) or partitioned data set extended (PDSE) libraries to store the configuration files and policy definition files as follows:

- Staging

### **Image-wide**

hlq.TCPPARMS.POLTRANS.SYSA

**TCPIP1***hlq.TCPPARMS.POLTRANS.SYSA.TCPIP1***TCPIP2***hlq.TCPPARMS.POLTRANS.SYSA.TCPIP2*

- Production

**Image-wide***hlq.TCPPARMS.POLPROD.SYSA***TCPIP1***hlq.TCPPARMS.POLPROD.SYSA.TCPIP1***TCPIP2***hlq.TCPPARMS.POLPROD.SYSA.TCPIP2*

- Backup and recovery

**Image-wide***hlq.TCPPARMS.POLBACK.SYSA***TCPIP1***hlq.TCPPARMS.POLBACK.SYSA.TCPIP1***TCPIP2***hlq.TCPPARMS.POLBACK.SYSA.TCPIP2*

You can maintain a number of members in each of these libraries, using your own naming convention or the following suggested naming convention:

- LPAR-wide configuration files
  - CONF (configuration file)
- Stack-specific configuration and policy definition files
  - TLSPOL (AT-TLS policy definitions)
  - IDSPOL (IDS policy definitions)
  - IPSPOL (IPSec policy definitions)
  - QOSPOL (QoS policy definitions)
  - PBRPOL (Policy-based routing policy definitions)
  - ZERTPOL (zERT policy-based enforcement policy definitions)

The following example shows the IKE daemon configuration file and the IPSec policy definitions for stack TCPIP1 as members of PDS or PDSE libraries:

```
USER.LPAR1.POLTRANS.SYSA.IKED(CONF)
USER.LPAR1.POLTRANS.SYSA.TCPIP1(IPSPOL)
```

## Steps for managing policy changes

Place your new policy flat file in the staging library, back up your current production policy flat file, and then replace the production copy with the new copy.

### Procedure

As shown in [Figure 112 on page 818](#), perform the following steps to activate changes to your policies:

1. Transfer the policy flat file to the staging library. *hlq.TCPPARMS.POLTRANS.SYSA.TCPIP1(xyz)*
2. Back up the current production policy flat file.
  - Copy *hlq.TCPPARMS.POLPROD.SYSA.TCPIP1(xyz)* to *hlq.TCPPARMS.POLBACK.SYSA.TCPIP1(xyz)*
3. Copy the new policy flat file into production.
  - Copy *hlq.TCPPARMS.POLTRANS.SYSA.TCPIP1(xyz)* to *hlq.TCPPARMS.POLPROD.SYSA.TCPIP1(xyz)*

## Results

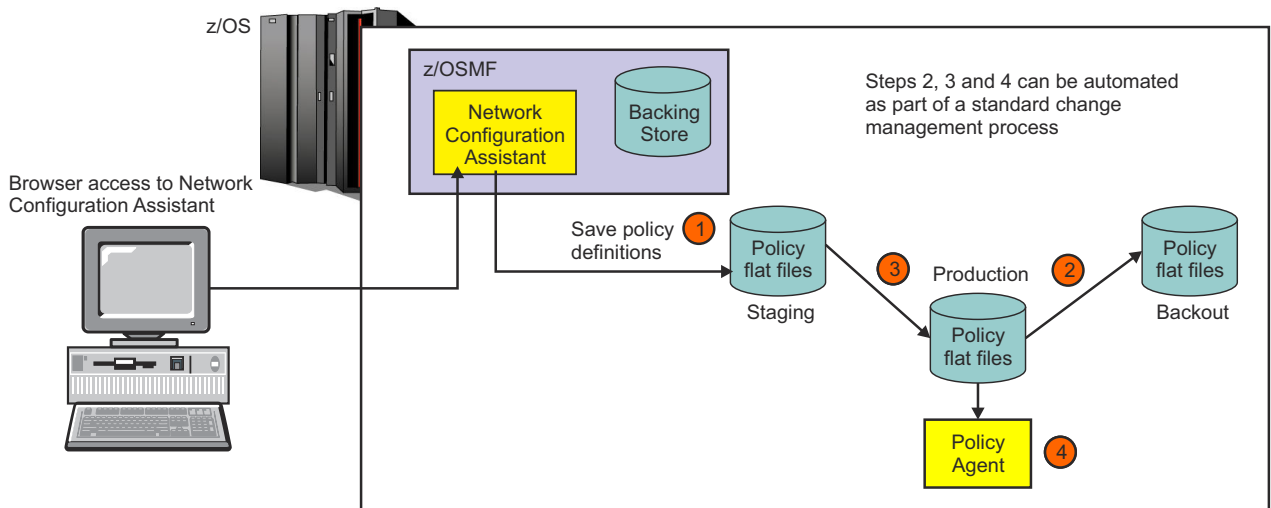

Figure 112. Activating changes to your policies

Policy Agent reads the definitions from the production location, as shown by step 4 in [Figure 112 on page 818](#).

### Tips:

- If the changes you make are in error, you can back out the changes by copying your original production definitions from the recovery location to the production location and restarting your policy infrastructure components.
- In your procedure to move objects from POLTRANS to POLPROD, you might have to include a utility step to change location references from POLTRANS to POLPROD.

Some configuration files might include references to other configuration file locations or policy definition file locations. Those locations are initially the POLTRANS location.

- You can override names suggested by the IBM Configuration Assistant for z/OS Communications Server and choose to use other names.

If you are using the IBM Configuration Assistant for z/OS Communications Server, you are prompted for the base location for a z/OS image. For each configuration file, policy definition file, sample RACF job, sample JCL procedure, and so on, the IBM Configuration Assistant for z/OS Communications Server suggests a name to serve as the file name in the z/OS UNIX file system directories, or as the member name in the PDS or PDSE libraries.

- Specifying an EBCDIC code page that matches your default country settings makes it easier to browse the files with ISPF.

Most policy-related configuration files and all the policy definition files support an optional Codepage parameter that you can use to indicate the EBCDIC code page in which the contents are encoded. When you use the IBM Configuration Assistant for z/OS Communications Server, you specify the EBCDIC code page when you define the base location for a z/OS image. The IBM Configuration Assistant for z/OS Communications Server transfers configuration files and policy definitions files to that z/OS image using the specified code page and includes the Codepage option in the files. The following example shows the initial section of a Policy Agent configuration file that uses the Codepage option:

```

Configuration Assistant, 2008.11.25 09:33:12
Pagent Configuration for system MVS098
Target Codepage = IBM-278
TcpImage TCPDS 'USER1.TCPPARMS.MVS098.TCPDS(STKPAG)' FLUSH NOPURGE 360
Codepage IBM-278
Loglevel 127 ## default 31

```

## Policy infrastructure components

---

Based on the policy types that you want to implement, you must configure and start one or more policy infrastructure components.

For more information about syslogd, see [“Configuring the syslog daemon” on page 235](#).

### TCP/IP stack

Most policy types are implemented by the TCP/IP stack. IPsec dynamic VPNs are implemented by the IKE daemon.

As packets are sent or received, they are matched against policies of the appropriate type as needed. In general, policy processing occurs at the following layers in the stack:

- Application layer - AT-TLS
- IP layer - IPsec filtering, IDS, and policy-based routing
- Transport layer - IDS , QoS and zERT policy-based enforcement (ZERT)

Some types of IDS checks are also performed at the IP layer in the stack.

When a matching policy is found, it is implemented against the packet. Depending on the policy type and packet contents, this results in a wide variety of actions. For example, the packet might be discarded, processed according to its priority, or have its routing changed. For information about the policy action statements and the kinds of processing that can be applied for each policy type, see the [Policy Agent and policy applications](#) information in [z/OS Communications Server: IP Configuration Reference](#).

### Policy Agent

Policy Agent can act in any of several roles, and provides various services, such as managing dependent components of the policy infrastructure.

The term *Policy Agent* refers to any roles or services provided by Policy Agent. The terms *policy server* and *policy client* refer to those specific roles, and the term *import requester* refers to the TCP/IP address discovery service.

### Policy Agent roles

The Policy Agent runs in the z/OS environment and can act in any of several roles, depending on configuration options:

- The Policy Agent can act as a self-contained Policy Decision Point (PDP) on a single system, installing policies in one or more z/OS Communications Server stacks on that z/OS image, as shown by system SYSA in [Figure 113 on page 820](#).
- The Policy Agent can act as a policy client, retrieving remote policies from the policy server, as shown by system SYSB in [Figure 113 on page 820](#). Each stack in a Common INET (CINET) environment that is configured to the Policy Agent acts as a separate policy client.
- The Policy Agent can act as a centralized policy server, providing PDP services for one or more remote policy clients, as shown by system SYSC in [Figure 113 on page 820](#).
- A single Policy Agent can act as a policy client or a policy server, but not both.

Figure 113. Policy Agent roles

## Policy Agent services

Policy Agent provides the following services:

- Reads and parses policy definitions, and provides those policies to one or more TCP/IP stacks or policy clients. The Policy Agent actively participates in maintaining the policies by monitoring the policy files, detecting changes, and informing the TCP/IP stacks or policy clients about any changes.
- Imports TCP/IP interface information through a passive service. The main user of this service is the IBM Configuration Assistant for z/OS Communications Server (Network Configuration Assistant) IPsec technology. This function imports TCP/IP interface information from a running stack into Network Configuration Assistant for use as IPsec stack symbols and is not related to the TCP/IP profile import function of Network Configuration Assistant.

For this request, the Policy Agent retrieves information from the TCP/IP stack. The import requester can retrieve this information and use it as configuration data.

- Starts, monitors, stops, and restarts dependent components of the policy infrastructure. You can instruct Policy Agent to manage the following components:
  - DMD
  - IKED
  - NSSD
  - syslogd

- TRMD per stack on a system

## Policy Agent policies

Policies can be defined in several different ways.

Table 40 on page 821 shows the format you can use for different policy types.

| Table 40. Policy formats                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |                               |                  |
|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------|------------------|
| Policy type                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | Text file format <sup>1</sup> | LDAP format      |
| QoS                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | Yes                           | Yes <sup>2</sup> |
| IDS                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            | Yes                           | Yes <sup>2</sup> |
| AT-TLS                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         | Yes                           | No               |
| IPSec                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          | Yes                           | No               |
| Policy-based routing                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           | Yes                           | No               |
| zERT policy-based enforcement                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  | Yes                           | No               |
| <sup>1</sup> The IBM Configuration Assistant for z/OS Communications Server builds policy definitions only in text file format.<br><sup>2</sup> The format of the LDAP schema for IDS and QoS policies was stabilized in z/OS V1R2. Only IDS and QoS policies supported by that release are supported when you are using an LDAP server to store IDS and QoS policies. For information about defining policies on an LDAP server, see <a href="#">Appendix F, “Using an LDAP server for policy definitions,”</a> on page 1407. |                               |                  |

When acting as the Policy Decision Point (PDP) for a single system, Policy Agent can read policy definitions from local configuration files, a central repository that uses the Lightweight Directory Access Protocol (LDAP), or both. The Policy Agent also installs policies in one or more z/OS Communications Server stacks. It can be used to replace existing policies or to update them as necessary.

When acting as a policy server, Policy Agent also acts as a PDP for the local system, and thus can read policies from local configuration files or an LDAP server and install them in local stacks. However, it also reads policies from local configuration files on behalf of policy clients. These policies are retrieved by policy clients, but are not installed in the local stacks on the policy server.

**Restriction:** Dynamic monitoring for file updates using the `-i` startup option is not supported for files read on behalf of policy clients.

When acting as a policy client, Policy Agent retrieves remote policies from the policy server, and can also use local policies from configuration files or an LDAP server. The choice of local or remote policies can be made separately for each supported policy type (QoS, IDS, IPSec, Routing, AT-TLS or ZERT). The policy client informs the policy server of its local capabilities, so that the policy server can perform appropriate parsing of the policies. For example, the policy client might not support the IPSec 3DES encryption algorithm, so the policy server needs to fail IPSec policies that specify 3DES, even if the policy server itself does support 3DES.

If the policy client and policy server are at different release levels, you must be careful when defining policies on the policy server.

- If the policy client is at a higher release level than that of the policy server, you can define policies using the syntax and semantics of only the lower-level policy server. You cannot use the capabilities that exist only in the higher release level, such as new statements, parameters, or parameter values. Error checking might also be unavailable for use; rules or restrictions might be added to or removed from the higher release level.
- If the policy server is at a higher release level than that of the policy client, you cannot define policies using syntax and semantics that are available only in the higher release level. The policy server cannot

parse such policies on behalf of a policy client at a lower release level, so the policies are reported as containing errors.

- If the policy server is at a lower release level than that of the policy client, any policies using syntax and semantics that were removed from the higher release level are still parsed and returned from the policy server to the policy client.

As a general rule, configure policies based on the target system, not on the system where the policies are defined.

For a [table](#) of statements, parameters, parameter values, and rules or restrictions that are valid only for certain release levels, see [z/OS Communications Server: IP Configuration Reference](#).

The policy client can be configured with a backup as well as a primary policy server. The policy client continually tries the connection to the primary policy server (and the connection to the backup if a backup is configured) using the connection retry values configured on the ServerConnection statement, until a connection is successfully established.

For more information, see the following topics:

- [“Policy-based routing” on page 377](#)
- [Chapter 15, “Quality of service,” on page 857](#)
- [Chapter 16, “Intrusion detection services,” on page 877](#)
- [Chapter 17, “IP security,” on page 911](#)
- [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#)
- [“Defining a zERT enforcement policy” on page 198](#)

**Restriction:** You cannot define AT-TLS policies, IPsec policies, routing policies, or ZERT on LDAP servers.

**Tip:** Policies defined on an LDAP server use the configuration files and mechanisms provided by the LDAP server product. The definition of the elements of policies is known as the *schema*. z/OS Communications Server provides the schema definition for policies that may be defined on an LDAP server in a set of sample files. The sample files are provided in LDAP protocol version 3 format (see [“LDAP sample files” on page 1417](#) for the names of these samples). These sample files must be installed on the LDAP server as the schema definition. Policy Agent uses the z/OS Integrated Security Server LDAP Client library to communicate with an LDAP server. See [z/OS IBM Tivoli Directory Server Administration and Use for z/OS](#) for more information about LDAP. A copy of the LDAP definition files that define the policy definitions for LDAP is available in [z/OS Communications Server: IP Configuration Reference](#).

Local policies are defined in Policy Agent configuration files, in the LDAP server, or both. Remote policies are defined in Policy Agent configuration files on the policy server. Policies from configuration files and the LDAP server are combined into a single list. This requires unique policy object names per type (QoS, IDS, IPsec, Routing, AT-TLS, and ZERT). On a policy client, policies for a given type are retrieved either locally or remotely, but not both.

For policies defined on the LDAP server, the distinguished name (DN) must be unique, but the user-friendly name does not have to be unique (although it should be). The Policy Agent appends a unique suffix if it is required to make LDAP user-friendly names unique within the scope of policies defined on the LDAP server. When policies from a configuration file are combined with LDAP-defined policies, the LDAP user-friendly names must be unique with respect to the names defined in the configuration file. Any policy objects of the same type (that is, QoS or IDS) with duplicate names at this point are discarded by the Policy Agent and an error is reported.

## Import services

The IBM Configuration Assistant for z/OS Communications Server can request TCP/IP interface information be imported from a running TCP/IP stack for use as stack symbols by IPsec technology. When the Policy Agent provides this import service, the IBM Configuration Assistant for z/OS Communications Server is acting as an *import requester*. When the IBM Configuration Assistant for z/OS Communications Server is acting as an import requester, the required input values are configured on request panels for discovery import (the Discover Stack Local Addresses panel):

- Host connection IP address and port for the Policy Agent
- Host connection user name and password to identify resources that this user can access
- Indication of whether a secure connection (SSL) should be used. For more details, see [“Step 6: Configure Policy Agent for import services” on page 844.](#)

#### **Restrictions:**

- The import requester's port value must be the same as the port value defined on the ServicesConnection statement.
- The import requester's TLS/SSL security configuration must match the security configuration for the Policy Agent provider.

For detailed configuration information, see [“Step 6: Configure Policy Agent for import services” on page 844.](#)

## **Additional QoS services**

The Policy Agent supports QoS functions other than reading and installing policies, such as sysplex distributor policy performance monitoring, and mapping IPv4 Type of Service (ToS) byte or IPv6 Traffic Class values to outbound interface and virtual LAN (VLAN) user priorities. The QoS specific Policy Agent functions are further described in [“QoS-specific Policy Agent functions” on page 859.](#)

## **Policy API**

A Policy API (PAPI) is provided to allow access to policy information by external user applications. The PAPI interface can be used by policy performance monitoring applications to retrieve policy performance data. For more information on PAPI, see [z/OS Communications Server: IP Programmer's Guide and Reference.](#)

## **Traffic regulation management daemon**

The TRMD application provides the ability for IDS, IPsec, and ZERT messages to be logged to syslogd. A separate instance of TRMD must be started for each TCP/IP stack.

## **IKE daemon**

IPsec services include IP filtering and support for manual and dynamic VPN tunnels. The Internet Key Exchange (IKE) daemon works with the stack to provide IPsec support. IPsec policy can be defined for IP filtering (including manual VPN tunnels), key exchange, and dynamic VPN tunnels.

## **Network security services daemon**

A network security services daemon (NSSD) provides network security services for one or more security disciplines, including IPsec. For the IPsec discipline, these services include the IPsec certificate service and the IPsec remote management service. For more information, see [Chapter 18, “Network security services,” on page 1111.](#)

**Tip:** You do not define policies for NSSD.

## **Defense Manager daemon**

The Defense Manager daemon (DMD) provides defensive filters, which are IP filter rules to discard packets that are separate from IP security filters, and which are typically installed for a short duration (for example, 30 minutes) to block a specific attack or a pattern of attacks. For more information, see [Chapter 19, “Defensive filtering,” on page 1135.](#)

**Tip:** You do not define policies for DMD.

## SNMP Network SLAPM2 subagent

The z/OS CS Network SLAPM2 subagent (nslapm2) allows network administrators to retrieve data and determine if the current set of Network SLAPM2 policy definitions are performing as needed or if adjustments need to be made. The Network SLAPM2 subagent supports the Network Service Level Agreement Performance Monitor (NETWORK-SLAPM2) MIB. See `usr/lpp/tcpip/samples/slapm2.mi2` for more information about the Network SLAPM2 MIB.

## Sample policy infrastructure

---

[Figure 114 on page 825](#) shows the Policy Agent in a sample policy infrastructure.

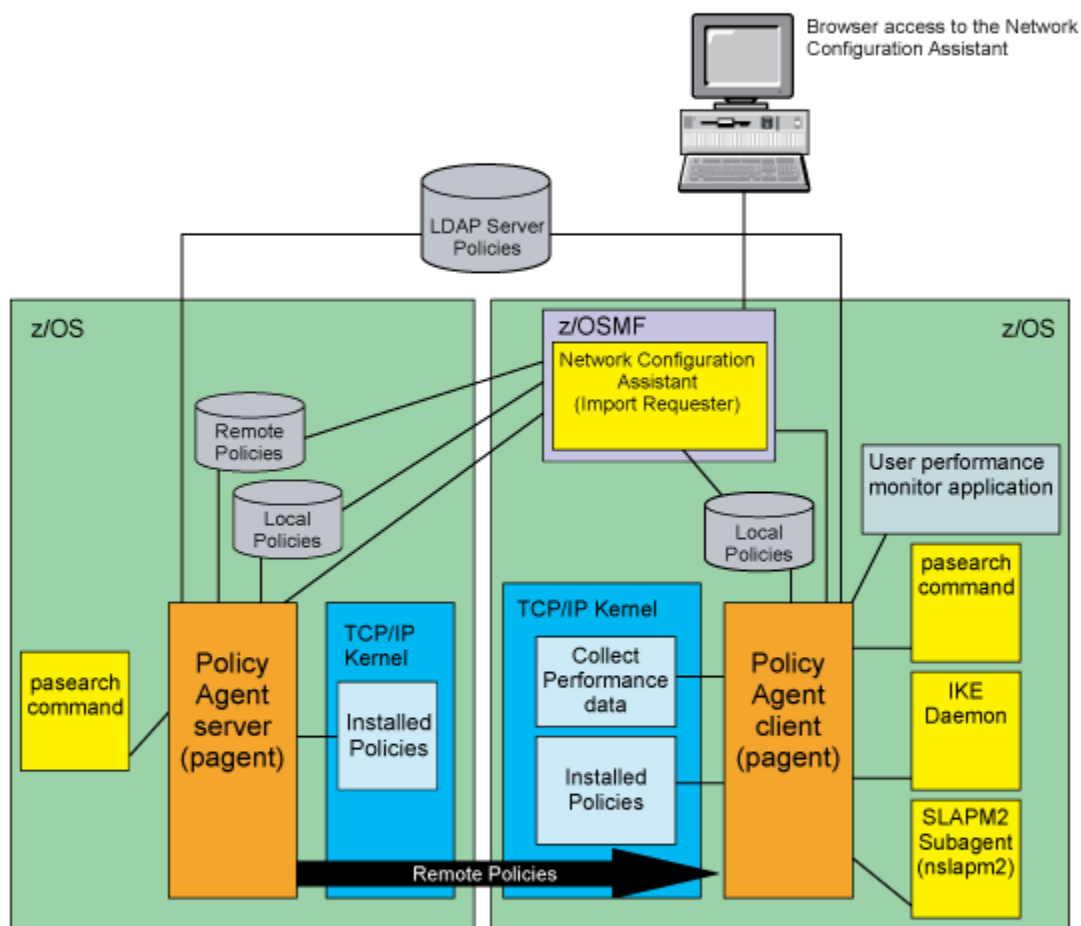

Figure 114. Sample policy infrastructure

The IBM Configuration Assistant for z/OS Communications Server performs the following functions:

- GUI to build the configuration flat-files for IPsec, AT-TLS, IDS, Routing, ZERT, and QoS policies.
- Import requester to request TCP/IP interface information import services from the Policy Agent, for use as stack symbols by IPsec technology. For details, see [“Import services”](#) on page 822.

## Policy sample files

---

A set of sample files is shipped with z/OS CS that provides several functions. The first sample file provides an example of policy definitions in a Policy Agent configuration file.

### **/usr/lpp/tcpip/samples/pagent.conf**

This file contains overall policy definition rules, syntax and semantics for defining policies in a configuration file, and examples of such policy definitions.

The next set of sample files provide sample IPsec policy definitions.

### **/usr/lpp/tcpip/samples/pagent\_CommonIPSec.conf**

This file contains sample common IPsec policy definitions. These can be referenced and reused by multiple stack-specific IPsec configuration files.

### **/usr/lpp/tcpip/samples/pagent\_IPSec.conf**

This file contains sample stack-specific IPsec policy definitions. Some of these refer to common definitions in /usr/lpp/tcpip/samples/pagent\_CommonIPSec.conf.

The following file provides sample AT-TLS policy definitions.

### **/usr/lpp/tcpip/samples/pagent\_TTLS.conf**

This file contains sample AT-TLS policy definitions. These definitions can either be in a common or stack-specific AT-TLS file. If these definitions are in a common AT-TLS file, they can be referenced and reused by multiple stack-specific AT-TLS configuration files. If these definitions are in a stack-specific AT-TLS file, they are used only by that specific stack.

The following file provides sample IDS policy definitions.

### **/usr/lpp/tcpip/samples/pagent\_IDS.conf**

This file contains sample IDS policy definitions. These definitions can either be in a common or stack-specific IDS file. If these definitions are in a common IDS file, they can be referenced and reused by multiple stack-specific IDS configuration files. If these definitions are in a stack-specific IDS file, they are used only by that specific stack.

The following file provides sample policy-based routing policy definitions.

### **/usr/lpp/tcpip/samples/pagent\_Routing.conf**

This file contains sample policy-based routing policy definitions. These definitions can either be in a common or stack-specific routing file. If these definitions are in a common routing file, they can be referenced and reused by multiple stack-specific routing configuration files. If these definitions are in a stack-specific routing file, they are used only by that specific stack.

The following file provides sample zERT policy-based enforcement policy definitions.

### **/usr/lpp/tcpip/samples/pagent\_ZERT.conf**

This file contains sample zERT policy-based enforcement policy definitions. These definitions can only be in a stack-specific ZERT file, hence, they are used only by that specific stack.

The following files include sample C applications that can be used to develop policy performance monitoring applications.

### **/usr/lpp/tcpip/samples/pagent/README**

This file contains instructions for compiling and running the following sample C applications.

### **/usr/lpp/tcpip/samples/pagent/pCollector.c**

This file is a sample C application (pCollector) that uses the Policy API (PAPI) interfaces to access policy performance data. It can be used as the base for an application that provides near real-time policy performance monitoring.

### **/usr/lpp/tcpip/samples/pagent/pCollector.h**

This file is a header file for the pCollector sample application.

### **/usr/lpp/tcpip/samples/pagent/pLogReader.c**

This file is a sample C application (pLogReader) that reads the policy performance log file to access policy performance data. It can be used as the base for an application that provides offline policy performance monitoring.

This documentation refers to Version 1 through Version 4 when defining policies.

- Version 1 refers to policy definitions defined with the ServicePolicyRules and ServiceCategories statements or LDAP objects.
- Version 2 through Version 4 refer to policy definitions defined with other policy statements or LDAP objects.
- The primary difference between Version 2 and Version 3 is in the definition of the LDAP schema.
- Version 3 is used with configuration file IPsec and AT-TLS policies.
- Version 4 is used with configuration file IDS, Routing, and ZERT policies.

For information about LDAP samples and schema definition files, see [Appendix F, “Using an LDAP server for policy definitions,”](#) on page 1407.

## Policy types

---

The Policy Agent supports the following types of policies. Each policy type is referred to as a discipline.

- Quality of service (QoS) policies
  - Differentiated Services (DS) policies
  - Integrated Services (RSVP) policies
  - Sysplex distributor (SD) policies
- Intrusion detection services (IDS) policies
  - Scan policies
  - Attack policies
  - Traffic Regulation policies
- IP security (IPsec) policies
  - IP filtering policies
  - Key exchange policies
  - Local dynamic VPN policies
- Application Transparent Transport Layer Security (AT-TLS) policies
- Policy-based routing (Routing) policies
- zERT policy-based enforcement (ZERT) policies

For information about [how IPv6 affects the Policy Agent](#) and which types of policies support IPv6, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

These policy types are defined using different policy schemas. They use a common rule, but have separate conditions and actions. None of the different policy types can be mixed in a given policy object. All policy rules can contain time-related information that indicates when the policy rule should be considered active or inactive.

For the QoS, IDS, Routing, , AT-TLS and ZERT types, active policy rules are installed in the TCP/IP stack, so they can be applied as traffic filters, while inactive policy rules exist only in the Policy Agent. For the IPsec type, both active and inactive IP filtering policies are installed in the TCP/IP stack. However, only manual VPN tunnels that are active as a result of a time condition are installed in the stack. For the Routing policy type, active route tables are installed in the stack, while inactive route tables exist only in the Policy Agent. Configured route tables are active when they are referenced by an active Routing rule and its associated Routing action.

The Policy Agent supports all of the previously mentioned policy types, installing them into one or more TCP/IP stacks as configured. However, policies to be retrieved by policy clients are not installed in any stacks on the policy server.

## QoS policy

Policy conditions consist of a variety of selection criteria that act as traffic filters. Traffic can be filtered based on source and destination IP addresses, source and destination ports, protocol, inbound and outbound interfaces, application name, application specific data or application priority. Only packets that match the filter criteria are selected to receive the accompanying action. Policy rules can refer to several policy actions, but only one policy action is executed per policy scope. A given policy action may be referred to by several policy rules.

The type of policy defined is in general controlled by the policy scope value defined for the policy action. SD policies are an exception. SD policies are a subset of DS policies, so use the DS scope.

Although RSVP policies are installed into the TCP/IP stack, they are used only for collecting policy statistics. For policy use and limit enforcement, these policies are requested from the Policy Agent by the RSVP Agent, to apply to RSVP reservation requests from RSVP applications.

## IDS policy

Policy conditions primarily determine the portion of IDS function that is being configured. A given IDS policy rule refers to a single IDS policy action. A given IDS policy action may be referred to by several policy rules of the same IDS type. See [Chapter 16, “Intrusion detection services,” on page 877](#) for more details.

## IPSec policy

Policy conditions consist of a variety of selection criteria that act as filters for IP filtering rules. Traffic can be filtered based on source and destination IP addresses, source and destination ports, protocol, direction, routing information, and security class. For other types of IPSec policies, policy conditions contain information about dynamic key exchange filters or dynamic VPN tunnels. For more details, see [Chapter 17, “IP security,” on page 911](#).

IP filter rules and key exchange rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, while one with more conditions is known as a complex rule. Complex IP filter rules and key exchange rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details on CNF, see [“Policy object model overview” on page 1407](#).

Complex IP filter rules (rules that contain groupings, or sets, of individual conditions) are split to produce multiple simple rules to be installed in the TCP/IP stack. The conditions in the IpFilterRule statement that can make a filter rule complex are:

- IpSourceAddr

If multiple source addresses (or address ranges) are specified in a rule, the rule is considered complex. Multiple source addresses can be specified by referencing a set or group of addresses from the rule (IpSourceAddrGroupRef).

- IpDestAddr

If multiple destination addresses (or address ranges) are specified in a rule, the rule is considered complex. Multiple destination addresses can be specified by referencing a set or group of addresses from the rule (IpDestAddrGroupRef).

- IpService

If multiple IpService statements are specified in a rule, the rule is considered complex. Multiple IpService statements can be specified either inline or by referencing a group of IpService statements (IpServiceGroupRef).

- IpService Direction

If the Direction parameter in an IpService statement is configured as bidirectional, the rule is considered complex.

Complex key exchange rules are split to produce multiple simple rules. The IKE daemon retrieves simple rules when necessary. The following conditions can make a complex key exchange rule:

- LocalSecurityEndpoint Location

If multiple IP addresses (or address ranges) are specified in a local security endpoint, the associated key exchange rule is considered complex. You can specify multiple IP addresses by referencing a set or group of addresses from the local security endpoint (LocationGroupRef).

- RemoteSecurityEndpoint Location

If multiple IP addresses (or address ranges) are specified in a remote security endpoint, the associated key exchange rule is considered complex. You can specify multiple IP addresses by referencing a set or group of addresses from the remote security endpoint (LocationGroupRef).

For more details on these [IPSec policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

The **pasearch** command displays IP filter rules and key exchange rules as complex rules, and not split as installed in the TCP/IP stack or retrieved by the IKE daemon.

For IP filter rules and key exchange rules, the condition level summaries are not applicable and are always displayed as all zeros.

## AT-TLS policy

Policy conditions consist of a variety of selection criteria that act as filters for AT-TLS rules. Traffic can be filtered based on local addresses, remote addresses, local port range, remote port range, job name, user identification, and direction. For more details, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149.

AT-TLS policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, while one with more conditions is known as a complex rule. Complex AT-TLS policy rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details on CNF, see [“Policy object model overview”](#) on page 1407.

When AT-TLS rules are read and parsed, Policy Agent creates the rule as a complex rule. For example, consider the following TTLSRule statement:

```
TTLSRule ttlsRule1
{
 LocalAddrGroupRef addrGroup1
 RemoteAddrGroupRef addrGroup2
 LocalPortGroupRef portGroup1
 RemotePortGroupRef portGroup2
 Jobname jobABC
 Userid user1
 Direction Outbound
 TTLSGroupActionRef ttlsAction7
}

IpAddrGroup addrGroup1
{
 IpAddr
 {
 Addr 9.1.1.1
 }
 IpAddr
 {
 Addr 10.1.1.1
 }
}

IpAddrGroup addrGroup2
{
 IpAddr
 {
 Addr 200.1.1.1
 }
 IpAddr
 {
 Addr 201.1.1.1
 }
}
```

```

 }
 }
 PortGroup portGroup1
 {
 PortRange
 {
 Port 21
 }
 PortRange
 {
 Port 23
 }
 }
 PortGroup portGroup2
 {
 PortRange
 {
 Port 10
 }
 PortRange
 {
 Port 15
 }
 }
}

```

This rule is represented as a CNF rule with the following condition levels (levels are ANDed together):

- Level 1 = local address 9.1.1.1 OR local address 10.1.1.1
- Level 2 = remote address 200.1.1.1 OR remote address 201.1.1.1
- Level 3 = local port 21 OR local port 23
- Level 4 = remote port 10 OR remote port 15
- Level 5 = job name jobABC, user ID user1, direction outbound

The **pasearch** command displays the AT-TLS policy as complex rules.

## Policy-based routing policy

Policy conditions consist of a variety of selection criteria that act as filters for policy-based routing (Routing) rules. Traffic can be filtered based on source addresses, destination addresses, source port range, destination port range, protocol, job name, security zone, and security label. For more details, see [“Policy-based routing” on page 377](#).

Routing policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, and one with more conditions is known as a complex rule. Complex routing policy rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details about CNF, see [“Policy object model overview” on page 1407](#).

When routing rules are read and parsed, Policy Agent creates the rule as a complex rule. For example, consider the following RoutingRule statement:

```

RoutingRule rule1
{
 TrafficDescriptorGroupRef tdGroup
 IpSourceAddrGroupRef addrGroup
 RoutingActionRef action1
}
TrafficDescriptor td1
{
 SourcePortRange 1-5
 DestinationPortRange 10
 SecurityZone zone1
 SecurityLabel label1
 JobName jobABC1
}
TrafficDescriptor td2
{
 SourcePortRange 6-9
 DestinationPortRange 25
 SecurityZone zone2
 SecurityLabel label2
}

```

```

 JobName jobABC2
 }
 TrafficDescriptorGroup tdGroup
 {
 TrafficDescriptorRef td1
 TrafficDescriptorRef td2
 }
 IpAddrGroup addrGroup
 {
 IpAddr
 {
 Addr 9.1.1.1
 }
 IpAddr
 {
 Addr 10.1.1.1
 }
 }
}

```

This rule is represented as a CNF rule with the following condition levels (levels are ANDed together):

- Level 1 = source address 9.1.1.1 OR source address 10.1.1.1
- Level 2 = (source port range 1-5 AND destination port range 10 AND job name jobABC1 AND security zone zone1 AND security label label1) OR (source port range 6-9 AND destination port range 25 AND job name jobABC2 AND security zone zone2 AND security label label2)

The **pasearch** command displays the Routing policy as a complex rule.

## zERT policy-based enforcement (ZERT) policy

Policy conditions consist of a variety of selection criteria that act as filters for zERT policy-based enforcement (ZERT) rules. Connections can be filtered based on local addresses, remote addresses, local port range, remote port range, job name, user identification, and direction. A number of security protection attributes can also be used as filters. For more details, see [“Defining a zERT enforcement policy”](#) on page 198.

ZERT policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a simple rule, while one with more conditions is known as a complex rule. Complex ZERT policy rules have their conditions evaluated according to Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. For details about CNF, see [“Policy object model overview”](#) on page 1407. When ZERT rules are read and parsed, Policy Agent creates the rule as a complex rule. The **pasearch** command displays the ZERT policy as complex rules. For example, consider the following ZERTRule statement:

```

ZERTRule Rule1
{
 LocalAddrGroupRef l~addrGroup
 RemoteAddrGroupRef r~addrGroup
 ZERTActionRef act1
 SecurityProtocol TLS
 ZERTTLSProtocolRef tlsVersion
 ZERTSymmetricEncryptionRef symEnc
 ZERTMessageAuthenticationRef msgAuth
 ConnectionDescriptorGroupRef connDescGrp
}

IpAddrGroup l~addrGroup
{
 IpAddr
 {
 Addr 9.1.1.1
 }
 IpAddr
 {
 Addr 10.1.1.1
 }
}

IpAddrGroup r~addrGroup
{
 IpAddr
 {
 Addr 200.1.1.1
 }
}

```

```

 IpAddr
 {
 Addr 201.1.1.1
 }
}

ZERTTLSProtocol tlsVersion
{
 TLSProtocol TLSv1.2
 TLSProtocol TLSv1.3
}
ZERTSymmetricEncryption symEnc
{
 SymmetricEncryption AES_CBC_128
 SymmetricEncryption AES_CBC_256
 SymmetricEncryption AES_GCM_256
}
ZERTMessageAuthentication msgAuth
{
 MessageAuthentication HMAC_SHA2_256
 MessageAuthentication HMAC_SHA2_384
}
ConnectionDescriptorGroup connDescGrp
{
 ConnectionDescriptor
 {
 Protocol TCP
 LocalPortRange 1024-65535
 RemotePortRange 21
 Jobname JOBNAME1
 TcpConnectionDirection Inbound
 }
 ConnectionDescriptor
 {
 Protocol TCP
 LocalPortRange 1024-65535
 RemotePortRange 50000-50200
 Jobname JOBNAME2
 TcpConnectionDirection Outbound
 }
}
}

```

This rule is represented as a CNF rule with the following condition levels (levels are ANDed together):

- Level 1 = local address 9.1.1.1 OR local address 10.1.1.1
- Level 2 = remote address 200.1.1.1 OR remote address 201.1.1.1
- Level 3 = (local port range 1024-65535 AND remote port range 21 AND job name JOBNAME1 AND TCP connection direction Inbound) OR (local port range 1024-65535 AND remote port range 50000-50200 AND job name JOBNAME2 AND TCP connection direction Outbound)
- Level 4 = TLSv1.2 OR TLSv1.3
- Level 5 = SymmetricEncryption AES\_CBC\_128 OR SymmetricEncryption AES\_CBC\_256 OR SymmetricEncryption AES\_GCM\_256
- Level 6 = MessageAuthentication HMAC\_SHA2\_256 OR MessageAuthentication HMAC\_SHA2\_384

The **pasearch** command displays the ZERT policy as a complex rule. The security protection conditions (Level 4, 5, and 6 in this example) are only displayed in the summary condition.

## Policy configuration files

A single file, the main configuration file, is specified explicitly or by default when the Policy Agent is started. This main configuration file points to other configuration files, as shown in [Figure 115 on page 833](#).

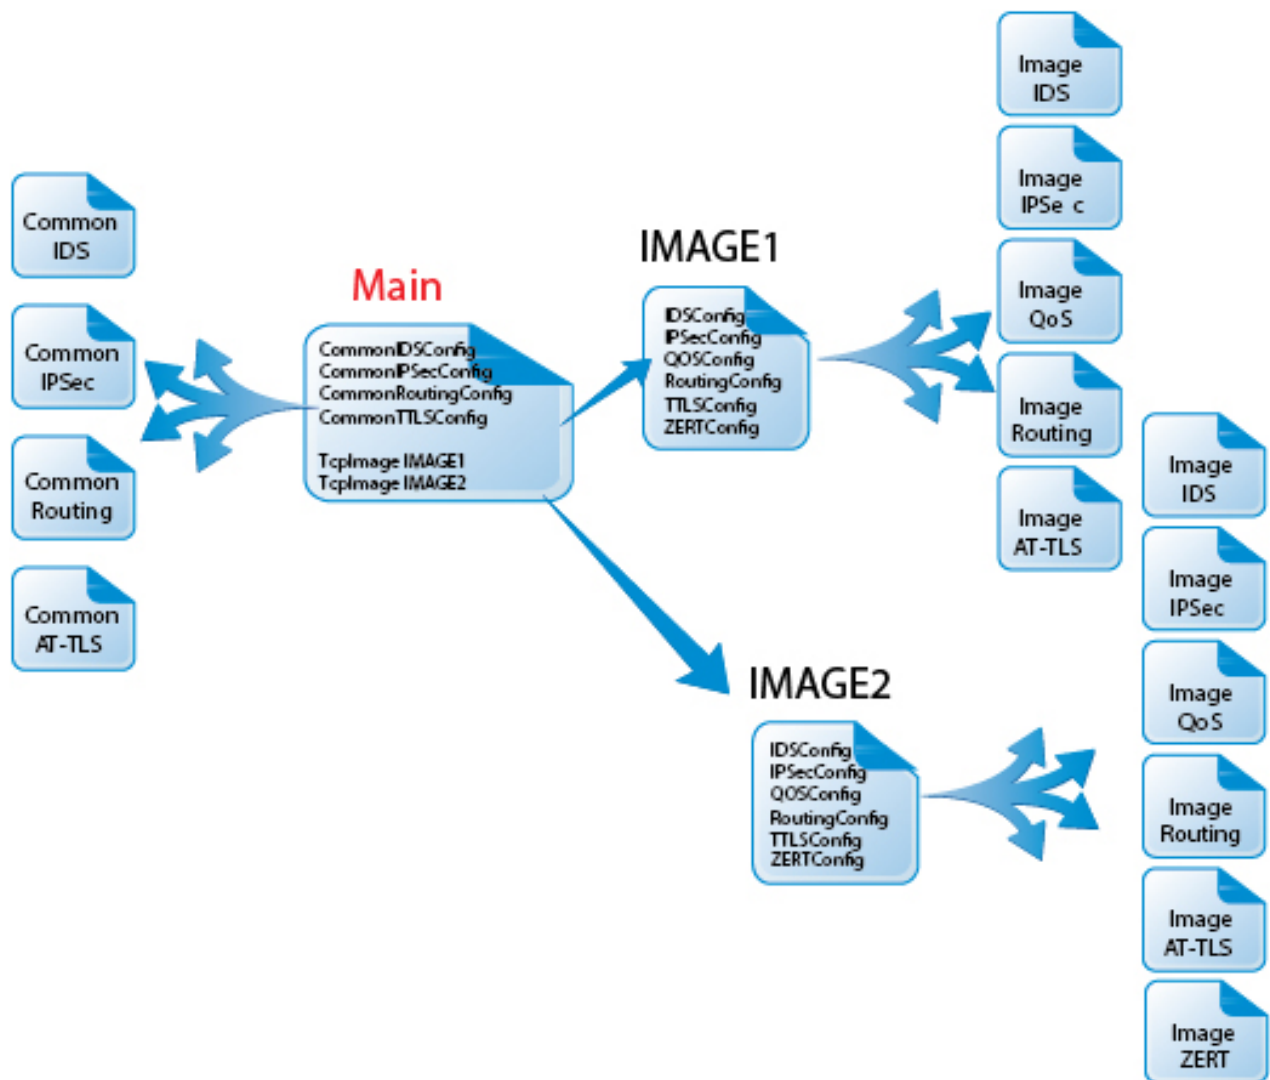

Figure 115. Policy Agent configuration files

For more information about the [Policy Agent search order](#), see [z/OS Communications Server: IP Configuration Reference](#).

You can specify statements in all configuration files using a variety of EBCDIC code pages. Use the `Codepage` configuration statement in the main configuration file to specify the code page to be used for all configuration files. The default code page is IBM-1047.

The main configuration file contains `TcpImage` or `PEPInstance` statements that define the TCP/IP stacks to be configured. The Policy Agent reads and installs policies for this set of stacks. Each `TcpImage` or `PEPInstance` statement can optionally specify the file name of an image-specific configuration file for that stack. If this file name is not specified, the main configuration file is also the image-specific configuration file for that stack. Thus, a single physical file can serve as two distinct logical files.

The main configuration file can also contain statements that specify the file names of one or more common configuration files for certain policy types. For example, the `CommonIDSConfig` statement points to a file containing IDS configuration statements that can be used for all configured stacks.

Each image-specific configuration file can contain statements that specify the file names of image-specific configuration files for different policy types. For example, the `IPSecConfig` statement points to a file containing IPSec configuration statements to be used for the stack that is represented by the image configuration file that contains the `IPSecConfig` statement. QoS policies can optionally be configured directly in the image configuration file, without using a `QoSConfig` statement.

The main configuration file on the policy server can also contain `DynamicConfigPolicyLoad` statements that determine the configuration files used when remote policy clients request policies. Each `DynamicConfigPolicyLoad` statement can serve a single policy client or a group of policy clients. Both common and policy client-specific configuration files can be specified for each policy type.

## Steps for configuring the Policy Agent

---

Details for each general step are described in a corresponding subtopic.

### Before you begin

You need to understand the hierarchy and relationships of the different configuration files. For more information, see [“Policy configuration files” on page 832](#).

### Procedure

Perform the following steps to configure the Policy Agent:

1. Configure general information.
2. Configure Policy Agent as a policy server.
3. Configure Policy Agent as a policy client.
4. Configure policies in Policy Agent configuration files.
5. Configure Policy Agent to use the LDAP server using the `ReadFromDirectory` statement.
6. Configure Policy Agent for import services.
7. Configure Policy Agent for automatic monitoring of applications.

## Step 1: Configure general information

Before defining policies, you need to configure some basic operational characteristics of the Policy Agent.

### Procedure

Follow these steps to configure these characteristics:

1. Set the `TZ` and `LIBPATH` environment variables.

Use the `TZ` environment variable to specify the correct time zone. Use the `LIBPATH` environment variable so that the required dynamic link library (DLL) files can be located when you start the Policy Agent. For information about how to specify these environment variables, see [“Starting and stopping the Policy Agent” on page 849](#). You can also refer to comments in the sample start procedure that is shipped in `SEZAINST(EZAPAGSP)`.

2. Specify the name of the main configuration file.

You can specify the name of the main configuration file using the following methods:

- `-c` start option
- `PAGENT_CONFIG_FILE` environment variable
- Default file name `/etc/pagent.conf`

For information about the search order that Policy Agent uses to locate the main configuration file, and for examples of different ways to specify the main configuration file name, see [“Starting and stopping the Policy Agent” on page 849](#). You can also refer to comments in the sample start procedure that is shipped in `SEZAINST(EZAPAGSP)`.

3. Define the `TcpImage` or `PEPInstance` statements in the main Policy Agent configuration file.

The `PEPInstance` statement is a synonym for `TcpImage`, and either can be used. `PEPInstance` refers to policy enforcement point (PEP), the component of a policy system that enforces policies, which for z/OS is the TCP/IP stack.

### Results:

- The refresh interval used for the main configuration file will be the smallest of the values specified for the image-specific configuration files.
- When the main configuration file is an MVS data set, it is reread at each refresh interval (which is the smallest of the individual stack refresh intervals), regardless of whether it has actually been changed or not. Because Policy Agent restarts all stack-related processing when the main configuration file is reread, this effectively makes the refresh interval for all stacks the same as this smallest configured interval.
- The TcpImage or PEPInstance statement and all its parameters have no effect on policies defined for policy clients.

To install a common set of policies to a set of stacks served by a single Policy Agent, do not specify image-specific configuration files for each image. In this case, there is only one configuration file (the main one) and the policy information contained in it is installed to all of the configured stacks. Different refresh intervals can also be configured for each image, but would probably be less useful in this case.

In either case, it is possible that TCP/IP stacks configured to the Policy Agent are not started or even defined. The Policy Agent will fail when trying to connect to those stacks and log appropriate error messages.

**Rule:** To dynamically add a TCP/IP stack to the Policy Agent configuration and have active policies automatically installed, in addition to adding the TcpImage statement to the configuration file, further action might be necessary as follows:

- If the Policy Agent was started with the `-i` startup option, no further action is necessary. Active policies will be automatically installed to the stack when it becomes active.
- If the Policy Agent was not started with the `-i` startup option, take one of the following actions:
  - Issue the `MODIFY REFRESH` or `MODIFY UPDATE` command after the stack becomes active. If you issue the `MODIFY REFRESH` or `MODIFY UPDATE` command before the stack becomes active, policies are not automatically installed.
  - Wait on the next update interval to check for configuration changes. If the stack is not active, policies are not automatically installed.

The Policy Agent does not end when any (or all) stacks end. When the stacks are restarted, active policies are automatically reinstalled.

The TcpImage statement specifies a TCP/IP image and its associated configuration file to be installed to that image. The following example installs the policy control file `/tmp/TCPCS.policy` to the TCPCS TCP/IP image, after flushing the existing policy control data:

```
TcpImage TCPCS /tmp/TCPCS.policy FLUSH
```

For information about the `FLUSH`, `NOFLUSH`, `PURGE`, and `NOPURGE` parameters, see [“FLUSH and PURGE considerations”](#) on page 853.

#### 4. Define the log file destination and the appropriate logging level.

You can specify that Policy Agent log messages should be written to the syslog daemon or to a z/OS UNIX file. To indicate the syslog daemon, specify `SYSLOGD` in uppercase. To indicate a z/OS UNIX file, specify the file name. Specify the log file destination using the `-l` start option or the `PAGENT_LOG_FILE` environment variable, or you can use the default value `/tmp/pagent.log`.

**Tip:** Specify `SYSLOGD` to take advantage of a centralized logging mechanism.

**Result:** If Policy Agent cannot read the start options, then it does not have a log file destination. Policy Agent might fail to open a z/OS UNIX log file. In these situations, Policy Agent logs error messages to the syslog daemon and exits abnormally.

**Guidelines:** If you run Policy Agent with a nonzero UID and you are using a z/OS UNIX log file, follow these guidelines:

- Specify the file permissions as either `776` or `766`.

- Make sure that the syslog daemon is not configured to log to the same z/OS UNIX file. The syslog daemon runs with UID 0, so Policy Agent might not be able to access its log file if the syslog daemon creates the file before Policy Agent starts.

The LogLevel statement is used to define the amount of information to be logged by the Policy Agent. The default is to log only event, error, console, and warning messages. This might be appropriate for a stable policy configuration, but more information might be required to understand policy processing or debug problems when first setting up policies or when making significant changes. Specify the LogLevel statement with the appropriate logging level in the main configuration file.

**Note:** The maximum logging level (511) can produce a significant amount of output, especially with large LDAP configurations. This is not a concern if a z/OS UNIX log file is used, because Policy Agent uses a set of log files with a finite size in a round-robin configuration (the number and size of these files is controllable with the PAGENT\_LOG\_FILE\_CONTROL environment variable). But when using the syslog daemon as the log file, the amount of log output produced should be taken into consideration.

5. Provide the following security authorizations.

Because the Policy Agent can affect system operation significantly, the following security authorizations are required.

- A user starting Policy Agent must be a superuser.
- Security product authority (for example, RACF(R)) is required to start the Policy Agent. For sample commands needed to create the profile name and permit users to it, see the EZARACF sample in SEZAINST.

6. If Policy Agent's PAPI clients, including the **pasearch** command, are not defined as a superuser, to retrieve policies you must define security product authority in the SERVAUTH class for that client.

The security product authority is always required in cases where the image name cannot be defined as a superuser. Remote policy clients are never defined as a superuser on the policy server, so security product authority is always required for them. These profiles can be defined by image name and policy type (ptype = QoS, IDS, IPSec, TTLS, Routing, or ZERT). Using a wildcard for profile names is allowed.

```
EZB.PAGENT.sysname.image.ptype
```

where:

- *sysname* - System name defined in sysplex
- *image* - Tcp name, policy client name, or import request name for policy information that is being requested
- *ptype* - Type that is being requested:
  - QOS - Policy QoS
  - IDS - Policy IDS
  - IPSec - Policy IPSec
  - TTLS - Policy AT-TLS
  - Routing - Policy Routing
  - ZERT - Policy ZERT
  - CFGSERV - TCP/IP profile information

For details about the import request name, see [“Import services” on page 822](#).

**Tip:** You can specify a wildcard on segments of the profile name.

**Rules:**

- When you use policy clients, the image portion of the profile name on the policy server must match or include the name of the policy clients. Configure each policy client name using the ClientName parameter on the PolicyServer statement, or use the default value for the ClientName parameter.

For information about specifying the client name on the [PolicyServer statement](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

- When you use import requesters, the image portion of the profile name on the policy server must match or include the import request name. If you use the IBM Configuration Assistant for z/OS Communications Server as the import requester, configure the import request name on the request panels for discovery import. For information about the import request name, see [“Import services” on page 822](#).

Policy Agent checks all client requests to verify that the SERVAUTH class is active and that the profiles exist for the images and types in the request.

If a client's request is for multiple images or policy types, and permission is granted for only a subset of what is requested, Policy Agent returns only information for the subset for which permission is granted. However, if permission is denied for an entire request, including instances when only a single image or policy type is requested, an error is returned to the client indicating that permission is denied.

If the SERVAUTH class is not active or profiles are not active for the client's request (image, policy type), an error is returned to the client indicating that permission is denied.

See the EZARACF sample in SEZAINST for sample commands needed to create the profile name and permit users to it.

## Step 2: Configure Policy Agent as a policy server

Define the port for clients to connect, and policy client matching statements to select the configuration files to be used for clients. Create user IDs on the server to match the user IDs of clients, and set up security.

### Procedure

If you want to use the Policy Agent as a policy server, perform these steps:

1. Define the port to which policy clients will connect.

If policy clients are to be used, the ClientConnection statement in the main configuration file provides the port that Policy Agent listens on for remote connections. You can use the default port (16310), but you must specify the ClientConnection statement to use Policy Agent as a policy server.

**Guideline:** Reserve the port specified on the ClientConnection statement using the PORT statement in the TCP/IP profile.

**Restriction:** The port value cannot match the port value that is configured on the ServicesConnection statement.

2. Define a set of policy client matching statements that select the configuration files to be used for policy clients.

When a policy client connects to the policy server, the DynamicConfigPolicyLoad statements in the main configuration file are evaluated to determine whether there is a match. The names are case sensitive with regard to matching. When a matching statement is found, the parameters identify both common and image-specific configuration files to be used for the policy client. If no matching statement is found, a default image-specific file is used. A matching statement (or default values) is bound to a policy client for the life of that client, until one of the following events occur:

- The policy client disconnects from the policy server.
- The connection between the policy server and policy client ends.
- The associated DynamicConfigPolicyLoad statement is removed. In this case, the policy client is bound to a different DynamicConfigPolicyLoad statement (or to default values).

You can use a regular expression for the policy client name on the DynamicConfigPolicyLoad statement to cause the statement to match multiple policy clients. For a description of supported regular expressions on the [DynamicConfigPolicyLoad statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

For example, the expression `(.+)_(.+)` matches any client name composed of one or more characters, followed by an underscore, followed by one or more characters. The default client names configured on the PolicyServer statement on the policy client would match this expression.

You can use two different methods to substitute all or part of the client name in parts of the image-specific file name.

- A single wildcard character (\*) is replaced with the entire client name.
- If you use a regular expression as the DynamicConfigPolicyLoad statement client name, you can use the symbolic replacement values \$0 through \$9 in the image-specific file name. The value \$0 represents the entire portion of the client name that matched, while the values \$1 through \$9 represent portions of the client name that match corresponding parenthesized sub-expressions in the regular expression. Using the regular expression `(.+)_(.+)` as an example, and a policy client name of `SYS123_TCPIP2`, the values of the possible replacement variables are as follows:
  - The value \* is replaced with `SYS123_TCPIP2`
  - The value \$0 is replaced with `SYS123_TCPIP2`
  - The value \$1 is replaced with `SYS123`
  - The value \$2 is replaced with `TCPIP2`

In this example, the value \$0 is the same as the value \*, but this does not hold true for all regular expressions. If you want to use the entire client name as a replacement value, specify the value \*.

The matching hierarchy used is as follows:

- a. Exact match between the policy client name and the DynamicConfigPolicyLoad statement.
- b. Regular expression match between the policy client name and the DynamicConfigPolicyLoad statement. The longest matching regular expression is chosen. If multiple statements match with the same length *clientname* parameter, the statement chosen is based on alphabetical order.
- c. No matching statement. A default file is used based on the policy type, as follows:

**Policy type**

**Default file**

**AT-TLS**

`/etc/pagent_remote.ttls`

**IDS**

`/etc/pagent_remote.ids`

**IPSec**

`/etc/pagent_remote.ipsec`

**QoS**

`/etc/pagent_remote.qos`

**Routing**

`/etc/pagent_remote.routing`

**ZERT**

`/etc/pagent_remote.zert`

The following example shows the DynamicConfigPolicyLoad statement matching by using a regular expression to simulate a simple wildcard, and the resulting configuration files that are used, using IPSec policies.

```
DynamicConfigPolicyLoad Rem.*
{
 PolicyType IPSec
 {
 CommonPolicyLoad //'ETC.COMMON.IPSEC'
 PolicyLoad //'ETC.IPSEC(*)'
 }
}

DynamicConfigPolicyLoad Remote.*
{
```

```

PolicyType IPSec
{
 PolicyLoad /etc/*.ipsec
}
}

DynamicConfigPolicyLoad Remote5
{
 PolicyType IPSec
 {
 CommonPolicyLoad /user10/common_remote.ipsec
 PolicyLoad /user10/pagent_remote5.ipsec
 }
}

```

The resulting configuration files used for a variety of policy clients are shown in [Table 41 on page 839](#):

| <i>Table 41. Configuration files used for various policy clients</i> |                           |                                        |                                       |
|----------------------------------------------------------------------|---------------------------|----------------------------------------|---------------------------------------|
| <b>Policy client name</b>                                            | <b>Matching statement</b> | <b>Common IPSec configuration file</b> | <b>Image IPSec configuration file</b> |
| Remote1                                                              | Remote.*                  | None                                   | /etc/Remote1.ipsec                    |
| Remote5                                                              | Remote5                   | /user10/common_remote.ipsec            | /user10/pagent_remote5.ipsec          |
| Rem42                                                                | Rem.*                     | //'ETC.COMMON.IPSEC'                   | //'ETC.IPSEC(REM42)'                  |
| remote5                                                              | Not applicable            | None                                   | /etc/pagent_remote.ipsec              |

The following example shows the DynamicConfigPolicyLoad statement matching by using a more complex regular expression, and the resulting configuration files that are used, using IDS policies. The regular expression matches two strings separated by an underscore character. Each string must begin with an uppercase alphabetic character and end with a numeric character.

```

DynamicConfigPolicyLoad ^([A-Z].+[0-9]+)_([A-Z].+[0-9]+)$
{
 PolicyType IDS
 {
 CommonPolicyLoad //'ETC.COMMON.IDS'
 PolicyLoad //'ETC.$1($2)'
 }
}

```

The resulting configuration files used for a variety of policy clients are shown in [Table 42 on page 839](#):

| <i>Table 42. Configuration files used for various policy clients</i> |                                    |                                      |                                     |
|----------------------------------------------------------------------|------------------------------------|--------------------------------------|-------------------------------------|
| <b>Policy client name</b>                                            | <b>Matching statement</b>          | <b>Common IDS configuration file</b> | <b>Image IDS configuration file</b> |
| SYS42_TCPIP2                                                         | ^([A-Z].+[0-9]+)_([A-Z].+[0-9]+)\$ | //'ETC.COMMON.IDS'                   | //'ETC.SYS42(TCPIP2)'               |
| Remote1_Image5                                                       | ^([A-Z].+[0-9]+)_([A-Z].+[0-9]+)\$ | //'ETC.COMMON.IDS'                   | //'ETC.REMOTE1(IMAGE5)'             |
| SYS123_TCPIP                                                         | Not applicable                     | None                                 | /etc/pagent_remote.ids              |

**Rule:** The policy client names and DynamicConfigPolicyLoad statement names are case sensitive, but MVS data set names are not. Therefore, be careful when defining MVS data set configuration files that include a wildcard that is to be substituted with the policy client name. For example, the policy client names `client42` and `Client42`, if used as a substitution variable in an MVS data set name, would result in the same configuration file being used for both policy clients.

3. Configure one or more user IDs on the policy server system to match the user IDs of the policy clients.

Each policy client uses a unique client name, but also must present valid credentials to the policy server. Valid credentials include a user ID and password or a user ID and PassTicket (if secure signon is enabled).

**Rule:** The password defined for the user ID must match the password configured using the AuthBy Password parameter on the PolicyServer statement on the policy client.

A SAF user ID representing a policy client must be defined to the security product. The user ID must be defined with an OMVS segment. When RACF is used as the security product, define the SAF user ID with the following command:

```
ADDUSER client PASSWORD(password) DFLTGRP(OMVSGRP) OMVS(UID(x) HOME('/home/
client'))
```

Each policy client does not need to use a unique user ID, although that is a configuration option. The user ID is used for two purposes on the policy server:

- User authentication when the policy client connects to the policy server
- Access to SERVAUTH profiles to determine which policies the client can access

4. Permit Policy Agent to the BPX.DAEMON FACILITY class profile.

For information about the use of the BPX.DAEMON profile, see [“BPX.DAEMON FACILITY class profile” on page 37](#). If you decide to use this profile, permit the Policy Agent user ID to it. When RACF is used as the security product, permit the user ID with the following command:

```
PERMIT BPX.DAEMON CLASS(FACILITY) ID(userid) ACCESS(READ)
```

5. If you want to use PassTicket security for policy clients, configure PTKTDATA class profiles.

Policy clients can be configured to use either a password or a PassTicket on the PolicyServer statement, used when they connect to the policy server. For information about the secured signon function and PassTickets, see [z/OS Security Server RACF Security Administrator's Guide](#). If you choose to use PassTickets, define the appropriate profiles in the PTKTDATA class to contain the application key used to generate and validate the PassTicket. When RACF is used as the security product, define the profiles with the following command:

```
RDEFINE PTKTDATA profile SSIGNON(KEYMASKED(key)) UACC(UPDATE)
```

The application name used by Policy Agent is PAGENT, so you need to define a profile with this name. The application key defined in the profiles must be the same on the policy client and policy server.

6. If you want to use secure connections between policy clients and the policy server, configure AT-TLS rules on the policy server to enable SSL connections from the policy clients.

If policy clients use SSL connections, you must define AT-TLS rules on the policy server for communications between the policy client and server to be secured using AT-TLS. AT-TLS processing for a stack is enabled by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#).

**Rules:**

- Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with policy clients. Failure to restrict the cipher suites to those requiring encryption might result in sensitive information flowing in the clear across an untrusted network.
- Define AT-TLS policy for each stack through which policy server and policy client communication can flow.
- If some policy clients use SSL and others do not use SSL, define AT-TLS policy to select only those policy clients that use SSL.

**Result:** If you choose not to use SSL for your policy client to policy server connections, sensitive information flows in the clear on the connections. Sensitive information includes, but is not limited to, the following information:

- The password that is sent from the policy client to the policy server for authentication (if you are using password credentials)
- Policy information that is sent from the policy server to the policy client, such as:
  - Passwords
  - Certificate labels
  - IPSec keys for IKE tunnels that use pre-shared keys
  - IPSec keys for manual tunnels

**Requirement:** The policy server acts as the server during an SSL handshake. To act in the server role of an SSL handshake, the policy server must have access to a private key and certificate verifying its ownership of that private key. For information about creating and managing keys and certificates for servers that use AT-TLS, see [Appendix B, “TLS/SSL security,”](#) on page 1359.

An example of the AT-TLS policy statements used to enable AT-TLS for the policy server is as follows:

```

TTLRule
{
 LocalPortRange 16310
 JobName PAGENT
 Direction Inbound
 TTLGroupActionRef PolicyServerGroup
 TTLEnvironmentActionRef PolicyServerConn
}

TTLGroupAction
PolicyServerGroup
{
 TTLEnabled On
}

 V3CipherSuites TLS_RSA_WITH_AES_128_CBC_SHA
 V3CipherSuites TLS_DHE_RSA_WITH_DES_CBC_SHA
 V3CipherSuites TLS_DHE_DSS_WITH_DES_CBC_SHA
 V3CipherSuites TLS_DH_RSA_WITH_DES_CBC_SHA
 V3CipherSuites TLS_DH_DSS_WITH_DES_CBC_SHA
 V3CipherSuites TLS_RSA_WITH_DES_CBC_SHA
 V3CipherSuites TLS_RSA_WITH_RC4_128_SHA
 V3CipherSuites TLS_RSA_WITH_RC4_128_MD5
 V3CipherSuites TLS_RSA_EXPORT_WITH_RC2_CBC_40_MD5
 V3CipherSuites TLS_RSA_EXPORT_WITH_RC4_40_MD5
}

```

**Rule:** The LocalPortRange value on the TTLRule statement must include the value specified on the ClientConnection statement in the policy server main configuration file.

7. If you use secure connections between any policy clients and the policy server, permit Policy Agent to the EZB.INITSTACK.sysname.tcpname SERVAUTH class profile.

Because AT-TLS policies are used to enable SSL connections from policy clients, Policy Agent must be permitted to the EZB.INITSTACK.sysname.tcpname SERVAUTH class profile if any policy clients use SSL. For more details, see [“TCP/IP stack initialization access control” on page 1150](#). When RACF is used as the security product, permit Policy Agent to the profile with the following command:

```
PERMIT EZB.INITSTACK.sysname.tcpname CLASS(SERVAUTH) ID(userid) ACCESS(READ)
```

### Step 3: Configure Policy Agent as a policy client

You can use the Policy Agent as a policy client.

#### Procedure

If you want to use the Policy Agent as a policy client, perform the following steps:

1. Define the parameters needed to connect to the policy server using the ServerConnection statement in the main configuration file:

- Specify the host name (or IP address) and port of a primary and an optional backup server.
- If you want to use a secure connection to the policy server, specify parameters for a secure SSL connection. For details, see [“Add TLS/SSL to Policy Agent connections” on page 847](#).

**Requirement:** Connectivity to the policy server is required for all images on the policy client that need to connect to the policy server.

2. Define the policy server parameters to be used for each image on the PolicyServer statement in the image configuration files:

- When the policy client connects to the policy server, the policy client needs to supply a user ID and authentication information (password or PassTicket). Specify these parameters on the PolicyServer statement. The user ID must be defined on the policy server system. For information about the PTKTDATA class profiles that are needed when a PassTicket is specified on the PolicyServer statement, see step [“5” on page 840](#) in [“Step 2: Configure Policy Agent as a policy server” on page 837](#).
- The policy server determines what configuration files to load based on a matching DynamicConfigPolicyLoad statement in its configuration. Specify the client name that the policy server is to use for matching. If this parameter is not specified, the default value is the policy client's system name concatenated to the image name with an intervening underscore character (\_). For example, if the client's system name is SYS42 and the image name for this policy client is TCPIP2, the default client name presented to the policy server is SYS42\_TCPIP2.
- Specify the types of policies to be retrieved from the policy server. You can specify one or more policy types. You can also specify parameters for each policy type (FLUSH, NOFLUSH, PURGE, or NOPURGE). These parameters have the same meaning as the corresponding parameters on the TcpImage or PEPInstance statement.

For each policy type specified, the corresponding xxxConfig statement for that type is ignored in the local configuration. For example, if PolicyType IPSec is specified on the PolicyServer statement, the IPSecConfig statement is ignored. This is true even if the primary and backup policy servers cannot be reached. You can use local or remote policy for each policy type, but not both.

### Step 4: Configure policies in Policy Agent configuration files

Policies can be defined in any referenced Policy Agent configuration file. For more information, see the appropriate information for each policy type:

- Policy-based routing (See [“Policy-based routing” on page 377](#))
- Quality of Service (See [Chapter 15, “Quality of service,” on page 857](#))
- Intrusion detection services (See [Chapter 16, “Intrusion detection services,” on page 877](#))

- IP filtering, and manual and dynamic VPN tunnels, collectively referred to as IPSec policies (See Chapter 17, “IP security,” on page 911)
- Application Transparent Transport Layer Security (See Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149)
- zERT policy-based Enforcement (See “Defining a zERT enforcement policy” on page 198)

## Step 5: Configure Policy Agent to use the LDAP server using the ReadFromDirectory statement

The ReadFromDirectory statement in the Policy Agent configuration file initializes the Policy Agent as an LDAP client. The policies are downloaded from the LDAP server, along with the policies specified in the Policy Agent configuration files.

When configuring the ReadFromDirectory statement, first specify the name (or IPv4 address) and port of the primary server and the same for the backup server (if one is used).

### Notes:

1. The LDAP client library used to connect to the LDAP server does not support IPv6.
2. When using the z/OS LDAP server, the server listens on a separate port for SSL connections. This means that you should specify the correct port depending on whether or not SSL is used.

Next, configure other connection attributes. The Policy Agent (as an LDAP client) must log in to the LDAP server. The user ID and password for logging in must be configured on the ReadFromDirectory statement. The user ID is also known as Distinguished Name for user ID, and it is in the form of an LDAP DN. If the user ID and password are not specified, the Policy Agent uses anonymous login to connect to the server.

The LDAP server can be configured with only LDAP protocol version 3. To use LDAP protocol version 3, you can set LDAP\_ProtocolVersion to 3 on the ReadFromDirectory statement. This is the default value. This statement also configures the version of the schema to be retrieved from the server.

Finally, configure attributes to indicate how to search the LDAP server for policies. Policy roles allow one or more roles, or role-combinations, to be assigned to policy rules using the `ibm-policyRoles` attribute. These roles represent the intended usage of the policy rules. For example, a role of "East Coast WAN" might be used to represent policies for the wide area network on the US East coast for an enterprise. Policy role values are not standardized; they are simply values used to assign roles to policies. When an entity that requires policies (such as Policy Agent) requests policies from an LDAP server, it can filter out policy rules that do not match the roles that it plays. Although similar to policy keywords, which also allow search scoping, policy roles are a bit more sophisticated. Specifically, role-combinations are allowed, which take the form of a specification like "roleA && roleB", meaning both roleA AND roleB. Because the `ibm-policyRoles` attribute is multi-valued, a form of CNF/DNF logic can be used for policy roles: the roles in a role-combination are ANDed, and the roles or role-combinations specified on different values of this attribute are ORed.

For the Version 1 schema, a base DN to start the search, and a *selector tag* value are configured. The selector tag is used to match against the SelectorTag attribute in the policy objects. For Version 1, the Policy Agent also automatically includes the stack name when searching for policies; this value is matched against the TcpImageName attribute in the policy objects. For the Version 2 schema, a base DN to start searching is also configured. This DN can specify a single LDAP object, a policy group, or an LDAP subtree containing many objects. For filtering the search, three keywords can be configured:

- SearchPolicyKeyword matches against the `ibm-policyKeywords` attribute in any policy object.
- SearchPolicyGroupKeyword matches against the `ibm-policyGroupKeywords` attribute in policy group objects.
- SearchPolicyRuleKeyword matches against the `ibm-policyRuleKeywords` attribute in policy rule objects.

Optionally, specify parameters for a secure SSL connection. For details, see “Add TLS/SSL to Policy Agent connections” on page 847.

The example that follows this list takes the following actions:

- Connects to the LDAP server at IP address 9.100.1.1, using the default port 389.
- Specifies a user ID and password to log in to the server.
- Specifies LDAP protocol version 3.
- Specifies schema version 3.
- Starts searching at the DN ou=policy, o=IBM, c=US object/subtree.
- Selects only policy objects that contain either the "POLICY" or "EASTERN" keywords.

```
ReadFromDirectory
{
 LDAP_Server 9.100.1.1
 LDAP_DistinguishedName cn=root, o=IBM, c=US
 LDAP_Password 4qr56jb
 LDAP_ProtocolVersion 3
 LDAP_SchemaVersion 3
 SearchPolicyBaseDN ou=policy, o=IBM, c=US
 SearchPolicyKeyword POLICY
 SearchPolicyKeyword EASTERN
}
```

## Step 6: Configure Policy Agent for import services

You can connect an import requester to the Policy Agent to provide TCP/IP information import services.

### Procedure

To configure the Policy Agent for import services, perform the following steps:

1. Define the port and TCP/IP image name to which import requesters will connect.

If import requesters are to be used, the ServicesConnection statement in the main configuration file provides the port and TCP/IP image name that the Policy Agent listens on for remote connections. An import requester is one type of services requester provided for by the ServicesConnection statement. The Policy Agent listens for services requester connections on only one TCP/IP image. You can specify the image name to be used, or use the name specified (or specified by default) on the TCPIUSERID statement or TCPIPJOBNAME statement in TCPIP.DATA. If the default TCP/IP image cannot be determined, the Policy Agent uses the image name INET. In any case, the image name might or might not match an image name specified on a TcpImage statement:

- If the specified name does not match any TcpImage statement, the Policy Agent generates an internal TcpImage statement with default values to represent the TCP/IP image. This means that you can specify a maximum of only 7 (instead of 8) TcpImage or PEPInstance statements.
- In a single stack (INET) environment, the Policy Agent uses the active TCP/IP image to listen for services connection requests.

**Rule:** The ServicesConnection statement is required for any Policy Agent that accepts connections from an import requester.

**Guideline:** Reserve the port specified on the ServicesConnection statement using the PORT statement in the TCP/IP profile.

**Restriction:** The port value cannot match the port value configured on the ClientConnection statement.

2. Optionally configure secure connections from the import requesters.

- By default, the ServicesConnection statement defines a basic connection that is not explicitly secured. This option can be used for an unsecured connection, or you can define AT-TLS policies for this import services connection to create a secure SSL connection.
- You can define a secure connection instead, and specify the level of tracing and the TLS/SSL key ring to use. You must specify the name of a SAF key ring. Key ring files created by the System SSL gskkyman utility are not supported. When you configure a secure connection, Policy Agent automatically creates an AT-TLS policy for the connection, and the import requester must

also specify that the connection is to be secured. You must enable the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile for the generated AT-TLS policy to be effective.

**Tip:** This option only supports TLSv1.0 and TLSv1.1. It is not recommended for secure TLS/SSL. It is recommended for secure TLS/SSL to configure Security Basic and to supply user defined AT-TLS policies.

The following example shows a ServicesConnection statement for a secure connection:

```
ServicesConnection
{
 Port 17000
 ImageName TCPIP1
 Security Secure
 Trace 14
 Keyring PAGENT/PAGRING
}
```

The following AT-TLS policy is generated from this ServicesConnection statement:

```
TTLSRule TTLS_RULE_____GENERATED
{
 LocalPortRange 17000
 JobName PAGENT
 Direction Inbound
 TTLSGroupActionRef TTLS_GROUP_ACTION_____GENERATED
 TTLSEnvironmentActionRef TTLS_ENVIRONMENT_ACTION_GENERATED
}

TTLSGroupAction TTLS_GROUP_ACTION_____GENERATED
{
 TTLSEnabled On
 Trace 14
}

TTLSEnvironmentAction TTLS_ENVIRONMENT_ACTION_GENERATED
{
 HandshakeRole SERVER
 TTLSKeyRingParms
 {
 Keyring PAGENT/PAGRING
 }
}
```

The Policy Agent installs this generated policy in the TCP/IP image specified explicitly or by default on the ServicesConnection statement. This generated policy uses a priority value that is lower than any specified AT-TLS policies, so it is installed as the last policy in the TCP/IP image. If local or remote AT-TLS policies are configured, the Policy Agent installs those policies before installing the generated policy. If you configure AT-TLS policies on a policy server, those policies must be successfully retrieved before the Policy Agent is able to accept connections from services requesters. Accepting connections from services requesters can be affected by problems or delays in retrieving the AT-TLS policies from the policy server.

If you change the ServicesConnection statement, the generated policy is uninstalled or reinstalled as follows:

- If you change the Port, Trace or Keyring parameters, the Policy Agent regenerates and reinstalls the policy.
- If you change the ImageName parameter, the Policy Agent uninstalls the generated policy from the previous image and installs the policy on the new image.
- If you change the Security parameter value from Secure to Basic, the Policy Agent uninstalls the generated policy.

If you delete the ServicesConnection statement, the Policy Agent uninstalls the generated policy.

3. To restart the listen for services requester connections and, if required, to reinstall the generated AT-TLS policy, issue the MODIFY SRVLSTN command. For information about when you might use the MODIFY command, see [z/OS Communications Server: IP System Administrator's Commands](#).

## Step 7: Configuring Policy Agent to automatically monitor applications

You can use the Policy Agent to automatically start, stop, and monitor a set of related applications. Policy Agent starts the applications and monitors them to ensure that they remain active.

### Before you begin

If Policy Agent determines that any applications have not started or have stopped, it continues to try to start or restart the applications, up to a configurable retry limit within a configurable retry period.

**Requirement:** To automatically monitor applications, you must start Policy Agent with a user ID that has superuser authority UID(0). For sample RACF commands, see the EZARACF member of SEZAINST.

### Procedure

To configure the Policy Agent for automatic monitoring, perform the following steps:

1. Decide what applications you want to monitor.

You can use the Policy Agent to monitor any or all of the following applications:

- Defense Manager daemon (DMD)
- Internet Key Exchange daemon (IKED)
- Network security services daemon (NSSD)
- Syslog daemon (SYSLOGD)
- Traffic Regulation Management daemon (TRMD)

Determine which of these applications you currently use, or want to start using, in your environment, and for each application, determine whether you want the Policy Agent to start, stop, and monitor the application.

#### Requirements:

- To start the application, you must use a cataloged procedure that accepts a number of variables that are provided by the Policy Agent. A sample procedure is included in SEZAINST(EZAPOLPR).
- If you want to manually start, restart, or stop the application, you must use MODIFY commands that are directed to the Policy Agent. If you issue the commands directly to the application itself, Policy Agent is not aware of the action and the monitoring logic will probably not produce the expected results.

#### Results:

- If you start the Policy Agent after you have already started an application to be monitored, Policy Agent starts monitoring the application if it was originally started with the same job name that is configured to the Policy Agent. If the application needs to be restarted later, it is restarted using the cataloged procedure configured to the Policy Agent. This might not be the same procedure that was originally used to start the application.
- If you start the Policy Agent after you have already started an application to be monitored, but the application does not use the same job name that is configured to the Policy Agent, then the Policy Agent is not able to detect that the application is active. The Policy Agent will try to start another instance of the application, which is likely to fail.

**Tip:** If you configure applications to be monitored by the Policy Agent, ensure those applications are not running before starting the Policy Agent. However, you probably want to start syslogd before starting the Policy Agent, so you should ensure that Policy Agent is configured with the correct syslogd job name.

2. Configure the applications that you want to monitor using the AutoMonitorApps statement.

You can configure applications that you want to monitor that are or are not associated with a particular TCP/IP stack. You can specify the cataloged procedure used to start each application, the job name for the application, and other application-specific parameters on the AutoMonitorApps statement.

Perform the following steps to configure the applications that you want to monitor:

- a. Specify the AutoMonitorApps statement in the main Policy Agent configuration file.
  - Use the AppName parameter to specify each application that is not associated with a particular TCP/IP stack. All supported applications except TRMD fall into this category.
  - Use the TcpImageName and AppName parameters to specify each application that is associated with a particular TCP/IP stack. TRMD is the only application that falls into this category.
- b. Use the ProcName parameter for each AppName parameter on the AutoMonitorApps statement to specify the cataloged procedure that is used to start each application. Because all key data is passed to the procedure as variables, you can use a single procedure for all configured applications. You can also use a unique procedure for one or more applications.
- c. Use the Jobname parameter for each AppName parameter on the AutoMonitorApps statement to specify the job name for each application.
- d. Use the StartParms parameter for each AppName parameter on the AutoMonitorApps statement to specify start parameters for each application.
- e. Use one or more EnvVar parameters for each AppName parameter on the AutoMonitorApps statement to specify application-specific parameters, such as time zone or configuration file name. You can specify any or all environment variables that are accepted by the specific application.

The following example shows the AutoMonitorApps statement:

```
AutoMonitorApps
{
 AppName IKED
 {
 Procname POLPROC
 }
 AppName TRMD
 {
 TcpImageName TCPIP1
 {
 Procname POLPROC
 Jobname TRMD1
 }
 TcpImageName TCPIP3
 {
 Procname POLPROC
 Jobname TRMD3
 }
 }
}
```

This example shows how to specify parameters for two types of applications:

- An application without stack affinity, meaning that a single copy of the application runs regardless of how many TCP/IP stacks are running. This example uses IKED as such an application.
  - An application with stack affinity, meaning that one instance of the application runs on each TCP/IP stack. This example uses TRMD as such an application.
3. Configure global monitoring parameters using the AutoMonitorParms statement.

Use the AutoMonitorParms statement in the main Policy Agent configuration file to specify global monitoring parameters, such as the monitor time interval and retry limits.

- Use the MonitorInterval parameter to specify the monitor interval in seconds.
- Use the RetryLimitCount and RetryLimitPeriod parameters to specify how many times within a given time period Policy Agent should try to start or restart an application. If the application fails to successfully start or restart after the retry limit has been reached, Policy Agent stops trying until the application is manually started using the *MODIFY procname,MON,START,application* command.

## Add TLS/SSL to Policy Agent connections

The Transport Layer Security (TLS) protocol is defined by the Internet Engineering Task Force (IETF) in RFCs 2246, 4346, 5246, and 8446. TLS is based on the Secure Sockets Layer (SSL) protocol. The TLS/SSL protocol begins with a handshake. During the handshake, the client authenticates the server, the

server optionally authenticates the client, and the client and server agree on how to encrypt and decrypt information.

**Server Authentication:** When using TLS/SSL to secure communications, the TLS/SSL authentication mechanism known as server authentication is used. With server authentication, the server must have a digital certificate that authenticates the server to the Policy Agent client. The server supplies the client with the certificate during the initial TLS/SSL handshake. If the client validates the server's certificate, a secure communication channel is established between the server and the Policy Agent client.

For server authentication to work, the server must have a private key and associated server certificate in the server key ring file.

To conduct commercial business on the Internet, you might use a widely known Certificate Authority (CA), such as VeriSign, to get a high assurance certificate. For a relatively small private network within your own enterprise or group, you can issue your own certificates, called self-signed certificates, for your own use.

**Client Authentication:** When using TLS/SSL Client Authentication, the client passes a digital certificate to the server as part of the TLS/SSL handshake. To pass authentication, the Certificate Authority (CA) that signed the client certificate must be considered trusted by the server.

**Self-signed Server Certificates:** Normally, a server certificate should be obtained from a known CA. However, for testing, an installation might use a self-signed server certificate. Because the clients will not know about the issuer of the self-signed server certificate, in most cases it is necessary to add the server's self-signed certificate to the client's signer certificates.

The gskkyman utility can be used to create public/private key pairs and certificate requests, receive certificate requests into a key ring, and manage keys in a key ring. The gskkyman utility is documented in [z/OS Cryptographic Services System SSL Programming](#). The gskkyman utility is shipped with z/OS in System SSL, which is part of the cryptographic services base element of z/OS. For detailed instructions on setting up certificates and key rings, see [Appendix B, "TLS/SSL security," on page 1359](#).

The set of SSL protocol cipher specifications to be allowed for the secure session can be set for the policy server connection.

**Rule:** Define AT-TLS policy on the policy server such that only cipher suites requiring TLS encryption are exchanged with policy clients. Failure to restrict the cipher suites to those requiring encryption might result in sensitive information flowing in the clear across an untrusted network.

For the list of cipher suites supported and the default order used if none is specified, see [z/OS Cryptographic Services System SSL Programming](#).

The Policy Agent connection to LDAP can be secured using SSL by tailoring the following parameters on the ReadFromDirectory statement. This allows for protection of policy retrieval from an LDAP server.

- LDAP\_SSLKeyringFile
- LDAP\_SSLKeyringPassword
- LDAP\_SSLName

The policy client connection to the policy server can be secured using TLS/SSL by tailoring the following parameters on the ServerConnection statement. This allows for protection of policy retrieval from the policy server.

- ServerSSLKeyring
- ServerSSLKeyringPassword
- ServerSSLKeyringStashFile
- ServerSSLName
- ServerSSLV3CipherSuites
- ServerSSLV3CipherSuites4Char
- ServerSSLv3
- ServerTLSv1
- ServerTLSv1.1

- ServerTLSv1.2
- ServerTLSv1.3

You can secure the connection used by services requesters by creating AT-TLS policy rules for the services requestor and services provider. Configure Security Basic on the ServicesConnection statement.

For more detail about these parameters, see [z/OS Communications Server: IP Configuration Reference](#). Additional information about the concepts of cryptography and SSL can be found at the following websites:

- [http://httpd.apache.org/docs/current/ssl/ssl\\_intro.html](http://httpd.apache.org/docs/current/ssl/ssl_intro.html)
- <http://www.verisign.com/ssl/ssl-information-center/how-ssl-security-works/index.html>

## Starting and stopping the Policy Agent

---

You can start the Policy Agent in any of the following ways:

- From the z/OS shell

If you use the shell, start the Policy Agent in a background shell session by specifying a trailing & on the command line.

- As a started task
- Using the COMMNDxx member of parmlib

Using the COMMNDxx member of parmlib enables Policy Agent to be automatically started when the system is IPLed. For more information about COMMNDxx, see [z/OS MVS Initialization and Tuning Reference](#).

- In some cases, using the TCP/IP AUTOLOG statement

For more information, see [“AUTOLOG considerations” on page 849](#).

## AUTOLOG considerations

If a procedure in the AUTOLOG list also has a PORT statement reserving a TCP or UDP port but does not have a listening connection on that port, TCP/IP periodically attempts to cancel that procedure and start it again.

**Guideline:** Do not use AUTOLOG to start the Policy Agent if any listening connections are used. The Policy Agent is unlike typical servers, and performs functions outside the realm of listening for connections from other applications. Sometimes during normal operation of the Policy Agent, listening connections are unavailable for short periods of time. When listening connections are unavailable, it is possible that the AUTOLOG timer could restart the Policy Agent.

Policy Agent optionally listens on one or more of the following ports:

- The pagentQosListener port (usually defined in the /etc/services file as port 1700). This happens only when the PolicyPerfMonitorForSDR statement is configured for a given TCP/IP stack.
- The port defined or specified by default on the ClientConnection statement, which is used to listen for remote policy client connections on all TCP/IP stacks.
- The port defined or specified by default on the ServicesConnection statement, which is used to listen for services requester connections on a single TCP/IP stack. For information about the [ServicesConnection](#) statement and specifying which stack to use to listen for these connections, see [z/OS Communications Server: IP Configuration Reference](#).

If you want to start Policy Agent with AUTOLOG, you must take one of the following actions:

- Ensure that none of the listening ports used by Policy Agent are reserved by the PORT statement in the TCP/IP profile.
- Add the NOAUTOLOG parameter to the PORT statement in the TCP/IP profile. For example:

```
PORT
1700 TCP PAGENT NOAUTOLOG
16310 TCP PAGENT NOAUTOLOG
16311 TCP PAGENT NOAUTOLOG
```

In addition, when the PolicyPerfMonitorForSDR statement is being used, if the pagentQosCollector port (usually defined in the /etc/services file as port 1701) is reserved in the PORT list it should always be specified with the NOAUTOLOG parameter, because this port is never used as a listening port. For example:

```
PORT
1701 TCP PAGENT NOAUTOLOG
```

**Tip:** When Policy Agent is not listening on any ports, you can use the autostart feature of AUTOLOG as previously described. However, the monitoring and automatic restart features of AUTOLOG are unavailable because AUTOLOG must listen to a TCP or UDP connection.

If you fail to take one of the above actions, Policy Agent will be periodically canceled and restarted by TCP/IP.

## Specifying environment variables

The Policy Agent requires access to one or more DLLs at run time. The LIBPATH environment variable needs to be set to include the /usr/lib directory, which normally includes all the required DLLs.

For policy time specifications to be properly acted upon, the TZ environment variable needs to be set to local time. You can set the LIBPATH and TZ environment variables as follows:

- When starting from the z/OS shell:

Export the LIBPATH and TZ environment variables before starting the Policy Agent. This is best accomplished in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States:

```
export LIBPATH=/usr/lib
export TZ=EST5EDT
```

- When starting as a started task, use either of the following methods:

- Specify LIBPATH and TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:

```
// PARM=('ENVAR("LIBPATH=/usr/lib","TZ=EST5EDT")/')
```

- Export the LIBPATH and TZ environment variables in a file specified with the STDENV DD statement. For example:

```
// PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
//STDENV DD PATH='/etc/pagent.env',PATHOPTS=(ORDONLY)
```

In the /etc/pagent.env file:

```
LIBPATH=/usr/lib
TZ=EST5EDT
```

The use of the STDENV DD statement works well when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

You can also set the TZ environment variable for all applications in the CEEPRMxx PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

```
CEEEOPT(ALL31(ON), ENVAR('TZ=EST5EDT')))
CEEDOPT(ALL31(ON), ENVAR('TZ=EST5EDT')))
CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT')))
```

For more information on Using the CLER CICS transaction to display and set runtime options, see [z/OS Language Environment Programming Guide](#). For details on setting the LIBPATH and Format of the TZ environment variable environment variables, see [z/OS UNIX System Services Command Reference](#).

## Main configuration file search order

Although the /etc/pagent.conf is the default configuration file, a specific search order is used when starting the Policy Agent. The following order is used:

1. File or data set specified with the -c startup option
2. File or data set specified with the PAGENT\_CONFIG\_FILE environment variable
3. /etc/pagent.conf

The syntax for a z/OS UNIX file is different than the syntax for an MVS data set. The following examples use the PAGENT\_CONFIG\_FILE environment variable:

- PAGENT\_CONFIG\_FILE=/dir/file
- PAGENT\_CONFIG\_FILE=/'mvs.dataset.name'

## Other considerations when starting the Policy Agent

If you start the Policy Agent with a user ID that does not have superuser authority [UID(0)], then read and write permission is required for the following directories and files:

- Directories
  - /tmp/
  - /var/tmp/
- Files
  - Files created when you configure the PerformanceLogFile parameter on the PolicyPerformanceCollection statement

For information about the PolicyPerformanceCollection statement, see [z/OS Communications Server: IP Configuration Reference](#).

- Policy Agent log files

For information about using the -l parameter when [starting Policy Agent from the z/OS shell](#) to specify the destination for the log file, see [z/OS Communications Server: IP Configuration Reference](#).

- Policy Agent pid file

The /tmp/pagent.pid is a temporary file that the Policy Agent creates. This file contains the process ID of the current invocation of the Policy Agent.

### Restrictions:

- If /tmp/pagent.pid is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the Policy Agent.
- If /tmp/pagent.pid is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which /tmp/pagent.pid is stored cannot have write access to the directory. Additionally, write access to /tmp/pagent.pid must be limited to the owning UID or group, for example, --w--w---permissions.

**Requirement:** To automatically monitor applications, you must start Policy Agent with a user ID that has superuser authority UID(0). For sample RACF commands, see the EZARACF member of SEZAINST.

To ensure that only one Policy Agent is started, the Policy Agent uses the following enqueue:

- Enqueue name is TCP\_TCPI
- Resource name is TCPIP.PAGENT

When starting from the shell, note that the Policy Agent executable file is in the /usr/lpp/tcpip/sbin directory. There is also a link from the /usr/sbin directory. Make sure your PATH statement contains either the /usr/sbin or /usr/lpp/tcpip/sbin directory.

For example, the following command starts Policy Agent with these characteristics:

```
pagent -c /u/user10/pldap.conf -l SYSLOGD &
```

- Policy Agent uses the configuration file /u/user10/pldap.conf
- Policy Agent logs output to the syslog daemon (SYSLOGD). Note that "SYSLOGD" must be specified in uppercase to obtain this behavior

Use the S PAGENT command on an MVS console or SDSF to start the Policy Agent as a started task. A sample procedure is shipped in member EZAPAGSP in SEZAINST.

## Stopping the Policy Agent

You can stop the Policy Agent by:

- Using the operator command STOP
- Using the kill command in the z/OS shell
- Using the operator command CANCEL. Use the CANCEL command only as a last resort if the STOP or kill commands do not completely stop the Policy Agent.

**Result:** When the Policy Agent is shut down normally (KILL or STOP), if the PURGE option is configured, all QoS, IDS, and AT-TLS policies are purged from this stack. IPSec, Routing, and ZERT policies are not automatically purged.

The following kill command with the TERM signal will enable Policy Agent to clean up resources properly before terminating itself:

```
kill -s TERM pid
```

where pid is the Policy Agent process ID.

The Policy Agent process ID can be obtained using the following z/OS UNIX command:

```
ps -A
```

It can also be obtained from the /tmp/pagent.pid file. The /tmp/pagent.pid file is a temporary file created by the Policy Agent. It contains the process ID of the current invocation of the Policy Agent. This temporary file is deleted when the Policy Agent is stopped.

## Refreshing policies

The MODIFY command may be used to interactively cause the Policy Agent to reread the configuration information and, if requested, download objects from the LDAP server. In addition to this, the Policy Agent will also accept SIGHUP signals to perform the refresh function. See the [z/OS Communications Server: IP System Administrator's Commands](#) for more detailed information on the [MODIFY command](#).

## FLUSH and PURGE considerations

The FLUSH/NOFLUSH and PURGE/NOPURGE parameters can be configured for each policy type supported by the Policy Agent.

These parameters determine whether or not policies are deleted from the associated TCP/IP stack under certain conditions, as detailed in [Table 44 on page 853](#).

[Table 43 on page 853](#) shows where you configure these parameters for each type of local or remote policy.

| <i>Table 43. Where Policy Agent FLUSH and PURGE are configured</i> |                                                     |
|--------------------------------------------------------------------|-----------------------------------------------------|
| Policy type                                                        | Statement where configured                          |
| Local Routing and ZERT policies                                    | Not configurable (always support FLUSH and NOPURGE) |
| Local IDS policies                                                 | IDSSConfig or TcpImage/PEPInstance                  |
| Local IPSec policies                                               | Not supported                                       |
| Local QoS policies                                                 | TcpImage/PEPInstance                                |
| Local AT-TLS policies                                              | TTLSSConfig or TcpImage/PEPInstance                 |
| Remote policies (all types except IPSec, Routing, and ZERT )       | PolicyServer or TcpImage/PEPInstance                |

### Results:

- IPSec policies do not use these parameters. Instead, IPSec functions as though the FLUSH and NOPURGE parameters are always specified, with the exception that the FLUSH parameter has no effect when the MODIFY REFRESH command is entered.
- Parameters specified on the TcpImage/PEPInstance statement are overridden by parameters configured on other statements.

[Table 44 on page 853](#) shows the results of using the FLUSH and PURGE parameters.

| <i>Table 44. How Policy Agent FLUSH and PURGE are used</i> |                                                |                                                              |                                                                                                               |
|------------------------------------------------------------|------------------------------------------------|--------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------|
| Event                                                      | IPSec policies                                 | Routing and ZERT policies                                    | Other policies                                                                                                |
| Policy Agent start (FLUSH defined)                         | All policies are replaced in the TCP/IP stack. | All policies are deleted and reloaded into the TCP/IP stack. | All policies are deleted and reloaded into the TCP/IP stack.                                                  |
| Policy Agent start (NOFLUSH defined)                       | All policies are replaced in the TCP/IP stack. | All policies are deleted and reloaded into the TCP/IP stack. | All changed policies are updated in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack. |
| Policy Agent termination (PURGE defined)                   | TCP/IP stack policies are unchanged.           | TCP/IP stack policies are unchanged.                         | All policies are removed from the TCP/IP stack.                                                               |
| Policy Agent termination (NOPURGE defined)                 | TCP/IP stack policies are unchanged.           | TCP/IP stack policies are unchanged.                         | TCP/IP stack policies are unchanged. Deleted policies are not removed from the TCP/IP stack.                  |

| Table 44. How Policy Agent FLUSH and PURGE are used (continued) |                                                                                                   |                                                                                                                         |                                                                                                                         |
|-----------------------------------------------------------------|---------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------|
| Event                                                           | IPSec policies                                                                                    | Routing and ZERT policies                                                                                               | Other policies                                                                                                          |
| Policy Agent update (FLUSH defined)                             | If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack. | Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack. | Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack. |
| Policy Agent update (NOFLUSH defined)                           | If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack. | Any changed policies are replaced in the TCP/IP stack, and then all deleted policies are removed from the TCP/IP stack. | Any changed policies are replaced in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.          |
| Policy Agent refresh (FLUSH defined)                            | If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack. | If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.         | If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.         |
| Policy Agent refresh (NOFLUSH defined)                          | If there are any changed or deleted policies, then all policies are replaced in the TCP/IP stack. | If there are any changed or deleted policies, then all policies are deleted and reloaded into the TCP/IP stack.         | Any changed policies are replaced in the TCP/IP stack. Deleted policies are not removed from the TCP/IP stack.          |

#### Rules:

- The TCP/IP stack results do not apply for policy client policies configured on the policy server.
- The PURGE and NOPURGE parameters have no effect on policy client policies configured on the policy server.

**Result:** When a TCP/IP stack is recycled, the result is the same as if the FLUSH parameter was specified; all active policies are reinstalled into the stack.

## Switching between local and remote policies

If you dynamically switch from local policies to remote policies by adding the PolicyServer statement or a new PolicyType parameter within that statement, the FLUSH and PURGE parameters that are specified on the PolicyServer statement (or that are configured by default from the TcpImage statement) take effect, if the parameters are supported by the policy type.

Likewise, if you dynamically switch from remote policies to local policies by removing the PolicyServer statement or a PolicyType parameter from within that statement, the FLUSH and PURGE parameters that are specified on the xxxConfig statement (or that are configured by default from the TcpImage statement) take effect, if the parameters are supported by the policy type.

When the NOFLUSH parameter is used due to one of these dynamic switches, the result is that both the local and remote policies exist in the configuration; existing policies are not deleted when NOFLUSH is in effect, as shown in [Table 44 on page 853](#).

The following examples show how switching between local and remote policies works:

- Switching from local IDS to remote IDS policies:
  1. The TcpImage statement is configured with the FLUSH parameter.
  2. The IDSCfg statement is not configured with the FLUSH or NOFLUSH parameters, so the TcpImage FLUSH value is used.
  3. The local IDS policies are read and installed.

4. The PolicyServer statement is added with a PolicyType parameter for IDS that specifies the NOFLUSH value.
  5. The remote IDS policies are retrieved and installed.
  6. Because the NOFLUSH parameter is in effect (from the PolicyServer statement), the local IDS policies are not deleted; both the local and remote IDS policies exist.
- Switching from remote AT-TLS to local AT-TLS policies:
    1. The TcpImage statement is configured with the NOFLUSH parameter.
    2. The TTLSConfig statement is configured with the FLUSH parameter.
    3. The PolicyServer statement is configured with a PolicyType parameter for AT-TLS that specifies the FLUSH value.
    4. The remote AT-TLS policies are retrieved and installed.
    5. The PolicyType parameter for AT-TLS is removed from the PolicyServer statement.
    6. The local IDS policies are read and installed.
    7. Because the FLUSH parameter is in effect (from the TTLSConfig statement), the remote AT-TLS policies are deleted; only the local policies exist.

**Result:** Because the IPSec , Routing, and ZERT policy types always use the FLUSH value, the local and remote policies never exist at the same time.

## Verifying that policies are correctly defined and functioning properly

---

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies defined correctly to the LDAP server?

See the documentation appropriate for the LDAP server which you are using. LDAP servers usually allow you to install multiple files (LDIF), each containing different objects in the LDAP hierarchy. Structural objects higher in the directory tree must be installed before objects that are contained below them. Check for any error messages as each LDIF is installed. Some LDAP servers interpret two consecutive blank lines as end of file. Ensure that all of the objects in the LDIF have been installed by the LDAP server.

- Are the policies defined correctly to the Policy Agent?

When starting the Policy Agent, first check for any error messages issued to the console. Message EZZ8434I indicates something is wrong with the Policy Agent environment. Message EZZ8438I indicates a syntax or semantic error in the policy definitions. Messages EZZ8439I and EZZ8440I indicate a problem with the LDAP server configuration or the server itself. For more information on diagnosing Policy Agent problems, see *z/OS Communications Server: IP Diagnosis Guide*. Use the UNIX **pasearch** command to display policy definitions. The output from this command indicates whether or not policy rules are active, and shows the parsed results of the policy definition attributes. One thing to note is that the Policy Agent is designed to ignore unknown attributes, so misspelled attributes will result in default values being used. The **pasearch** output can be used to verify that policies are correctly defined.

---

## Chapter 15. Quality of service

Applications and users of IP networks have different requirements for the service they receive from those networks. A network that treats all traffic as best effort does not meet the needs of such users. *Service differentiation* is a mechanism to provide different service levels to different traffic types based on their requirements and importance in an enterprise network. For example, it might be critical to provide Enterprise Resource Planning (ERP) traffic better service during peak hours than that of FTP or web traffic. The overall service provided to applications or users, in terms of elements such as throughput and delay, is termed *Quality of service* (QoS). Network service providers that need to provide different QoS levels express their business goals in *Service Level Agreements* (SLAs). There are two types of service in IP networks that relate to QoS. The first is *Differentiated Services*, which provides QoS to broad classes of traffic or users, for example all outbound web traffic accessed by a particular subnet. The second is *Integrated Services*, which provides end-to-end QoS to an application, by reserving resources along a data path. For z/OS Communications Server, Integrated Services is largely provided by the RSVP Agent, which implements the Resource Reservation Protocol.

Workload distribution also relates to QoS, in terms of the throughput and delay characteristics of a given server in a sysplex. The ability to dynamically monitor server performance and affect sysplex workload distribution is an important part of the overall QoS of a sysplex. Also important is the ability to limit the set of target systems considered for sysplex routing based on network selection criteria, such as source subnet.

---

### Differentiated Services policies

Policies for Differentiated Services (DS) are used to select and control DS traffic for selected IP servers, such as FTP server traffic. The policy administrator selects the IP traffic to be controlled by defining policy rules. These policy rules include several attributes that can be specified to identify the traffic to be managed. These attributes fall into 2 categories, general attributes and application specified attributes. General attributes can be used to identify the IP traffic of most IP applications using a variety of information, such as:

- The source or destination IPv4 or IPv6 addresses or subnets
- The source and destination ports used by the application
- The IP protocol the application is using (TCP or UDP)
- The network interface selected for the outgoing traffic
- The jobname of the application

Application specified attributes allow policy administrators to identify outgoing application IP traffic based on information that is provided and defined by an application. For example, the IBM HTTP Server Powered by Domino provides the TCP/IP stack with the URI (Universal Resource Identifier) associated with any outgoing data being sent to a client. This allows the policy administrator to define rules that identify traffic related to specific URIs and policy actions with unique DS controls for this traffic. For example, an installation can define a policy that specifies preferential treatment of outgoing traffic related to the servicing of any URIs beginning with `/product/placeorder`. For more information on defining policy rules for the IBM HTTP Server Powered by Domino based on URIs, see *z/OS HTTP Server Planning, Installing, and Using* and the [Policy configuration files in z/OS Communications Server: IP Configuration Reference](#).

Any IP application using the TCP protocol can provide application specified attributes using extensions to the `sendmsg()` socket API. For more information, see the [programming interfaces](#) appendix in the *z/OS Communications Server: IP Programmer's Guide and Reference*. Application provided attributes can be specified in 2 forms:

- Application defined data: This allows applications to provide free-form text data that can be used to classify the application's outgoing traffic in terms that should be familiar to the application's administrator (for example, URIs are provided by the IBM HTTP server).

- Application specified priority: This allows applications to associate an application priority on the outgoing IP traffic. This application priority in itself does not automatically cause the application's traffic to get preferential treatment. In order to make use of these application specified priorities the policy administrator needs to define policy rules that map these priorities to policy actions that will govern the outgoing traffic of each priority level.

Applications can pass both application defined data and application specified priorities to the TCP/IP stack. When both are specified, the administrator is free to use either or both criteria in their service policy rules. However, it is strongly recommended that any policy rules defined using the application specified attributes should also include at least one general attribute that uniquely identifies the application instance. For example, when defining rules for the HTTP server using URIs, you can help further identify the application by specifying the source port for the server or the HTTP Server's jobname. This will help ensure that unauthorized applications cannot exploit policy actions intended for the HTTP Server.

Several aspects of connection and throughput control can be specified with DS policies, including the following specifications:

- TCP connection limits
- Maximum and minimum TCP connection rates, TCP maximum delay
- Committed access bandwidth (mean rate and peak rate) control/enforcement, also known as token bucket traffic shaping
- IPv4 type of service (ToS) byte or IPv6 traffic class setting, and mapping to System z QDIO or EQDIO device priorities and VLAN user priorities.

The above DS service attributes are enforced by the TCP/IP stack in which the DS policies are installed. For additional information on the enforcement of these attributes, see [z/OS Communications Server: IP Configuration Reference](#).

Token bucket traffic shaping is defined using the following parameters:

- DiffServInProfileRate is the average or mean rate that you want to transmit over time. For example, 256 kilobits per second.
- DiffServInProfileTokenBucket is the *burst* size. This is how much data is allowed to be sent from the application to TCP/IP and still be allowed to be transmitted at the mean rate. It is suggested, if the application is not policing itself, that this burst size be at least one second's worth of data. Otherwise, if the application is sending large amounts of data at one time to TCP/IP, TCP/IP will slow that application down via congestion windows, and the mean rate may not be achieved.
- DiffServInProfilePeakRate is the highest rate that is allowed to be transmitted for a shorter interval of time. For example, though a customer might want on average only 256 Kb of data per second, they might allow a peak of 512 Kb of data for 1/4 second. The peak rate is used to control the spacing of outbound packets on the transmission line. By having a smaller peak rate, there will be longer spacing between packets, and thus less burstiness of traffic and increased efficiency. Higher peak rates result in shorter spacing and increased burstiness, which can result in lower link usage. However, some applications may require it, such as real time or video data.
- DiffServInProfileMaxPacketSize is the amount of data that will be policed at the peak cell rate. For example, if the peak rate is 512 Kb per second, and the maximum packet size is 120 Kb, TCP/IP will allow only about 10 packets of size 1492 bytes to be transmitted every .23 seconds. Again, if an application is sending large amounts of data at one time to TCP/IP, TCP/IP will enforce the peak rate, and anytime more than 10 packets are sent within .25 seconds, TCP/IP will begin to slow this TCP connection. The peak rate can be achieved over a longer period of time if the maximum packet size is entered in larger multiples of packets. However, this will cause greater burstiness as described above. For example, if the maximum packet size is entered as 240 Kb, TCP/IP will allow 20 packets in a .23 second range before enforcing slowdown.

Note that the peak rate cannot be enforced without mean rate policing. However, you can enforce mean rate without peak rate. Also, setting of these parameters depends on the type of applications and the network that carries it.

## Integrated Services policies

---

Integrated Services (RSVP) policies are used to set limits on certain parameters requested by RSVP applications. These applications interact with the RSVP Agent to establish resource reservations along a network path, using the RSVP API (RAPI). The reservation requests are in the form of an entity known as a Traffic Specification, or Tspec, which consists of the following values:

- Token bucket mean rate (r)
- Token bucket depth (b)
- Peak rate (p)
- Minimum policed unit (m)
- Maximum packet size (M)

RSVP policies can be used to limit the values requested for (r) and (b), as well as limiting the total number of RSVP reserved flows. The RSVP service attributes are enforced by the RSVP agent which gets RSVP policies from the Policy Agent. For additional information on the enforcement, see [z/OS Communications Server: IP Configuration Reference](#) or RFC 1363.

## Sysplex distributor policies

---

Sysplex distributor (SD) policies are used to specify a set of SD target nodes for a given set of traffic. For example, all traffic destined to a given port or application from a specified subnet can be assigned one group of SD target nodes, while traffic for the same port or application from another subnet can be assigned to a different group of target stacks. These policies can be used in conjunction with other sysplex distributor controls to assist in load balancing. For more information, see [“Policy interactions” on page 513](#).

## QoS-specific Policy Agent functions

---

In addition to supporting the various types of policies, the Policy Agent performs functions related to the sysplex distributor. The Policy Agent can be configured to collect network QoS performance data relevant to SD on behalf of policies defined for a target port or application, and assign a default QoS weight fraction to such policy traffic. This weight is then used by SD (in conjunction with weights assigned by the Workload Manager) to assist in load balancing decisions. This function is performed by the Policy Agent on SD target nodes within the sysplex.

The Policy Agent also supports load distribution by service level. Performance data is kept for each Policy Action (service level) that a target's DVIPA port or application supports. A Policy Action weight fraction is generated. If available, this weight is used (instead of the default QoS weight fraction) in conjunction with the Workload Manager weight to assist in load distribution decisions for traffic assigned to this service level. If the Policy Action weight fraction is unavailable, the sysplex distributor will continue to use the default QoS weight fraction.

Another function related to policy performance is the performance collection function. When so configured, the Policy Agent collects policy performance data from the stack and caches it. This performance data is then made available to user applications through the Policy API (PAPI), for near real-time performance monitoring applications. The data are also optionally logged to a performance log file for offline performance monitoring. Sample C applications are provided to show how to use the PAPI interfaces to access performance data, and how to access and read the performance log file.

Policy performance data collected is affected by the FLUSH or NOFLUSH parameter on the Policy Agent TcpImage statement that defines the corresponding stack that is collecting the data. When FLUSH is specified, policies are deleted at the following times:

- When a new TcpImage statement is processed for the first time, including Policy Agent starting. This should not be a concern in most cases.
- When a MODIFY REFRESH command is entered.

As a result, all previously collected metrics start again from 0 when the policies are reinstalled. Conversely, policies are never deleted when NOFLUSH is specified, so performance metrics are never reset to 0.

Sysplex distributor policy performance monitoring and policy performance collection are similar in some respects but distinctly different in others:

- Sysplex distributor policy performance monitoring is actively performed by the Policy Agent. This performance monitoring is used only to assist with load balancing in a sysplex distributor environment.
- Policy performance collection is performed without regard to whether or not the Policy Agent is running in a sysplex distributor environment. Also, the Policy Agent does not actively participate in performance monitoring, only making the performance data available to user applications that perform the actual monitoring.

Policy performance data might not immediately change when changes are made to policy definitions. Some of the performance metrics are average values, and some are smoothed over several sampling intervals. As a result, when making changes to policies, some period of time will need to elapse before a new steady state is achieved.

Another function supported by the Policy Agent is to map IPv4 type of service (ToS) byte or IPv6 traffic class values to outbound interface priority values for outbound traffic. The ToS byte is also referred to as the Differentiated Services (DS) byte as an alternative definition (see RFC 2474). Note that outbound interface priority values are meaningful only for OSA interfaces. A set of mappings can be defined to cover various ToS byte or traffic class values and map them to an appropriate interface priority. All outbound packets over the associated interfaces with a given ToS byte or traffic class value will then be assigned the corresponding priority value. ToS byte or traffic class values can also be mapped to Virtual LAN (VLAN) user priorities for propagation over LANs directly connected through the OSA feature.

**Note:** Coding the virtual LAN (VLAN) user priority causes a frame to be sent out based on the IEEE 802.1Q specification, which establishes a standard method for tagging Ethernet frames with VLAN priority and membership information. Specifically, a VLAN priority-tagged frame is used to convey packet priority to the switches; it has a value of NULL for VLANID. A full VLAN-tagged frame contains both the priority and non-null VLANID. If you have switches in your network that do not support the IEEE 802.1Q standard or that are not properly configured for these types of frames, the frames might be dropped by the switch.

## Sysplex distributor policy performance monitoring configuration

Before activating the sysplex distributor policy performance monitoring function, see [“Policy interactions” on page 513](#) for information on workload balancing and policy interactions with sysplex distributor.

The following example illustrates how to activate the policy performance monitoring function for sysplex distributor.

**Note:** This function is activated on SD target servers and is used to monitor the performance of outbound traffic being serviced by the target servers. The goal is to detect TCP traffic that exceeds defined thresholds for dropped packets or time-outs, and derive a default QoS weight fraction for the target server. This default QoS weight fraction is then used to reduce the WLM weight assigned to the target servers, so that the SD distributing stack can take QoS performance into account.

The following statements apply to the example in this topic:

- The policy performance monitoring sampling interval is 60 seconds.
- Policy Agent assigns a loss ratio weight fraction of 25% when the TCP loss ratio (dropped packets to total packets) starts to exceed 2%.
- The loss ratio weight fraction is increased to 50% when the loss ratio starts to exceed 4%, continuing in this manner up to the maximum loss ratio weight fraction of 95%.
- In a similar manner, a TCP timeout weight fraction of 50% is assigned when the timeout ratio starts to exceed 5%, increasing up to a maximum timeout weight fraction of 100%.
- The loss ratio weight fraction and TCP timeout weight fraction are added together to form a single default QoS weight fraction for the target server, up to a maximum of 100%. When the Traffic Regulation

policy connection limit reaches constrained threshold (90%), the default QoS weight fraction is set to 100% and forces SD to route requests to other target nodes with better routing weights.

- The default QoS weight fraction is used at the SD distributing stack to reduce the WLM weight. For example, if the WLM weight is 40, a weight fraction of 50% results in the weight being reduced to 20.
- The traffic to be monitored must be represented by at least one Differentiated Services policy defined for the target application (in this example a policy is defined for Telnet).
- An additional Policy Action weight fraction is calculated for a target's DVIPA/Port if there are any active connections to the target using that service level.

The Policy Action weight fraction is calculated as the largest of three fractions:

- The number of active connections to this target DVIPA/Port will be compared with the maximum connections allowed for this Policy action.
    - When the number of active connections reaches 50% of maximum connections, then the Policy Action weight fraction will be set to MAX (50%, current calculated value).
    - When the number of active connections reaches 65% of maximum connections, then the Policy Action weight fraction will be set to MAX (85%, current calculated value).
    - When the number of active connections reaches 80% of maximum connections, then the Policy Action weight fraction will be set to 100%.
  - The throughput rate for this timer interval will be calculated and compared to the DiffServ mean rate of this Policy action. If the throughput rate is greater than 85% of the DiffServ mean rate, the average throughput rate per connection will be calculated. If the throughput rate per connection is less than the DiffServ min rate, the minimum throughput requirement per connection is not being met and the Policy Action weight fraction will be set to 100%.
  - The default QoS weight fraction.
- Only one policy rule and policy action are defined here.

As a result, only Telnet QoS performance information is monitored by the Policy Agent for sysplex distributor to route incoming Telnet connections to this target node relative to other target nodes which presumably can also accept Telnet requests.

```
PolicyPerfMonitorForSDR enable
{
 samplinginterval 60
 LossRatioAndWeightFr 20 25
 TimeoutRatioAndWeightFr 50 50
 LossMaxWeightFr 95
 TimeoutMaxWeightFr 100
 MaxConnWeightFr 50 65 80
}
```

```
policyAction telnetGold
{
 MinRate 500 # Provide minimum rate of 500 Kbps.
 OutgoingTOS 10100000 # the TOS value of outgoing telnet packets.
}

policyRule targettelnet
{
 ProtocolNumberRange 6
 SourcePortRange 23
 policyactionreference telnetGold
}
```

## Policy performance collection configuration

The following example shows how to activate the policy performance collection function. Policy performance data for all active policies is maintained by the TCP/IP stack. This function allows this data to be collected and made available for policy performance monitoring applications. The following statements apply to the example in this topic:

- Performance data is collected for both rules and actions. Action data is an aggregate of the data for the rules that refer to the action. For policies that have a single action per rule, the performance data will be the same for both the rule and action.
- The default minimum sampling interval is 30 seconds. This is the minimum value accepted for the acceptableCachedTime parameter on the PAPI papi\_get\_perf\_data() function that gets performance data.
- Performance data will be logged to the file /u/user10/perflog, based on a sampling interval of 60 seconds.
- The number of performance log files maintained is 10, each of which is the default 300 kilobytes in size. In this example, the log files will be named assuming a stack name of TCPCS:

```
/u/user10/perflog.TCPCS
/u/user10/perflog.TCPCS.1
/u/user10/perflog.TCPCS.2
:
/u/user10/perflog.TCPCS.9
```

- Each performance data record is 232 bytes, so a file size of 300 kilobytes can contain 1324 records. Because 10 files are maintained, the total set of log files can contain 13240 records. Assuming that 50 policy rules and actions exist in the configuration, this means that the set of log files will wrap in approximately 4.4 hours, according to the following formula:

```
number of records (13240) / number of policies (50) = number of refresh cycles (264)
number of refresh cycles (264) * refresh interval in minutes (1) = 264 minutes worth of data
```

```
PolicyPerformanceCollection Enable
{
DataCollection Rule Action
LogSamplingInterval 60
PerformanceLogFile /u/user10/perflog
NumberOfLogFiles 10
}
```

## IPv4 type of service or IPv6 traffic class mapping configuration

There are two mappings provided by the SetSubnetPrioTosMask statement:

- IPv4 type of service (ToS) or IPv6 traffic class to device priority

Quality of service (QoS) support in z/OS Communications Server allows the IPv4 ToS byte, also known as the Differentiated Services (DS) field, or the IPv6 traffic class to be set for outbound IP packets according to defined policies managed by the z/OS Communications Server UNIX Policy Agent. When IP packets are sent out over OSA devices, the ToS/DS or traffic class value is mapped to a OSA priority value. Device priority values are 1-4, where 1 is the highest priority.

- IPv4 ToS or IPv6 traffic class to VLAN user priority

ToS/DS or traffic class values can be mapped to user priorities for directly attached LANs using an OSA feature. VLAN user priority values are 0-7, where 7 is the highest priority. This allows assigned user priorities to be propagated through such networks, resulting in no loss of priority information for data being served by z/OS.

See [z/OS Communications Server: IP Configuration Reference](#) for more detail on these statements.

The following example shows a mapping of various ToS byte or traffic class values to associated interface priority values. Note that the mapping can be applied to individual interfaces or all interfaces:

- The first example defines a mapping for a specific interface. Note that the specified interface must be a valid interface specified in the HOME list. The second example shows a different mapping for all other interfaces.
- The subnet mask defines the bits in the ToS byte or traffic class that are significant. These examples use the leftmost 3 bits.

- The first example shows a set of mappings defining the complete set of ToS byte or traffic class values and the device and VLAN user priorities to be assigned for each value.
- The second example shows a set of mappings defining the complete set of ToS byte or traffic class values and the device priority to be assigned for each value.

```
SetSubnetPrioTosMask
{
 SubnetAddr 10.10.1.5
 SubnetTosMask 11100000
 PriorityTosMapping 1 11100000 7
 PriorityTosMapping 1 11000000 7
 PriorityTosMapping 2 10100000 6
 PriorityTosMapping 2 10000000 5
 PriorityTosMapping 2 01100000 5
 PriorityTosMapping 3 01000000 3
 PriorityTosMapping 4 00100000 2
 PriorityTosMapping 4 00000000 0
}
SetSubnetPrioTosMask
{
 SubnetTosMask 11100000
 PriorityTosMapping 1 11100000
 PriorityTosMapping 1 11000000
 PriorityTosMapping 1 10100000
 PriorityTosMapping 1 10000000
 PriorityTosMapping 2 01100000
 PriorityTosMapping 2 01000000
 PriorityTosMapping 3 00100000
 PriorityTosMapping 4 00000000
}
```

## Options for configuring QoS

You configure QoS using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the QoS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

### Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create QoS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are four types of reusable objects:

- Traffic descriptors that define the local application by describing the TCP traffic with ports or identifying the application using its job name.
- Priority levels that define the level of network priority or type of service (ToS).
- Traffic shaping levels that define settings to enforce specific traffic thresholds.
- Requirement maps that map traffic descriptors to priority levels and traffic shaping levels. A single requirement map should contain a complete set of QoS requirements that will govern the level of service for multiple IP traffic types.

For each TCP/IP stack, you select a requirement map that provides QoS for the stack.

The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors, priority levels, traffic shaping levels and requirement maps that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create QoS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing QoS.

This information primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and QoS function.

## Option 2: Manual configuration

You can manually create the QoS policy configuration files by coding all of the required statements in a file. There are a large number of configuration options provided by QoS policy statements that permit advanced users to carefully fine-tune QoS policy on a per-stack basis. This information describes the procedure for creating a QoS policy by manually creating and editing the configuration files. For details about the [QoS policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Specifying the QoS configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see [“Policy types and infrastructure overview” on page 813](#). Regardless of which option is used to configure QoS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves QoS policies from the policy server, specify the configuration files using the `DynamicConfigPolicyLoad` statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve QoS policies from the policy server, specify the configuration files using the `QOSConfig` statement on the policy client, or configure the QoS policies directly in the image file specified on the `TcpImage` statement.
- If you are not using a policy client/policy server environment, specify the configuration files using the `QOSConfig` statement on the single Policy Agent, or configure the QoS policies directly in the image file specified on the `TcpImage` statement.

When specifying configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

## Defining policies in a Policy Agent configuration file

---

Configure the following statements in the configuration file to define policies:

- [enforcement of these attributes](#)
- [PolicyRule](#)

See [z/OS Communications Server: IP Configuration Reference](#) for more information about these [Policy configuration files](#).

The following subtopics contain examples of these tasks.

**Note:** These examples are for illustrative purposes only. The policies deliberately use a wide variety of attributes, and they do not necessarily represent real-world usage. Some examples show continued and indented statements that were modified to fit within the margin and therefore are not an actual representation of correct syntax.

## Differentiated Services policy examples

The goal of this Differentiated Services policy is to map a subset of the traffic outbound from an FTP server.

This policy is identified as a Differentiated Services policy by the PolicyScope DataTraffic attribute on the PolicyAction statement, as well as the use of several DS-only attributes.

The following statements apply to the example in this topic:

- The policy rule selects traffic originated by ports in the range 20-21 (FTP outbound data connection uses port 20) from the source address 200.50.23.11.
- The policy rule is active on weekdays between 6 a.m. and 10 p.m. local time, between the dates 7/1/2000 and 7/1/2005..
- The policy action specifies that the ToS byte be set to '10000000' for traffic that conforms to this policy.
- The action establishes a *token bucket* traffic conditioner with a mean rate of 256 kilobits per second, a peak rate of 512 kilobits per second, and a burst size of 64 kilobytes. Any traffic that exceeds these specifications will be sent as *best effort*, with an accompanying ToS byte of '00000000'.

```

PolicyRule diffServ
{
 ProtocolNumberRange 6
 SourceAddressRange 200.50.23.11
 SourcePortRange 20-21
 PolicyActionReference tokenbucket
 PolicyRulePriority 10
 ConditionTimeRange 20000701000000:20050630235959
 DayOfMonthMask 1111111111111111111111111111
 DayOfWeekMask 01111110
 TimeOfDayRange 06:00-22:00
}
PolicyAction tokenbucket
{
 PolicyScope DataTraffic
 OutgoingTOS 10000000
 DiffServInProfileRate 256 # 256 Kbps
 DiffServInProfileTokenBucket 512 # 512 Kbits
 DiffServInProfilePeakRate 512 # 512 Kbps
 DiffServInProfileMaxPacketSize 120 # 120 Kbits
 DiffServOutProfileTransmittedTOSByte 00000000
 DiffServExcessTrafficTreatment BestEffort
}

```

The goal of this policy is to ensure that outgoing data that match the specified attributes will be assigned a QoS service level defined in action "interactive1".

The following statements apply to the example in this topic:

- This rule will match traffic only on TCP connections (protocol 6) with a source port of 80 (i.e. HTTP server) and application defined data beginning with the string "/catalog".
- Because we are dealing with HTTP traffic, this rule is basically indicating that all outgoing traffic associated with a URI that begins with "/catalog" should be managed using the DS characteristics specified in the "interactive1" policy action.

```

PolicyRule web-catalog # web catalog traffic
{
 protocolNumberRange 6
 SourcePortRange 80
 ApplicationData /catalog
 policyActionReference interactive1
}

PolicyAction interactive1
{
 policyScope DataTraffic
 outgoingTOS 10000000
}

```

## RSVP policy example

The goal of this RSVP policy is to establish limits on resource reservations requested by RSVP applications using the RSVP API (RAPI) interface. The policy is identified as an RSVP policy by the PolicyScope attribute on the PolicyAction statement, as well as the use of RSVP-only attributes.

The following statements apply to the example in this topic:

- The policy rule selects traffic from source ports in the range 8000 to 8001, with a protocol ID of 6 (TCP).
- The DataTraffic policy action specifies that the ToS byte be set to 01100000 for differentiated services traffic that conforms to this policy. Essentially, any traffic sent by the target application without an RSVP reservation in place will use this policy action. After an RSVP reservation is in place, the RSVP action gets used.
- The RSVP policy action specifies that the ToS byte be set to 01100000 while an RSVP reservation is in place. It also limits the type of RSVP service requested by RSVP applications to Controlled Load. Applications requesting Guaranteed service are downgraded to using Controlled Load service. In addition, the action limits the mean rate and token bucket size to 50000 bytes per second and 6000 bytes, respectively. These values are requested by RSVP applications in the traffic specification, or Tspec.
- The action also limits the number of active RSVP flows that map to this policy to 10.

```

PolicyRule intserv
{
 SourcePortRange 8000 8001
 ProtocolNumberRange 6
 PolicyActionReference intserv1
 PolicyActionReference intserv2
}
PolicyAction intserv1
{
 PolicyScope DataTraffic
 OutgoingTOS 01100000
}
PolicyAction intserv2
{
 PolicyScope RSVP
 OutgoingTOS 01100000
 FlowServiceType ControlledLoad
 MaxRatePerFlow 400 # 50000 bytes/second
 MaxTokenBucketPerFlow 48 # 6000 bytes
 MaxFlows 10
}

```

## Sysplex distributor policy example

The goal of this sysplex distributor policy is to limit the number of SD target stacks for inbound Telnet traffic. The policies are identified as SD policies by the ForLoadDistribution TRUE attribute on the PolicyRule statement. The corresponding policy on the target is also shown.

The following statements apply to the example in this topic:

- Separate policies are defined on the sysplex distributor distributing and target stacks.
- The policy rules select incoming Telnet connection requests.
- The selected target stack will be based on WLM information and QoS information if activated at the target stacks.
- The rule (disttelnet) is coded on the distributing stack to select inbound traffic destined to the Telnet server.
- The rule (targettelnet) is coded on the target stack to select outbound data from the Telnet server.
- If none of the specified target stacks is available to service incoming requests (either the node is down or the Telnet server is not active), then sysplex distributor will distribute the requests to any available target stack.

**Result:** If the OutboundInterface 0.0.0.0 statement (for IPv4) and the OutboundInterface :: statement (for IPv6) are not present, and the defined target stacks are not available, sysplex distributor rejects the request.

```

policyAction telnetGold
{
 MinRate 500 # Provide minimum rate of 500 Kbps.
 OutgoingTOS 10100000 # the TOS value of outgoing telnet packets.
}

```

```

 outboundinterface 129.100.11.1

```

#### Notes:

1. The ApplicationName attribute is valid only for a target rule and should not be coded on a distributor rule because the application name determined for inbound traffic (which is always the case on a distributor) will always be the stack's TCP jobname.
2. If you are using Telnet with multiple stacks in conjunction with the sysplex distributor, see [Chapter 11](#), “Accessing remote hosts using Telnet,” on page 593 for more information.

## Defining policies using LDAP

For information about defining QoS policies using LDAP, see [“Defining QoS policies using LDAP”](#) on page 1419.

## RSVP

Resource ReSerVation Protocol (RSVP) is a protocol that provides a mechanism to reserve resources in support of Integrated Services. The z/OS UNIX RSVP agent provides the following services on behalf of applications that want to use Integrated Services:

- An RSVP API (RAPI) that allows applications to explicitly request RSVP services. Using RAPI, applications indicate their intent to send or receive data, describe the characteristics of the data traffic and request that RSVP reserve resources along the data path to provide a given QoS to one or more traffic flows. For more information about RAPI, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).
- Mapping of IP ToS settings to RSVP traffic, using policies defined for RSVP.
- Support for VIPA addresses as well as real IP addresses.
- Communication with other RSVP agents on hosts and routers in the network to communicate application resource reservation requests.

Network administrators can use the z/OS UNIX Policy Agent to define RSVP-specific policies. These policies can be used to limit the parameters of application-requested resource reservations, provide ToS mappings for RSVP traffic, and limit the number of traffic flows that can use RSVP services simultaneously.

RSVP is designed to be implemented on both end systems (hosts) and routers. Different functions are provided by RSVP in these two environments. The z/OS RSVP agent is supported as a host RSVP implementation only. It can communicate with router RSVP implementations, but is not itself supported as such. For more information about RSVP, see RFC 2205.

## Configuring the RSVP agent

To configure the RSVP agent, update the configuration file to specify RSVP agent operational parameters using the `LogLevel`, `TcpImage`, `Interface` and `RSVP` statements. See [z/OS Communications Server: IP Configuration Reference](#) for detailed information about the statements.

To start the RSVP agent, you must first authorize the RSVP Agent using the security product. See `SEZAINST(EZARACF)` for SAF considerations for started tasks.

The following example is an RSVP configuration file. This example:

- Runs the RSVP Agent on the stack selected using the standard resolver search order, because a `TcpImage` statement is not configured.
- Disables RSVP processing on interface 10.11.12.13, while enabling it for all other interfaces.
- Disables traffic control on interface 200.1.1.1. This means that no reservations will be made on this interface.
- Allows a maximum of 50 active RSVP flows per interface.

```
Interface 10.11.12.13 Disabled
{}
Interface 200.1.1.1 Enabled
{
TrafficControl Disabled
}
Interface Others Enabled
{}
Rsvp All Enabled
{
MaxFlows 50
}
```

## Starting and stopping RSVP

RSVP can be started from the z/OS shell or as a started task.

The RSVP agent uses the following search order to locate the configuration file (highest priority is listed first):

- z/OS UNIX file or MVS data set specified by the `-c` startup option. The syntax for a z/OS UNIX file is `'/dir/file'`, and the syntax for an MVS data set is `"//MVS.DATASET.NAME"`.
- z/OS UNIX file or MVS data set specified with the `RSVPD_CONFIG_FILE` environment variable.
- `/etc/rsvpd.conf` z/OS UNIX file.
- `'hlq.RSVPD.CONF'` MVS data set.

**Note:** If this file is not present, RSVP is enabled on all network interfaces with default parameters.

When starting from the shell, note that the RSVP executable file is in the `/usr/lpp/tcpip/sbin` directory. There is also a link from the `/usr/sbin` directory. Make sure your path statement (in the profile) contains either the `/usr/sbin` or `/usr/lpp/tcpip/sbin` directory.

Use the `S RSVPD` command on an MVS console or SDSF to start RSVP as a started task. A sample procedure is shipped in member `EZARSVPP` in `SEZAINST`.

The `/tmp/rsvpd.pid.tcpname` is a temporary RSVP daemon pid file that the RSVP daemon creates. This file contains the process ID of the current invocation of the RSVP daemon.

### Restrictions:

- If `/tmp/rsvpd.pid.tcpname` is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the RSVP daemon.
- If `/tmp/rsvpd.pid.tcpname` is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which `/tmp/rsvpd.pid.tcpname` is stored cannot have write access to the directory. Additionally, write access to `/tmp/rsvpd.pid.tcpname` must be limited to the owning UID or group, for example, `--w--w----` permissions.

RSVP can be stopped using the cancel command (C RSVPD) or using the kill command in the z/OS shell. The following kill command with the TERM signal will enable RSVP to clean up resources properly before terminating itself:

```
kill -s TERM pid
```

where *pid* is the RSVP process ID.

The RSVP process ID can be obtained using the following z/OS UNIX command:

```
ps -A
```

It can also be obtained from the `/tmp/rsvpd.pid.tcpname` file. See [z/OS Communications Server: IP Configuration Reference](#) for more information.

## SNMP Network SLAPM2 (nslapm2) performance monitor

The SLAPM2 subagent provides information about defined service policies and performance data for applications that are mapped to those policies. Statistics are retrieved by this subagent and monitored for possible Network SLAPM2 performance deviations. For more information about the Network-SLAPM2 MIB, see `usr/lpp/tcpip/samples/slapm2.mi2`.

### Configuring the Network SLAPM2 subagent

The z/OS CS Network SLAPM2 subagent allows network administrators to retrieve data and determine if the current set of Network SLAPM2 policy definitions are performing as needed or if adjustments need to be made. Before starting the Network SLAPM2 subagent, some basic operational characteristics of the Network SLAPM2 subagent need to be configured.

#### Procedure

Perform the following steps to configure the Network SLAPM2 subagent:

1. Configure the Network SLAPM2 subagent security authorization.

For the subagent to retrieve performance monitor data from the Policy Agent, the Network SLAPM2 subagent must have superuser authority or security product authority in the SERVAUTH class.

These profiles can be defined by TCP/IP stack and policy type as follows, where *sysname* is the system name defined in the sysplex, *TcpImage* is the TCP name for policy information that is being requested, and *ptype* is the policy type (QOS) that is being requested:

```
EZB.PAGENT.sysname.TcpImage.ptype
```

Wildcarding is allowed on segments of the profile name.

If SERVAUTH class is absent (not RACLIST) or profiles are absent for the subagent's request (*TcpImage* and policy type), permission is denied and data is not returned.

If SERVAUTH class is active, profiles are present for the subagent's request (*TcpImage* and policy type), and an MVS user is defined for all profiles, permission is granted and data is returned.

If SERVAUTH class is active, profiles are present for the subagent's request (*TcpImage* and policy type), and an MVS user is not defined for all profiles, permission is refused and data is not returned.

For the sample commands needed to create the profile name and permit users to it, see the EZARACF sample in SEZAINST.

2. Configure the Policy Agent as follows:

- Configure QoS policy rules and QoS policy actions in Policy Agent. The Network SLAPM2 subagent keeps statistics only for active QoS policies. For details, see [“Steps for configuring the Policy Agent” on page 834](#).

- Configure PolicyPerformanceCollection in Policy Agent. The PolicyPerformanceCollection statement for rules needs to be enabled to retrieve performance monitoring information from Policy Agent for the Network SLAPM2 Subagent. For details on the PolicyPerformanceCollection statement, see [“Policy performance collection configuration”](#) on page 861.
3. Configure and start the SNMP agent. For details, see [“Step 1: Configure the SNMP agent”](#) on page 1275.

## Starting and stopping the Network SLAPM2 subagent

Before you start the Network SLAPM2 subagent, the following applications need to be started and initialized:

- Policy Agent - For details, see [“Starting and stopping the Policy Agent”](#) on page 849.
- SNMP agent - For details, see [“Start the SNMP agent”](#) on page 1285.

The Network SLAPM2 subagent can be started from the z/OS shell or as a started task.

- When starting from the shell:

The Network SLAPM2 subagent executable file (nslapm2) is in /usr/lpp/tcpip/bin. There is also a link from /bin. Make sure your PATH statement (in the profile) contains either /bin or /usr/lpp/tcpip/bin.

The Network SLAPM2 subagent requires access to one or more DLLs at run time. The LIBPATH environment variable needs to be set to include the /usr/lib directory, which normally includes all the required DLLs.

Export the LIBPATH environment variable before starting the subagent. This is best accomplished in /etc/profile or in .profile in the HOME directory. For example:

```
export LIBPATH=/usr/lib
```

The following command is an example:

```
nslapm2 -d 3 -t 1800 -c special -P 5000
```

The command above starts the Network SLAPM2 subagent with the following characteristics:

- Connect to the SNMP agent using a community name of *special* and a port of 5000.
  - The debugging level is set to 3, to log the following debugging messages to syslog:
    - Trace Network SLAPM2 subagent error and system console messages
    - Trace Network SLAPM2 subagent warning messages
  - The MIB table cache time is set to 30 minutes.
- When starting as a started task:
- Use the S NSLAPM2 command on an MVS console or SDSF. A sample procedure is shipped in member EZAPAGSB in SEZAINST.

- Specify LIBPATH using the ENVAR parameter on the PARM statement in the started procedure. For example:

```
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("LIBPATH=/usr/lib")')
```

- Export the LIBPATH environment variable in a file specified with the STDENV DD statement. For example:

```
//STDENV DD PATH='/etc/nslapm2.env',PATHOPTS=(ORDONLY)
```

In the /etc/nslapm2.env file:

```
LIBPATH=/usr/lib
```

For more information on [Using the CLER CICS transaction to display and set runtime options](#), see [z/OS Language Environment Programming Guide](#). For details on setting the LIBPATH environment variable, also see [z/OS UNIX System Services Command Reference](#).

The `/tmp/nslapm2.tcpname.pid` is a temporary NSLAPM2 subagent pid file that the Network SLAPM2 subagent creates. This file contains the process ID of the current invocation of the Network SLAPM2 subagent.

#### Restrictions:

- If `/tmp/nslapm2.tcpname.pid` is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the Network SLAPM2 subagent.
- If `/tmp/nslapm2.tcpname.pid` is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which `/tmp/nslapm2.tcpname.pid` is stored cannot have write access to the directory. Additionally, write access to `/tmp/nslapm2.tcpname.pid` must be limited to the owning UID or group, for example, `--w--w----` permissions.

The Network SLAPM2 subagent can be stopped using the stop command (P NSLAPM2), or using the kill command in the z/OS shell. For example, the following kill command with the TERM signal, where *pid* is the nslapm2 process ID, enables the Network SLAPM2 subagent to clean up resources properly before terminating itself:

```
kill -s TERM pid
```

The nslapm2 process ID can be obtained using the following z/OS UNIX command:

```
ps -A
```

## Verification

---

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies installed in the TCP/IP stacks?
- Is the expected traffic mapping to the correct policies?
- Are the sysplex distributor policy functions working correctly?
- Does anything need to be tuned?

The following subtopics provide more details about these considerations.

### Verifying that the policies are installed in the TCP/IP stacks

Use the Netstat SLAP/-j command to display QoS policy statistics. This command displays statistics for only active (installed) QoS policies, so it can be used to verify the correct policies are installed, even if all the statistics are 0. Because the Policy Agent can install policies on multiple stacks, issue this command on each stack to verify the correct set of QoS policies is installed.

### Verifying that the expected traffic is mapping to the correct QoS policies

While connections are active, use the Netstat ALL/-A command to display details about the active connections. One piece of information displayed is the policy rule name. If this name is blank, then the traffic is not mapped to any active rule. Also, use the Netstat SLAP/-j command to display QoS policy statistics. The output shows the time that each policy was last mapped to traffic, and accumulated statistics for each policy. Monitor these values over time to verify that new traffic is mapping as expected.

**Note:** The values displayed by the Netstat SLAP/-j commands can wrap around to 0. If some of the values do not seem correct (for example, total out bytes less than total out bytes in profile), then wrapping has probably occurred.

## Verifying that the sysplex distributor policy functions are working correctly

To verify that the distributor is using the expected service levels when deciding how to distribute traffic to each DVIPA/Port target, use the Netstat VDPT/-O DETAIL command on the distributing stack. The following QoS related information will be displayed for each DVIPA/Port target:

- WLM weight unmodified by QoS
- Modified WLM/QoS aggregate weight, identified by \*DEFAULT\*
- Modified WLM/QoS service level weights, identified by service level name

To verify that active connections distributed to DVIPA/Port targets are using the expected service level, use the Netstat VCRT DETAIL command on the distributing stack. This will display the following policy related information:

- PolicyRule: the policy rule that the distributor used in selecting the policy action for this connection.
- PolicyAction: the policy action that this connection is currently using. If PolicyAction is specified by \*NONE\*, then the distributor is using the \*DEFAULT\* fraction to distribute this connection.

See [z/OS Communications Server: IP Diagnosis Guide](#) for more information.

## Monitoring performance and tuning policies

Poor performance, such as low throughput, long response times, and so on, might be suddenly and consistently experienced by a certain set of users or applications. Also, traps might be generated by the Network SLAPM2 subagent. When this happens, the problem might be the way the QoS policy is defined for the corresponding set of users or applications.

For example, the IPv4 ToS/DS or IPv6 traffic class value might be set incorrectly to a lower QoS level than is intended, for example, medium or low priority instead of high priority. It is important to remember that given a fixed amount of network resources, changing some traffic demand from a lower to higher QoS level will mean that other traffic demands will be affected. Therefore, use care to ensure that in attempting to meet one set of QoS requirements, different or worse problems do not result.

Another cause for poor performance might be in the way the bandwidth allocation defined via the DiffServ token bucket parameters, or TCP maxrate or minrate, is not adequate to accommodate the traffic demand. Yet another possibility might be that either network or the server capacity is not adequate to handle the traffic demand. This is evident when a majority of users or applications do not have their QoS requirements met. When this happens, the network planning process must be revisited.

For more information, see [“Using the Network SLAPM2 MIB to monitor policies”](#) on page 872.

## Using pasearch

Use the **pasearch** command to display policy details. This command displays both active (installed in the stack) and inactive policies. Various parameters can be specified to filter the results, for example to display only policies for certain stacks, only QoS policies, only policy names, or only a single policy specified by name. See [z/OS Communications Server: IP System Administrator's Commands](#) for the complete syntax and sample output for **pasearch**.

## Using the Network SLAPM2 MIB to monitor policies

The Network SLAPM2 subagent provides information about service policies and performance data for applications mapped to those policies through the `slapm2PolicyRuleStatsTable`.

**Note:** The Network SLAPM2 subagent can be used to monitor Differentiated Services policies.

### **slapm2PolicyRuleStatsTable**

Provides statistics on a per policy rule basis.

The Network SLAPM2 subagent also supports performance monitoring with the `slapm2PRMonTable` object. Entries are created in the monitor table to establish the wanted criteria for monitoring. The following level of monitoring is provided:

## Aggregate

Monitoring is performed based on the aggregate of all TCP or UDP applications that are mapped to one or more service policies.

Three types of monitoring are provided for measuring application performance:

### TCP round-trip time

The current TCP round-trip time of applications are compared to the threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

### TCP packets retransmit ratio

The current TCP packets retransmit ratios of applications are compared to the threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

### Average accept queue delay

The current average accept queue delay of applications are compared to threshold values established in the monitor table entry. If the current rates exceed the high threshold or go below the low threshold, an SNMP trap is sent if traps are enabled.

For more details about how to make the various monitoring calculations, see the NETWORK-SLAPM2-MIB in the sample file slapm2.mi2 in the /usr/lpp/tcpip/samples directory.

When SNMP traps are enabled, and a *not achieved* trap is sent as described above, a corresponding *okay* trap is sent when the traffic again conforms to the boundaries established in the monitor table entry.

For example, suppose the slapm2PRMonTcpRttDelayHigh value is set to 2 seconds and the slapm2PRMonTcpRttDelayLow value is set to 1 second. If the TCP round-trip delay rises above 2 seconds, a *not achieved* trap is sent. If the TCP round-trip delay then drops below 1 second, an *okay* trap is sent to indicate the problem has been resolved. However, if the row becomes inactive before conforming to the established boundaries, an *okay* trap is never sent, because this removes monitoring for this entry.

The following traps are used to monitor table administration:

### Policy deleted

A slapm2PolicyRuleDeleted trap is sent when an entry is deleted from the slapm2PolicyRuleStatsTable, if slapm2PolicyDeletedTrapEnabled is enabled(1).

### Monitor deleted

A slapm2PolicyRuleMonDeleted trap is sent when a slapm2PRMonEntry is deleted, if the value of slapm2PolicyDeletedTrapEnabled is enabled(1).

## Creating monitor table entries and enabling SNMP traps

Several MIB objects are used when establishing monitor table entries and when configuring whether and how often traps are sent. To establish monitor table entries, set the following MIB object variables. Most of these objects have default values, so you might be able to achieve the wanted monitoring using only a subset of the objects.

### slapm2PRMonTcpRttDelayHigh, slapm2PRMonTcpRttDelayLow

Establishes the threshold values for the average TCP round-trip time. The minimum and maximum rates are in units of milliseconds.

### slapm2PRMonTcpReXmitHigh, slapm2PRMonReXmitLow

Establishes the threshold values for the TCP packets retransmit ratio. The minimum and maximum rates are in tenths of a percent units.

### slapm2PRMonTcpAcceptQDelayHigh, slapm2PRMonTcpAcceptQDelayLow

Establishes the threshold values for the average accept queue delay. The minimum and maximum rates are in units of milliseconds.

### slapm2PRMonRowStatus

This object allows entries to be created and deleted in the slapm2PRMonTable.

In addition, the following MIB objects are used to control the generation of traps:

### slapm2PRMonTrapEnable

Indicates whether slapm2PolicyRuleMonNotOkay and slapm2PolicyRuleMonOkay notifications should be generated for this conceptual row.

### slapm2PRMonTrapFilter

The purpose of this object is to suppress excessive slapm2PolicyRuleMonNotOkay notifications. A monitored quantity must exceed its high threshold for the number of consecutive intervals indicated by this object for a notification to be generated. The length of the intervals is specified by the slapm2PolicyMonInterval object.

## Creating the monitor table index

When you create monitor table entries, specify the appropriate index value. The index is composed of:

- slapm2PRMonOwnerIndex
- slapm2PolicyRuleIndex

The OwnerIndex is expressed in the following format, where *character* is in ASCII decimal form:

```
length.character.character...
```

For example, the value *u1* is expressed as 2.117.31. The PolicyRuleIndex that maps to the policy name value is the index into the slapm2PolicyRuleTable.

The Network SLAPM2 subagent creates an entry in the slapm2PolicyRuleTable to represent a policy rule. The index value for this entry is arbitrary and assigned by the subagent. Corresponding entries in the other MIB tables, including the monitor table, contain the index value that maps to the entry in the name table.

To assist you in creating the index for the monitor table entries, note that the index value used in the slapm2PolicyRuleStatsTable entries consist of the last value used in the monitor table index, namely the PolicyRuleIndex. Thus, you can walk through the policy statistics table using the following command:

```
osnmp -v walk slapm2PolicyRuleStatsTable
```

Then, cut and paste the index value from the PolicyRuleStatsTable and add an OwnerIndex of your choosing at the beginning of the index.

For the above example, the complete index using an OwnerIndex of *u1* is:

```
2.117.31.3
| +--- name table index value (PolicyRuleIndex)
+----- length + "u1" (OwnerIndex)
```

## Monitor table examples

If you are going to change any of the monitor table object values for an existing table entry or row, you must take the row out of service to make the changes. To do this, set the value of slapm2PRMonRowStatus to 2. After your changes are made, set the row status to a value of 1 to put it back in service.

The following examples show how to create monitor table entries to monitor.

- This example assumes SNMP version 1 security and no SNMPD.CONF file.

1. Enable traps. The snmptrap.dest file should contain the IP address and protocol of an entity to receive traps:

```
/etc/snmptrap.dest contains: 9.67.191.5 UDP
/etc/pw.src contains: public 0.0.0.0 0.0.0.0
```

In this example, use the osnmp command running in the background to receive traps:

```
osnmp trap > /tmp/trap.output &
```

2. Change status to notInService:

```
osnmp set slapm2PRMonRowStatus.index 2
```

3. Enable monitoring for slapm2PolicyRuleMonNotOkay and slapm2PolicyRuleMonOkay (traps):

```
osnmp set slapm2PRMonTrapEnable.index 1
```

4. If wanted, change default thresholds:

- TCP round trip, where  $l$  is the lower boundary and  $h$  is the upper boundary:

```
osnmp set slapm2PRMonTcpRttDelayLow.index 1
osnmp set slapm2PRMonTcpRttDelayHigh.index h
```

- TCP retransmit ratio, where  $l$  is the lower boundary and  $h$  is the upper boundary:

```
osnmp set slapm2PRMonTcpReXmitDelayLow.index 1
osnmp set slapm2PRMonTcpReXmitDelayHigh.index h
```

- Accept Queue delay ratio, where  $l$  is the lower boundary and  $h$  is the upper boundary:

```
osnmp set slapm2PRMonAcceptQDelayLow.index 1
osnmp set slapm2PRMonAcceptQDelayHigh.index h
```

5. Make row active:

```
osnmp set slapm2PRMonRowStatus.index 1
```

- Evaluate the following fields to determine why the slapm2PolicyRuleMonNotOkay trap was generated:
  - If the maxTcpRttDelayExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonTcpRTTCurrentDelay to determine the average round-trip time over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxTcpReXmitRatioExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonTcpCurrentTcpReXmit to determine the TCP retransmit ratio over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxAcceptQueueDelayExceeded bit in the previous slapm2PRMonStatus is off, indicating below the high threshold, and the bit in the current slapm2PRMonStatus is on, indicating above the high threshold, this indicates that at the end of this monitor interval this is a rising quantity and the threshold has exceeded its high threshold. Evaluate the slapm2PRMonAcceptQCurrentDelay to determine the smoothed average accept queue delay over the most recent interval for all flows affected by this policy rule.
- Evaluate the following fields to determine why the slapm2PolicyRuleMonOkay trap was generated:
  - If the maxTcpRttDelayExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonTcpRTTCurrentDelay to determine the average round-trip time over the most recent interval for all outgoing TCP packets affected by this policy rule.
  - If the maxTcpReXmitRatioExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonTcpCurrentTcpReXmit to determine the TCP retransmit ratio over the most recent interval for all outgoing TCP packets affected by this policy rule.

- If the maxAcceptQueueDelayExceeded bit in the previous slapm2PRMonStatus is on, indicating above the low threshold, and the bit in the current slapm2PRMonStatus is off, indicating below the low threshold, this indicates that at the end of this monitor interval this is a falling quantity and the threshold has fallen below its low threshold. Evaluate the slapm2PRMonAcceptQCurrentDelay to determine the smoothed average accept queue delay over the most recent interval for all flows affected by this policy rule.

---

## Chapter 16. Intrusion detection services

It is becoming increasingly important to not just protect systems from attacks but to detect patterns of usage that might indicate impending attacks. Many attacks follow a sequence of information gathering, unauthorized access to resources (information, applications, storage), and denial of service. It can be difficult, or at times, impossible to determine the originator of denial of service attacks. Correlating information gathering activities with access violation might help identify an intruder before they succeed.

Intrusion detection services (IDS) provides the following support:

- Scan detection and reporting
- Attack detection, reporting, and prevention
- Traffic regulation for TCP connections and UDP receive queues

You can use IDS policies to specify event conditions and the actions to take for particular events. All IDS policies support logging events to a specified message priority level in syslogd, on the system console, or both. Most IDS policies support the following functions:

- Discarding packets when a specified limit is reached
- Writing statistical records to the INFO message level of syslogd at a specified time interval, and the option to write these records only when exceptional events have occurred
- Tracing all or part of the triggering packet to an IDS-specific CTRACE facility, SYSTCPIS

IDS assigns a correlator value to each event. All messages written to the system console and syslogd use this correlator, and records written to the IDS trace use this correlator. A single detected event can involve multiple packets; the correlator value identifies which messages and packets are related to each other. Each IDS policy has additional attributes that you can specify, either in conditions or in the action.

---

### Scan policies

Scans are recognized when a single source IP address makes multiple attempts to gather information within a defined period of time. Although a scan is not harmful, many serious attacks, especially access violation attacks, are preceded by scans to gather information. Scans must use reliable source IP addresses and can be interesting events to monitor.

IDS support defines a scanner as a source host that accesses multiple unique resources (ports or interfaces) over a specified period of time. You can specify the number of unique resources (Threshold) and the time period (Interval) by policy. Two categories of scans are supported:

- Fast scan

Many resources are rapidly accessed in a short time period (usually less than 5 minutes and program driven)

- Slow scan

Different resources are intermittently accessed over a longer period of time (many hours). This could be a scanner trying to avoid detection.

The following scenarios are some examples of a scanner:

- Source host A has a program that loops through all low ports and tries to connect to each port on target host X (fast scan). Each port is considered a unique resource.
- Source host B manually sends a **ping** command to each interface on target host X, and then tries to access well-known ports on target host X (most likely a slow scan). Each interface accessed by a **ping** command is considered a unique resource, and each port accessed is considered a unique resource.

The following scenario is not considered to be an example of a scanner:

- Source host C starts 20 connections to port 23. Because these connections are to the same port, only one unique resource is accessed, and host C is not considered a scanner.

Scans like the one in the following scenario might not be detected by IDS:

- Source host E issues a **ping** command to IP addresses 9.1.1.1 through 9.255.255.255. Because host X collects data only for the ping commands that are directed to interfaces of host X, this event is not detected by host X as a scan. Network IDS might detect this as wide scan.

Scan policy provides the ability to specify the following conditions and actions:

- Fast scan time interval
- Slow scan time interval
- Fast scan threshold
- Slow scan threshold
- Exclude well-known legitimate scanners by using an exclusion list
- Specify a sensitivity level by port or port range (to reduce performance impacts)
- Provide notification of a detected scan by issuing a console message or a syslogd message
- Trace potential scan packets

The individual packets used in a scan are categorized as normal, possibly suspicious, or very suspicious. To control the performance impact and analysis load of scan monitoring, set the sensitivity level for potential scan events to high, medium, or low.

Table 45 on page 878 shows how the policy-specified sensitivity affects the counting of scan events. The event suspicion level is determined by the stack.

| <i>Table 45. Effect of sensitivity level on the counting of scan events at each suspicion level</i> |                     |                                  |                              |
|-----------------------------------------------------------------------------------------------------|---------------------|----------------------------------|------------------------------|
| <b>Sensitivity (from policy)</b>                                                                    | <b>Normal event</b> | <b>Possibly suspicious event</b> | <b>Very suspicious event</b> |
| Low                                                                                                 |                     |                                  | counted                      |
| Medium                                                                                              |                     | counted                          | counted                      |
| High                                                                                                | counted             | counted                          | counted                      |

To help reduce or eliminate false positive results, IDS allows policy-specified source IP addresses, subnet masks, and optionally, source port numbers, to be excluded from scan detection. For UDP and TCP port scans, you can limit scan detection to specific destination port ranges. You can specify the sensitivity level (high, medium, or low) for these port ranges.

Another way that IDS reduces false positive results is by counting only unique events from a specific source IP address within a scan interval. An event is considered unique if the IP protocol, destination IP address, and destination port (UDP or TCP) or type (ICMP) have not been encountered before during this scan interval.

IDS scan policy supports a fast scan interval and threshold, and a slow scan interval and threshold:

- Fast scan

A fast scan is recognized if the number of unique events within the fast scan interval reaches the fast scan threshold.

- Slow scan

A slow scan is recognized if the number of unique events within the slow scan interval reaches the slow scan threshold.

IDS counts scan events using an internal interval that is no greater than half of the fast scan interval. During an internal interval, after the number of unique events reaches the slow scan threshold, additional events are not counted. These additional events are traced if requested by policy using the trace data parameter in the action.

**Restriction:** When system resources are constrained, IDS might temporarily suspend scan detection.

Scan events are categorized by the following scan types:

- ICMP scans
- ICMPv6 scans
- UDP port scans
- TCP port scans

Any countable scan event is counted against the origin source IP address, and the total number of countable events from all categories is compared to the policy thresholds. When an origin source IP address has reached the fast or slow threshold defined by policy, the following actions are taken if you requested them using the notification options in the action:

- A notification is sent to the traffic regulation management daemon (TRMD) for logging to syslogd
- A console message is issued
- The packet is logged to the IDS packet trace

When IDS detects a scan for a particular source IP address, no further scan events are reported for that source IP address during the specified interval. The intervals and thresholds for fast and slow scans are global; one set of values applies to all event categories.

## ICMP scans

Internet Control Message Protocol (ICMP) requests (Echo, Information, Timestamp, and Subnet Mask) are used to map network topology. Receipt of an ICMP request is classified as a normal, possibly suspicious, or highly suspicious event. Any request sent to a multicast or broadcast address is treated as a very suspicious event. Echo requests (ping) and Timestamp requests are common and are treated as normal events when they do not include the IP Options for Record Packet Route or Record Timestamp. Events are classified by the first matching entry in [Table 46 on page 879](#):

| <i>Table 46. Classification of ICMP events</i>                             |                        |                      |
|----------------------------------------------------------------------------|------------------------|----------------------|
| Event                                                                      | Destination address    | Event classification |
| Receive any ICMP request (Echo, Information, Timestamp, or Subnet Mask)    | Multicast or broadcast | Very suspicious      |
| Receive any ICMP request that is denied by Quality of Service (QoS) policy | Unicast                | Normal               |
| Receive Information Request or Subnet Mask                                 | Unicast                | Possibly suspicious  |
| Receive Echo Request with IP Option Record Route or Record Timestamp       | Unicast                | Possibly suspicious  |
| Receive Echo Request or receive Timestamp Request                          | Unicast                | Normal               |

## ICMPv6 scans

ICMPv6 provides ICMP function for IPv6. [Table 47 on page 879](#) shows the ICMPv6 events that are considered for scan detection and the suspicion level associated with each event. Events are classified by the first matching entry in the table.

| <i>Table 47. Classification of ICMPv6 events</i> |                     |                      |
|--------------------------------------------------|---------------------|----------------------|
| Event                                            | Destination address | Event classification |
| Receive Echo Request                             | Multicast           | Very suspicious      |

| <i>Table 47. Classification of ICMPv6 events (continued)</i>           |                            |                             |
|------------------------------------------------------------------------|----------------------------|-----------------------------|
| <b>Event</b>                                                           | <b>Destination address</b> | <b>Event classification</b> |
| Receive Echo Request that is denied by Quality of Service (QoS) policy | Unicast                    | Normal                      |
| Receive Echo Request with Routing Header                               | Unicast                    | Possibly suspicious         |
| Receive Echo Request without Routing Header                            | Unicast                    | Normal                      |

## UDP port scans

Because UDP is stateless, the stack cannot differentiate between a client port and a server port. A scanner that is sending messages to many ephemeral ports looks similar to a DNS server that is sending replies to many clients on ephemeral ports. You can specify the RESERVED keyword on the PORT or PORTRANGE statement in the TCP/IP profile to prohibit the use of a UDP port. Any datagram that is received for a prohibited port is treated as a very suspicious event. Any datagram that is received for a port that is not prohibited but is unbound is treated as a possibly suspicious event, and any datagram received for a bound port is treated as a normal event. You can also limit event generation to specific port ranges and destination addresses. UDP port scans apply to IPv4 and IPv6 packets. Events are classified by the first matching entry in [Table 48 on page 880](#):

| <i>Table 48. UDP port event classification</i> |                                                            |                                                            |
|------------------------------------------------|------------------------------------------------------------|------------------------------------------------------------|
| <b>Socket state</b>                            | <b>Event</b>                                               | <b>Event classification</b>                                |
| Any state                                      | Receive any packet that is denied by IP security filtering | Possibly suspicious                                        |
| Use prohibited by RESERVED keyword             | Receive any packet                                         | Very suspicious                                            |
| Unbound, use not prohibited                    | Receive any packet                                         | Possibly suspicious; application could be temporarily down |
| Bound                                          | Receive any packet                                         | Normal                                                     |

## TCP port scans

Because TCP is a stateful protocol, many different events might be classified as normal, possibly suspicious, or very suspicious. The identified conditions are listed in [Table 49 on page 880](#). You can use the RESERVED keyword on the PORT or PORTRANGE statement in the TCP/IP profile to prohibit the use of a TCP port. You can also limit event generation to specific port ranges and destination IP addresses. TCP port scans apply to IPv4 and IPv6. Events are classified by the first matching entry in [Table 49 on page 880](#):

| <i>Table 49. TCP port event classification</i> |                                                                |                             |
|------------------------------------------------|----------------------------------------------------------------|-----------------------------|
| <b>Socket state</b>                            | <b>Event</b>                                                   | <b>Event classification</b> |
| Any state                                      | Receive unexpected flags (for example, SYN+FIN)                | Very suspicious             |
| Any state                                      | Receive standalone SYN that is denied by IP security filtering | Possibly suspicious         |
| Use prohibited by RESERVED keyword             | Receive standalone SYN                                         | Very suspicious             |

| <i>Table 49. TCP port event classification (continued)</i> |                                                                          |                                                            |
|------------------------------------------------------------|--------------------------------------------------------------------------|------------------------------------------------------------|
| <b>Socket state</b>                                        | <b>Event</b>                                                             | <b>Event classification</b>                                |
| Unbound, use not prohibited                                | Receive standalone SYN                                                   | Possibly suspicious; application could be temporarily down |
| Listen                                                     | Receive standalone SYN that is denied by Quality of Service (QoS) policy | Normal                                                     |
| Listen                                                     | Receive standalone SYN                                                   | No event (classification deferred)                         |
| Half open connection                                       | Receive ACK                                                              | Normal; connection handshake completed                     |
| Half open connection                                       | Receive duplicate SYN                                                    | Normal; perhaps duplicate packet                           |
| Half open connection                                       | Receive RST                                                              | Possibly suspicious; peer covering tracks                  |
| Half open connection                                       | Final time out                                                           | Very suspicious; peer abandoned handshake                  |
| Any connected state                                        | Seq# out of window                                                       | Normal; perhaps duplicate packet                           |
| Any connected state                                        | Receive standalone SYN                                                   | Normal; perhaps peer reboot                                |
| Any connected state                                        | Final timeout                                                            | Possibly suspicious; peer abandoned connection             |

## Attack policies

An attack can be a single packet designed to cause a system to fail or hang. An attack can also consist of multiple packets designed to consume a limited resource, which causes a network, system, or application to be unavailable to its intended users (denial of service). You can use intrusion detection services (IDS) attack policy to activate attack detection for one or more categories of attacks independently of each other. In general, the types of actions that you can specify for an attack policy are event logging, statistics gathering, packet tracing, and discarding of the attack packets. Most attack checking is performed for inbound packets to a stack.

IDS includes the following categories of attacks:

- Malformed packet events

Many attacks are designed to cause the protocol stack of a system to fail by providing incorrect or partial header information. These packets are always discarded when they are received, regardless of IDS policy. The source IP address is rarely reliable for these attacks. This type of attack applies to both IPv4 and IPv6 packets.

You can use IDS policy to provide notification of malformed packet attacks.

- Inbound fragment events

Many attacks are the result of fragment overlays in the IP or transport header. You can use this support to detect fragmentation overlays that change the data in a packet, including changes to the length of the packet. This type of attack applies to both IPv4 and IPv6 packets.

You can use IDS policy to provide notification of suspicious fragments, and optionally to discard them.

- IP protocol restrictions

Although there are 256 possible values that can be specified in the protocol field of the IP header, only a handful are commonly used. You can protect your system against future attacks by prohibiting those values that you are not actively and intentionally using.

**Restrictions:**

- This attack type applies to IPv4 packets only. The IPv6 next header restrictions attack type provides analogous function for IPv6 packets.
- This attack type applies only to unicast packets destined for an interface on this TCP/IP stack. It does not apply to broadcast or multicast packets. It does not apply to routed traffic.

You can use IDS policy to provide notification of a packet with a restricted IP protocol value, as well as to discard the packet.

- IPv6 next header restrictions

The IPv6 header and any subsequent extension headers include a next header field. The value in the next header field identifies the next header in the packet, either an upper layer protocol header (such as a TCP or UDP header) or an extension header (such as a fragmentation or routing header). Although there are 256 possible values that can be specified as a next header value, only a small number are commonly used. You can protect your system by prohibiting next header values in inbound packets that you are not actively and intentionally using.

**Restriction:** This attack type applies to IPv6 packets only. The IP protocol restrictions and IP option restrictions attack types provide analogous function for IPv4 packets.

You can use IDS policy to provide notification of an inbound packet with a restricted next header value, as well as to discard the packet.

- IP option restrictions

As with IP protocols, there are 256 possible values that can be specified as IP options in received packets, with only a small number currently in common use. You can prevent misuse of values that you are not intentionally using. A check for restricted IP options is performed on all inbound packets, including those that are forwarded to another system.

**Restriction:** This attack type applies to IPv4 packets only. The IPv6 destination option restrictions, IPv6 hop-by-hop option restrictions, and IPv6 next header restrictions attack types provide analogous function for IPv6 packets.

You can use IDS policy to provide notification of a packet with a restricted IP option, as well as to discard the packet.

- IPv6 destination option restrictions

Although there are 256 possible values that can be specified as IPv6 destination options in received packets, only a small number of values are currently defined. You can prevent misuse of values that you are not intentionally using.

**Restriction:** This attack type applies to IPv6 packets only. The IP option restrictions attack type provides analogous function for IPv4 packets.

You can use IDS policy to provide notification of a packet with a restricted value for an IPv6 destination option, as well as to discard the packet.

- IPv6 hop-by-hop option restrictions

Although there are 256 possible values that can be specified as IPv6 hop-by-hop options in received packets, only a small number of values are currently defined. You can prevent misuse of values that you are not intentionally using. A check for restricted IPv6 hop-by-hop options is performed on all inbound packets, including those that are forwarded to another system.

**Restriction:** This attack type applies to IPv6 packets only. The IP option restrictions attack type provides analogous function for IPv4 packets.

You can use IDS policy to provide notification of a packet with a restricted value for an IPv6 hop-by-hop option, as well as to discard the packet.

- UDP perpetual echo

Some UDP applications unconditionally respond to every datagram that is received. In some cases, such as Echo, CharGen or TimeOfDay, this is a useful network management or network diagnostic tool. In other cases, an application might send error messages in response to incorrectly formed requests. If a datagram is inserted into the network with one of these applications as the destination and another one of these applications spoofed as the source, the two applications will respond to each other continually. Each inserted datagram results in another perpetual echo conversation between them. You can use IDS policy to define the application ports that exhibit this behavior. This type of attack applies to both IPv4 and IPv6 packets.

You can use IDS policy to provide notification of a perpetual echo packet, as well as to discard the packet.

- ICMP redirect events

ICMP redirect packets and ICMPv6 redirect packets can be used to modify your routing tables. You can use IDS policy to provide notification of attempts to modify your routing tables in this manner. You can also use IDS policy to ignore ICMP redirect packets and ICMPv6 redirect packets.

**Tip:** ICMP redirect packets are ignored if IPCONFIG IGNOREREDIRECT is specified in the TCP/IP profile, you are using OMPROUTE and you have IPv4 interfaces configured to OMPROUTE, or IDS policy is active for ICMP redirect attacks and the associated policy action requests that the packet be discarded. ICMPv6 redirect packets are ignored if IPCONFIG6 IGNOREREDIRECT is specified in the TCP/IP profile, you are using OMPROUTE and you have IPv6 interfaces configured to OMPROUTE, or IDS policy is active for ICMP redirect attacks and the associated policy action requests that the packet be discarded.

- Outbound raw restrictions

Most network attacks require the ability to create packets that would not typically be built by an appropriate protocol stack implementation. You can use IDS policy to detect and prevent many of these attempts so that your system is not used as the source of attacks on other systems. As a part of this checking, you can restrict the IP protocols that are allowed in an outbound raw packet.

**Guideline:** You should restrict the TCP protocol (6) on the outbound raw rule.

**Restriction:** This attack type applies to IPv4 packets only. The IPv6 outbound raw restrictions attack type provides analogous function for IPv6 packets.

You can use IDS policy to provide notification of an outbound raw packet that is considered an attack, as well as to discard the packet.

- IPv6 outbound raw restrictions

Most network attacks require the ability to create packets that would not normally be built by an appropriate protocol stack implementation. You can use IDS policy to detect and prevent many of these attempts so that your system is not used as the source of attacks on other systems. As a part of this checking, you can restrict the protocols that are allowed in an outbound raw packet for IPv6 traffic.

**Guideline:** You do not need to restrict the TCP protocol (6) for IPv6 because a TCP packet cannot be generated using AF\_INET6 raw sockets.

**Restrictions:**

- You cannot restrict which IPv6 extension headers are allowed in an outbound raw packet with this attack type. The restricted protocol list applies to only the upper layer protocol for which the raw socket is opened. If any of the following extension header values are included in the restricted protocol list, it will have no effect:
  - HOPOPT (0)
  - IPv6 (41)
  - IPv6-Route (43)
  - IPv6-Frag (44)
  - ESP (50)

- AH (51)
- IPv6-NoNxt (59)
- IPv6-Opts (60)
- This attack type applies to IPv6 packets only. The outbound raw restrictions attack type provides analogous function for IPv4 packets.

You can use IDS policy to provide notification of an outbound IPv6 raw packet that is considered an attack, as well as to discard the packet.

- Flood events

Two types of floods are currently detected:

- TCP SYN floods

A popular denial of service attack is to flood a public server with connection requests from incorrect or nonexistent source IP addresses. The intent is to use up the available slots for connection requests and thereby deny legitimate access from completing. z/OS CS provides protection from this attack regardless of IDS policy.

- Interface floods

If a large number of discards are occurring in proportion to the number of inbound packets, a malicious user might be attempting a denial of service attack. If this percentage of discards for an interface exceeds a specified percentage, this is considered an interface flood. The default percentage of discards used is 10%. You can override this default by specifying the interface flood percentage parameter.

To prevent the false detection of an interface flood condition when there is a low volume of inbound traffic on an interface, a minimum number of discards must occur in a one minute period to qualify as a flood. The default minimum is 1000 discards per minute. You can override this default by specifying the interface flood minimum discard parameter.

When an interface flood condition is reported for an interface, the discard rate for the interface is evaluated for each subsequent 1-minute interval. An interface flood condition end is reported when the number of discards for the 1-minute interval falls below the interface flood minimum discard parameter value or the discard percentage falls below 50% of the interface flood percentage parameter value.

If the interface flood continues for more than 5 minutes and logging was requested by policy, an interface flood continues record is logged at 5 minute intervals while the interface flood conditions exist. This log data contains additional information about the discarded packets for the interface.

Because it can be difficult to distinguish between a malicious user trying to flood a system, unusual spikes in traffic, and problems that can be caused by setup problems, it is possible for an interface flood condition to be reported when the source of the problem is not actually a flood. For example, if enough storage is not configured to handle the inbound traffic, a large percentage of the inbound packets might be discarded and cause the interface flood percentage to be exceeded.

This type of attack applies to both IPv4 and IPv6.

You can use IDS policy to provide notification of an attack so that you can address the situation with your network administrators and service providers in a timely manner. Notification of a flood can include flood start and flood end event messages and tracing of the first 100 packets discarded due to the flood.

- Enterprise Extender (EE) malformed packet events

Malformed packets for EE can be designed to disrupt the TCP/IP and SNA protocol stacks. These packets might have incorrect information in the IP and UDP headers, and the received packet might be too short or too long depending on the Logical Data Link Control (LDLC) command present. Any packet received that is not a valid EE command is flagged as malformed.

You can use the IDS policy option to discard malformed packets or to forward them to VTAM for further processing. You can use IDS policy to provide notification of the EE malformed packets. You can code

an exclusion list in the policy to exclude packets from certain IP addresses from the malformed packet checks.

**Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from malformed packet checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally the remote ports.

This type of attack applies to both IPv4 and IPv6 packets.

- EE LDLC check events

EE architecture defines five ports that map to SNA data priorities. The lowest port, usually 12000, is used for signaling data. If signaling data is received on any of the other ports, it is suspicious. If the EE LDLC check attack type is enabled, receiving signaling data on any of the other ports is detected as an attack. This type of attack can be a denial of service (DoS) attack designed to keep resources busy, so that SNA LUs are not able to start sessions with applications on this host.

IDS policy gives you the option of discarding these packets or forwarding them to VTAM for further processing. You can configure the policy to provide notification of the LDLC events. You can code an exclusion list in the policy to exclude packets from certain IP addresses from the LDLC checks.

**Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from LDLC event checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally, the remote ports.

This type of attack applies to both IPv4 and IPv6 packets.

- EE port check events

You can use IDS policy to check the source and destination ports in the UDP header of received EE packets. The port values are expected to be the same; for example, both source and destination port are 12000 in a received packet. If the port values are not the same, this packet is considered an attack packet.

IDS policy gives you the option of discarding these packets or forwarding them to VTAM for further processing. You can configure the policy to provide notification of the port detection events. You can code an exclusion list in the policy to exclude packets from certain IP addresses from the port checks. For example, some products send the null XID using an ephemeral source port value, but expect the reply to be sent to the EE signaling port.

**Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from port checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally, the remote ports.

This type of attack applies to both IPv4 and IPv6 packets.

- EE XID flood event

A flood of XIDs can consume all available EE lines, causing additional EE connection requests to fail. You can enable the EE XID flood attack type to receive notification when an XID flood is occurring for a specific VIPA.

An XID flood is detected when a large number of XID exchanges time out. No discard action exists for this attack type. You can code an exclusion list in the policy to exclude XID exchanges that time out from being counted toward the XID flood if the peer's IP address is in the exclusion list.

**Guideline:** If the existing behavior of a remote peer is flagged as an attack and you determine that it is not an actual problem, you can choose to exclude the peer from XID flood checking by adding the peer to the exclusion list. You can configure an exclusion by specifying the remote IP address, and optionally, the remote ports.

This type of attack applies to both IPv4 and IPv6 packets.

- Data hiding events

Certain fields within a packet can be used to hide data. This support enables you to detect inbound IP packets that might contain hidden data. The following checks for hidden data can be enabled:

- Check IP option pad fields for hidden data:
  - For IPv4 packets, the options field is in the IP header and can contain padding for alignment purposes.
  - For IPv6 packets, a hop-by-hop options extension header or a destination options extension header can include one or more PadN options for alignment purposes.
- Check embedded packets within ICMP and ICMPv6 error messages for hidden data.

This type of attack applies to both IPv4 and IPv6 packets.

You can use IDS policy to provide notification of a suspicious packet that might contain hidden data, as well as to discard the packet.

- TCP queue size events

You can use IDS policy to detect when the send, receive, or out-of-order queue for a TCP connection becomes constrained. A queue can be constrained due to the amount of data on the queue or due to the age of the data on the queue. When a designated amount of data that is configured in policy remains on the queue for at least 30 seconds, the queue becomes constrained. When any data remains on the queue for at least 60 seconds, the queue becomes constrained. Optionally, you can reset the TCP connection when a constraint is detected. If you do not reset the TCP connection, IDS continues to monitor the queue and detect when it becomes unconstrained. This type of attack applies to both IPv4 and IPv6 connections.

IDS policy for TCP queue size events specifies one of four abstract queue sizes:

- VERY\_SHORT
- SHORT
- LONG
- VERY\_LONG

The actual queue sizes associated with these abstract values are internal values that represent a percentage of the total size of each queue, and are subject to change. Most TCP applications have timeout values that are based on human perceptions of responsiveness. These values tend to stay constant, while system processing speeds and network delivery speeds continue to advance rapidly, which might require that the queue sizes associated with these abstract values be changed over time.

A TCP connection might have data queued on the send queue for a long period of time for a legitimate reason. For example, a TCP connection that is associated with a printer that has run out of paper can remain in a persist state while waiting for paper to be loaded. To exclude a device, such as a printer, from TCP send queue size checking, you can configure an exclusion specifying the IP address, and optionally the port, of the device.

You can use IDS policy to provide notification of a constrained send, receive, or out-of-order queue, as well as to reset the connection.

- Global TCP stall events

There are attacks designed to consume system resources by creating many TCP connections and causing them to stall, making them unable to send data. This support detects a global TCP stall condition for a TCP/IP stack when at least 50% of the active TCP connections are stalled and at least 1000 TCP connections are active. Optionally, you can reset the stalled connections. This type of attack applies to both IPv4 and IPv6 connections.

For each attack category (for example, restricted IP protocol) the single highest priority rule is mapped at policy change.

One or more notification options can be specified in the action to provide the wanted documentation of detected attacks.

For IDS attack policy, the notification options enable attack events to be logged to syslogd and to the system console. The console messages provide a subset of the information provided in the syslogd messages.

For all attack categories except flood, EE XID flood, TCP queue size, and global TCP stall, a single packet triggers an event. To prevent message flooding to the system console, you should use the maximum event message parameter to specify the maximum number of console messages to be logged per attack category within a 5-minute interval. To prevent message flooding to syslogd, a maximum of 100 event messages per attack category are logged to syslogd within a 5-minute interval. Specify the syslogd detail parameter with the global TCP stall attack type to request that a syslogd message be generated for each stalled connection when a global TCP stall is detected.

For IDS attack policy, the statistics action provides a count of the number of attack events detected during the statistics interval. The count of attacks is kept separately for each category of attack (for example, malformed packet events) and a separate statistical record is generated for each. If you want to receive statistics for attacks, you should specify exception statistics. With exception statistics, a statistical record is generated for the category of attack only if the count of attacks is nonzero. If you request normal statistics, a record is generated for every statistics interval regardless of whether an attack has been detected during that interval.

If you want to provide overrides to the interface flood parameters (interface flood minimum percentage parameter and interface flood minimum discard parameter), you should not use exception statistics. In this case, use normal statistics for a period for the flood attack category to collect data to help determine the appropriate policy parameter values. After you determine the appropriate values, specify exception statistics.

For IDS attack policy, the trace data and trace record size parameters indicate whether packets associated with attack events are to be traced. For all attack categories except flood, EE XID flood, TCP queue size, and global TCP stall, a single packet triggers an event and the packet is traced. To prevent trace flooding, a maximum of 100 attack packets per attack category are traced within a 5-minute interval.

- For the flood category, the first 100 packets discarded during a SYN flood are traced. In the case of an interface flood, the flood is detected on an interface basis and the trace limit is applied on an interface basis.
- For EE XID flood, TCP queue size, and global TCP stall, no data is traced.

For all attack categories except EE XID flood, TCP queue size, and global TCP stall, you can specify that packets associated with attack events should be discarded. However, malformed and flood packets are always discarded regardless of this setting.

For the TCP queue size attack category, you can specify that connections associated with attack events should be reset.

For the global TCP stall attack category, you can specify that stalled connections should be reset when a global TCP stall condition is detected.

The EE XID flood attack category monitors the number of XID exchange timeouts. There is no associated packet to discard or connection to reset.

An action can be unique to a specific category of attack (for example, malformed) or shared by one or more categories of attacks. If an action is shared, statistical data is still kept separately for each type of attack. Also, the maximum console message limit is enforced individually for each category of attack.

## Traffic regulation policies

---

IDS traffic regulation (TR) policies are used to limit memory resource consumption and queue delay time during peak loads.

## Traffic regulation policies for TCP ports

IDS traffic regulation (TR) policies for TCP ports limit the total number of connections an application has active at one time. This can be used to limit the number of address spaces created by forking applications such as FTPD and otelnetd. A *fair share* algorithm is also provided based on the percentage of remaining available connections already held by a source IP address.

The percentage is applied against the number of available connections for the port. Therefore, as fewer connections become available, each host is allowed fewer new connections. The percentage is applied against the number of available connections, rather than the total number of connections allowed, in order to allow access to a larger number of different hosts when resources are low.

When a host requests a connection, the number of connections it currently holds for the port is compared to the percentage applied to the connections currently available for the port. If the number currently held is less than the percentage of currently available connections, the host is allowed to open an additional connection. If equal or greater, the host is not allowed to open further connections until more connections are freed up. All connection requesters for the port are regulated by this mechanism. If a host does not currently have any connections open on the port and unused connections are available, a host will always be allowed at least 1 connection. Multi-user source IP addresses can be allowed a larger number of connections by specifying a QoS policy with a higher number of connections (MaxConnections) than allowed by the TR policy. TR will honor the QoS differentiated services policy if the port is not in a *constrained state*. A QoS exception is made only when QoS differentiated service policy is applied for the specific source server port and specific outbound client destination IP address; if either of these attributes specify a range or are null, the QoS exception will not be made.

TR TCP generates a Constrained Event when a port reaches about 90% of its Connection Limit. An Unconstrained Event is generated when the port falls below about 88% of its limit. An IDS correlator is assigned for the duration of each constrained state. If tracing is requested in the policy, the first 100 packets that exceed the limit in each constrained state are traced along with the correlator. TR TCP also generates events for each connection allowed because of a QoS override policy and for each connection denied for exceeding either the application's connection limit or the percent available limit.

To prevent possible flooding of syslog, TR TCP limits the number of connection refused, would have been refused, or QOS exception log records written in a five minute interval. For a listening port, a maximum of 100 of these log records are written within a five minute interval. Globally, TR TCP writes a maximum of 1000 of these log records within a five minute interval. If a log record was not written due to these limits, the count of refused or would have been refused connection log records that were not logged is recorded in the EZZ8660I TRMD TCP connection log records suppressed log message after the five minute interval ends. Similarly, the count of QOS exception records that were not written is recorded in the EZZ8661I TRMD TCP QOS exception log records suppressed log message.

TCP traffic regulation policy applies to IPv4 and IPv6.

**Guideline:** TR TCP is intended for use with long-running servers, which typically use well-known ports or ports that are reserved for TCP applications. You should not use TR TCP to monitor transitory listeners; doing so can result in high storage usage. An example of a transitory listener is an FTP data connection that lasts only as long as it takes to move one file and typically uses ports above 1023.

## Traffic regulation policies for UDP ports

Previously, control over UDP based applications consisted of application priority management and the TCP/IP profile parameter UDPQueueLimit ON | OFF. Inbound datagrams for bound UDP ports are accepted and queued until the queue limit is reached or buffer memory is exhausted. If UDPQueueLimit is set to OFF, any single bound port under a flood attack or with a stalled application could consume all available buffer storage. It is recommended that UDPQueueLimit always be set to ON. This limits the amount of storage that can be consumed by inbound datagrams for any single bound port. Sockets that use the Pascal API, have a limit of 160 KB in any number of datagrams. Sockets that use other APIs, have a limit of 2000 datagrams or 2880 KB.

IDS traffic regulation (TR) policies for UDP ports specify one of four abstract queue sizes for specified bound IP addresses and ports. The four abstract sizes are VERY\_SHORT, SHORT, LONG and VERY\_LONG.

The actual queue sizes associated with these abstract values are internal values that are subject to change. Most UDP applications have timeout values based on human perceptions of responsiveness. These values tend to stay constant while system processing speeds and network delivery speeds continue to advance rapidly. This might require the queue sizes associated with these abstract values to change over time. The initial implementation uses the values of 16, 256, 2048 and 8192 for the number of datagrams and an average datagram size of 2 KB to calculate the byte sizes (32 KB, 512 KB, 4 MB, 16 MB). For performance reasons, sockets that use the Pascal API will enforce only the byte limit. Sockets that use other APIs will enforce both limits. Sockets without a policy specified for their port will use the existing UDPQueueLimit mechanism.

For applications that can process datagrams at a rate faster than the average arrival rate, the queue acts as a speed matching buffer that shifts temporary peak workloads into following valleys. The more that the application processing rate exceeds the average arrival rate and the larger the queue, the greater the variation in arrival rates that can be absorbed without losing work. Very fast applications with highly variable ("bursty") traffic patterns might benefit from LONG or VERY\_LONG queue sizes.

For applications that consistently receive datagrams at a higher rate than they are able to process them, the queue limits the effective arrival rate to the processing rate by discarding excess datagrams. In this case the queue size influences only the average wait time of datagrams in the queue and not the percentage of work lost. In fact, if the wait time gets too large, the peer application might have given up or retransmitted the datagram before it is processed. Slow applications with consistently high traffic rates might benefit from SHORT queue sizes.

In general, client side applications will tend to have lower system priority giving them lower datagram processing rates. They also tend to have much lower datagram arrival rates. Giving them SHORT or VERY\_SHORT queue sizes might reduce the risk to system buffer storage under random port flood attacks with little impact on percentage of datagrams lost.

TR UDP generates a Constrained Event when a port reaches about 90% of its Queue Limit. An Unconstrained Event is generated when the port falls below about 88% of its limit. An IDS correlator is assigned for the duration of each constrained state. If tracing is requested in the policy, the first 100 packets that exceed the limit in each constrained state are traced along with the correlator.

UDP traffic regulation policy applies to IPv4 and IPv6.

## Options for configuring IDS

---

You configure IDS using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the IDS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

### Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, a GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create IDS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are two types of reusable objects:

- Traffic descriptors that define the IP traffic type, such as TCP or UDP.

- Requirement maps that contain attack protection, scan protection, and traffic regulation. For scan protection and traffic regulation, traffic descriptors are used to identify the local applications that are provided the protection and regulation. A single requirement map should contain a complete set of IDS requirements that will govern the level of IDS for a TCP/IP stack.

For each TCP/IP stack, you select a requirement map that provides IDS for the stack. The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors and a default requirement map that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create IDS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security configuration, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing IDS.

The information in [“Defining IDS policies”](#) on page 890 primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and IDS function.

## Option 2: Manual configuration

You can manually create the IDS policy configuration files by coding all of the required statements in a file. There are a large number of configuration options provided by IDS policy statements that permit advanced users to carefully fine-tune IDS policy on a per-stack basis. The information in [“Defining IDS policies”](#) on page 890 describes the procedure for creating an IDS policy by manually creating and editing the configuration files. For details about the [IDS policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

## Specifying the IDS configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see [“Policy types and infrastructure overview”](#) on page 813. Regardless of which option is used to configure IDS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves IDS policies from the policy server, specify the configuration files using the `DynamicConfigPolicyLoad` statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve IDS policies from the policy server, specify the configuration files using the `IDSConfig` statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the `IDSConfig` statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

## Defining IDS policies

IDS policies are stored in a Policy Agent IDS configuration file, a server that supports LDAP, or both. IDS policies are processed by Policy Agent and installed into a z/OS Communications Server TCP/IP stack. Before creating IDS policies, you should be familiar with the information about running Policy Agent, the IDS configuration file, and LDAP in [Chapter 14, “Policy-based networking,”](#) on page 813.

**Restriction:** Not all IDS policy options are available in an LDAP configuration file. Each of the policy example sections, IDS scan policy example, IDS attack policy examples, and traffic regulation policy example, indicate which policy options are not available if you are using LDAP to define IDS policy.

A conservative approach to defining IDS policy will avoid unexpected application outages and excessive rule processing. The examples here describe policies provided in the sample files shipped with the system. (See [“Policy sample files”](#) on page 826.)

## IDS policy definition considerations

IDS policies can be defined with different condition type values.

**Tip:** Condition type is configured in the IDS configuration file with the `ConditionType` statement, and in the LDAP configuration with the `ibm-idsConditionType` attribute.

The supported condition types are as follows:

### SCANGLOBAL

This policy is searched by condition type only. The highest priority scan global rule is mapped at policy change and cached. The policy defines the `FastScan` and `SlowScan` parameters, and the reporting and tracing actions to take when a scan is detected. The statistics reporting option is not applicable to scan processing. Scan processing does not impose limits, discard packets, or reset connections.

### SCANEVENT

These policies are searched by condition type and a protocol condition of ICMP, ICMPv6, TCP, or UDP. For protocols TCP and UDP, the policy search also includes the local destination port and the bound IP address. For ICMP and ICMPv6, the highest priority scan event rule is mapped at policy change and cached. The TCP and UDP rules are mapped when a potentially countable event occurs. If the event is associated with a bound socket, the rule is cached. The policies associated with these rules define the sensitivity level to use for counting events towards the scan thresholds and the source exclusion list to use for the mapped events. Packet tracing occurs if the action associated with the scan global rule activates tracing and the sensitivity level indicates that the event is countable. The statistics reporting option is not applicable to scan processing. Scan processing does not impose limits, discard packets, or reset connections.

### ATTACK

There are several attack types. For each attack type, the highest priority rule is mapped at policy change and cached. The reporting and statistics actions are supported for all attack types. The tracing action is supported for all attack types except `EE XID flood`, `TCP queue size`, and `global TCP stall`. For each attack type, the policy is searched by only condition type and attack type.

**Tip:** You can configure a discard action in the IDS configuration file as `ActionType ATTACK DISCARD`, and in the LDAP configuration using the `ibm-idsTypeActions:LIMIT` attribute.

Other supported actions are defined for each attack type. The supported attack types are:

#### MALFORMED\_PACKET

Malformed packets are always discarded by the stack, even if no discard was requested by the policy.

#### FLOOD

Flood packets are always discarded by the stack, even if no discard was requested by the policy.

#### ICMP\_REDIRECT

ICMP redirect packets are discarded if this policy specifies discard.

#### IP\_FRAGMENT

If this policy specifies discard, fragmented datagrams are discarded if a fragmentation overlay is detected that changes the data in the packet, including changes to the length of the packet.

#### RESTRICTED\_IP\_OPTIONS

A list of restricted IP options is specified for this attack type. IP option 0 (end of list) and 1 (NO-OP) cannot be restricted and are ignored if specified. If this policy specifies discard, IPv4 packets are discarded if they contain an IP option that is specified in the list of restricted IP options.

#### RESTRICTED\_IPV6\_DST\_OPTIONS

A list of restricted IPv6 destination options is required for this attack type. You cannot restrict options 0 (Pad1) or 1 (PadN); they are always allowed. If this policy specifies discard, IPv6 packets are discarded if they contain an IPv6 destination options extension header with an option that is specified in the list of restricted IPv6 destination options.

### **RESTRICTED\_IPV6\_HOP\_OPTIONS**

A list of restricted IPv6 hop-by-hop options is required for this attack type. You cannot restrict options 0 (Pad1) or 1 (PadN); they are always allowed. If this policy specifies discard, IPv6 packets are discarded if they contain an IPv6 hop-by-hop extension header with an option that is specified in the list of restricted IPv6 hop-by-hop options.

### **RESTRICTED\_IP\_PROTOCOL**

A list of restricted IP protocols is required for this attack type. IP protocols 1 (ICMP), 6 (TCP), and 17 (UDP) cannot be restricted and are ignored if specified. If this policy specifies discard, IPv4 packets are discarded if they contain a protocol that is specified in the list of restricted IP protocols.

**Restriction:** This attack type applies only to unicast packets destined for an interface on this TCP/IP stack. It does not apply to broadcast or multicast packets. It does not apply to routed traffic.

### **RESTRICTED\_IPV6\_NEXT\_HDR**

A list of restricted IPv6 next header values is required for this attack type. You cannot restrict next header values 6 (TCP), 17 (UDP), or 58 (ICMPv6); they are always allowed. If this policy specifies discard, IPv6 packets are discarded if they contain a next header value that is specified in the list of restricted IPv6 next headers.

### **OUTBOUND\_RAW**

A list of restricted IP protocols is required for this attack type. If this policy specifies discard, outbound IPv4 raw packets that meet any of the following criteria are discarded:

- Written to a raw socket that has a source IP address that is not in the stack's home list
- Fragmented by the application
- Specifies one of the ICMP reply types
- Specifies a protocol that is in the list of restricted IP protocols

### **OUTBOUND\_RAW\_IPV6**

A list of restricted IP protocols is required for this attack type. If this policy specifies discard, outbound IPv6 raw packets that meet any of the following criteria are discarded:

- Specifies one of the ICMPv6 reply types
- Specifies one of the ICMPv6 neighbor discovery (ND) types
- Specifies one of the ICMPv6 multicast listener discovery (MLD) types
- Specifies a protocol that is in the list of restricted IP protocols

### **PERPETUAL\_ECHO**

A list of local UDP ports and a list of remote UDP ports is necessary with this attack type. Each port list is limited by the stack to the first 20 ports specified. The ports in each inbound UDP packet are checked against these lists. The destination port is checked against the local port list. The source port is checked against the local port list if the source IP address is in the stack's home list. Otherwise, the source port is checked against the remote port list. If this policy specifies discard, UDP packets with both ports in the checked port lists are discarded.

When defining the policy in LDAP, this attack type condition must be specified in a complex rule using CNF and multiple condition levels. The attack type condition is at one of the condition levels. There must be a list of conditions defining the local port list at a second level. There must be a list of conditions defining the remote port list at a third level. The negated flag is ignored by the stack on port list conditions.

### **EE\_LDLC\_CHECK**

EE signaling data received on a port other than the signaling port is discarded if this policy specifies discard. An exclusion list is applied if one is configured. An EE packet is not flagged as an attack if the source IP address is found in the exclusion list.

**EE\_PORT\_CHECK**

EE packets with different source and destination ports are discarded if this policy specifies discard. An exclusion list is applied if one is configured. An EE packet is not flagged as an attack if the source IP address is found in the exclusion list.

**EE\_MALFORMED\_PACKET**

Malformed EE packets are discarded if this policy specifies discard. An exclusion list is applied if one is configured. A malformed EE packet is not flagged as an attack if the source IP address is found in the exclusion list.

**EE\_XID\_FLOOD**

An EE XID flood is detected when a large number of EE XID exchanges time out. No discard action is associated with this attack type. An exclusion list is applied if one is configured. An EE XID time out is not counted as part of flood detection if the source address of the XID is found in the exclusion list.

**DATA\_HIDING**

If this policy specifies discard and enables checking of IP option pad fields or embedded packets within an ICMP error message, packets containing hidden data are discarded.

**TCP\_QUEUE\_SIZE**

If this policy specifies reset, the TCP connection is reset if the send, receive, or out-of-order queue becomes constrained. A queue can be constrained due to the amount of data on the queue or the age of the data on the queue. A queue size is specified in the conditions. A list of remote IP addresses, that are to be excluded when monitoring the send queue, can optionally be specified in the conditions.

**GLOBAL\_TCP\_STALL**

If this policy specifies reset, the stalled TCP connections are reset when a global TCP stall condition is detected.

**TR**

These policies are searched by condition type, protocol (TCP or UDP), local IP address, and local port. TCP rules are mapped when a local application does a listen on a socket or when an inbound connection handshake is completed. UDP rules are mapped when an inbound packet arrives at a local bound socket. UDP TR policy supersedes the TCPIP PROFILE setting of UDPQUEUELIMIT for covered ports. Mapped rules are cached and associated with the bound socket.

For TCP, the policy defines the total number of allowed connections, the percentage of remaining available connections any single source IP can acquire and whether these limits are applied globally across all applications using this port number or applied individually to each application using an instance of this port number. For UDP, the policy defines which of the four available queue sizes is applied to each application using this port number. TR actions define the reporting, statistics and tracing actions for covered ports. If the policy specifies action LIMIT, connections or packets that exceed the limits are discarded.

**Notes:**

1. For TCP, a total connection limit or percentage available limit of zero, with an action of LIMIT effectively quiesces the application.
2. For TCP, a local host IP address cannot be specified in any condition if a TR TCP limit scope value of PORT is specified.
3. For UDP, a policy for a port without an action of LIMIT effectively makes the application unlimited.
4. Each LDAP IDS TR action must specify at least one `ibm-idsTypeActions` attribute.

**IDS scan policy example**

The goal of scan policy is to detect all scanners with potentially malicious intent while avoiding large numbers of false positives. You can make this process more efficient by reserving all unused low ports in the TCPIP profile. This will allow you to use the low sensitivity setting on scans for these ports. As you investigate the scans detected, you will initially find your own network management tools. These can be explicitly excluded. If you include UDP ephemeral ports in a high sensitivity policy, you will discover that

your DNS servers show up as scanners. You can explicitly exclude these as well. To activate scan policy, a scan global rule and at least one scan event rule must be defined.

The following scan rules are defined:

- Scan Global

Defines a global set of parameters for detecting scans, and also defines reporting parameters for scan events.

- A Fast Scan is defined as 5 unique events in 2 minutes from a single source IP address.
- A Slow Scan is defined as 10 unique events in 480 minutes (8 hours).
- The first 200 bytes of the packet associated with each countable event will be traced.
- When a scan is detected an event will be written to syslog warning level, along with a detailed list of all the unique events included in the scan.
- No message will be written to the console.

- Scan Event Low

Defines a set of traffic for which low sensitivity scan detection will be performed. Inbound traffic to all TCP and UDP ports between 1 and 1023 will be monitored. It is recommended that unused low ports be RESERVED in the TCPIP Profile.

- Scan Event Medium

Defines a set of traffic for which medium sensitivity scan detection will be performed. ICMP and ICMPv6 inbound traffic will be monitored.

The following example is an IDS configuration file:

If you are using LDAP to define policy, see [“IDS scan policy example” on page 1427](#).

**Restrictions:** LDAP policy cannot be used to:

- Define that ICMPv6 traffic should be monitored for scan events
- Exclude IPv6 addresses in the scan exclusion list

## IDS attack policy examples

The goal of attack policy is to help protect your system from both known and unknown attacks and to give you timely notification when attacks do occur.

A malformed packet attack policy covers many known attacks designed to cause system failures. These packets are always discarded and rarely have legitimate source address information. Many malformed packet attacks use fragmentation to overlay header fields. The IDS fragment restriction policy is intended to protect you from unknown attacks of this type by detecting fragment overlays that change the data in a packet, including changes to the length of the packet.

Unless you know that you need to process ICMP and ICMPv6 redirect messages, you should disallow them with policy.

There are several types of flood attacks. IDS can identify TCP SYN floods and interface floods. IDS policy should be used to notify you when a flood occurs. You will need to work with your network administrators and service providers to track the flood backwards, one physical hop at a time, to locate the sources.

The IP protocol restrictions and IP option restrictions provide additional protection against future unknown attacks. These are specific to IPv4. The philosophy behind them is to disallow anything that you do not have a known reason to allow. Similar protection is provided for IPv6 by the IPv6 next header restrictions, IPv6 destination option restrictions, and IPv6 hop-by-hop option restrictions.

A data hiding attack policy provides notification when an inbound packet might contain hidden data.

The global TCP stall detection provides protection against an attack that consumes systems resources by causing many TCP connections to stall, unable to send data.

The outbound raw policy is intended to help you detect someone using your system as the base for an attack. It looks for several behaviors associated with *spoofed* packets. This protection applies to IPv4 sockets. The IPv6 outbound raw policy provides similar protection for IPv6 sockets.

Attack rules define the set of conditions that define what constitutes an attack for a given attack type. The highest priority rule of each attack type is used. The action associated with an attack rule defines reporting and logging options for a detected attack.

The following types of attack rules are defined in the sample policy:

- Malformed packet

Protects against various types of known attacks based on malformed packets. Applies to IPv4 and IPv6 packets.

- Flood

Protects against TCP SYN flood and interface flood attacks. Applies to IPv4 and IPv6 connections and interfaces.

- ICMP redirect

Ignores received ICMP and ICMPv6 redirect messages.

- IP fragment

Disallows fragmentation overlays that change the data in a packet, including changes to the length of the packet. Applies to both IPv4 and IPv6 packets.

- IP protocol restrictions

Defines restricted IP protocols, and restricts everything except the following values:

- 1 (ICMP)
- 2 (IGMP)
- 4 (IPv4 encapsulation)
- 6 (TCP protocol)
- 17 (UDP protocol)
- 46 (RSVP protocol)
- 47 (GRE protocol)
- 50 (ESP extension header)
- 51 (AH extension header)
- 89 (OSPF protocol)
- 94 (IPIP encapsulation protocol)

Applies to IPv4 packets only.

- IPv6 next header restrictions

Defines restricted IPv6 next header values, and restricts everything except the following values:

- 0 (Hop-by-hop options extension header)
- 6 (TCP protocol)
- 17 (UDP protocol)

- 41 (IPv6 extension header)
- 43 (routing extension header)
- 44 (fragmentation extension header)
- 50 (ESP extension header)
- 51 (AH extension header)
- 58 (ICMPv6 protocol)
- 59 (No next header)
- 60 (Destination options extension header)
- 89 (OSPF protocol)
- 135 (Mobility header)

Applies to IPv6 packets only.

- IPv6 destination option restrictions

Defines restricted options in the IPv6 destination extension header, and restricts all options except the following options:

- 0 (Pad1)
- 1 (PadN)
- 4 (Tunnel encapsulation limit)
- 5 (Router alert)
- 6 (Quick-start)
- 7 (CALIPSO)
- 138 (Endpoint identification)
- 194 (Jumbo payload)
- 201 (Home address)

Applies to IPv6 packets only.

- IPv6 hop-by-hop option restrictions

Defines restricted options in the IPv6 hop-by-hop extension header. A common `IpOptionGroup` is referenced by the IPv6 destination and IPv6 hop-by-hop option rules. Applies to IPv6 packets only.

- Outbound raw restrictions

Validity checking for outbound packets using raw sockets. Restricts everything except ICMP, UDP, IGMP, and OSPFIGP. Applies to IPv4 packets only.

- EE LDLC check

Validity checking of the Logical Data Link Control (LDLC) command for inbound EE packets to ensure that the packet is received on the correct port. A packet with a source IP address in the exclusion list is not checked. Applies to IPv4 and IPv6 packets.

- IPv6 outbound raw restrictions

Validity checking for outbound packets using IPv6 raw sockets. Restricts everything except ICMPv6, UDP, and OSPF protocols. Applies to IPv6 packets only.

- Data hiding checks

Applies to IPv4 and IPv6 packets.

- TCP queue size restrictions

The queue size is defined as `SHORT`. Applies to IPv4 and IPv6 connections.

- Global TCP stall detection

Applies to IPv4 and IPv6 connections.

- A single reusable attack action is defined and shared among all the attack rules and specifies the following actions:
  - Events are written to syslog ALERT level.
  - Events are not written to the system console.
  - The first 200 bytes of packets associated with an attack are traced.
  - Statistics are evaluated every 60 minutes and written only if an attack occurred.
  - In the IDS configuration file, Nodiscard was specified, so packets that are associated with the following attack types are not discarded:
    - ICMP redirect
    - IP fragment
    - IP protocol restrictions
    - IPv6 next header restrictions
    - IPv6 destination options
    - IPv6 hop-by-hop options
    - Outbound raw
    - IPv6 outbound raw
    - Data hiding
    - EE LDLC check

In the LDAP example in [“IDS attack policy example” on page 1429](#), Limit was not specified, which has the same effect as Nodiscard.

- In the IDS configuration file, NoResetConn was specified, so when a TCP queue size or global TCP stall condition is detected, the TCP connections are not reset.

The following example is an IDS configuration file:

```

```

If you are using LDAP to define policy, see [“IDS attack policy example”](#) on page 1429.

**Restriction:** LDAP policy cannot be used to define rules for the following attack types:

- DATA\_HIDING
- OUTBOUND\_RAW\_IPV6
- RESTRICTED\_IPV6\_DST\_OPTIONS
- RESTRICTED\_IPV6\_HOP\_OPTIONS
- RESTRICTED\_IPV6\_NEXT\_HDR
- TCP\_QUEUE\_SIZE
- GLOBAL\_TCP\_STALL
- EE\_MALFORMED\_PACKET
- EE\_LDLC\_CHECK
- EE\_PORT\_CHECK
- EE\_XID\_FLOOD

## Traffic Regulation policy examples

The goal of Traffic Regulation (TR) policy is to protect your system from usage spikes. A phased approach to determine the correct policy for your system is recommended.

To gather baseline statistics, you should first run in normal statistics mode, with the traffic regulation management daemon (TRMD) running. In normal statistics mode, the following information is provided for the port on a policy defined interval:

- Total number of connections requested during the interval
- Total number of connections closed during the interval
- The IP address of the host that requested a connection during the interval and held the highest number of concurrent connections during the interval, and the highest number of concurrent connections held by this IP address
- A suggested value for TotalConnections based on this interval
- A suggested value for Percentage based on this interval

While the baseline statistics records provide suggested policy values for the interval, you should evaluate data from multiple intervals. The values suggested are those that would avoid denying any of the connections in the interval. Choose lower values if the interval represents a workload larger than you want to allow.

After you determine the policy values to use, try running with the Log and Nolimit actions specified. Specifying the Nolimit action basically tests out the policy. The connections that would have been denied (if the Limit action was specified) are logged, but the connection is allowed to occur. After you are satisfied with the experimental policy, the policy action can be set to Limit.

The following traffic regulation TCP rules are defined:

- TRTcp-rule: Defines TCP baseline statistics gathering for the low port range.  
This temporary rule provides statistical reports to determine normal traffic patterns for several applications. After the baseline values are determined, this rule should be replaced by rules that include the specific conditions to be regulated.
- TRTcpWeb-rule: Defines application limits and host percentage limits for a single application.
  - This rule enforces set limits.
  - The rule has a higher priority than the TR TCP rule.
  - The rule is limited to a single server application that is bound to a specific IP address.

The following example is an IDS configuration file:

```
#####
TR Policies
#####

#-----
TR - IDSRule
#-----
IDSRule TRtcpWeb-rule
{
 ConditionType TR
 Priority 7
 IDSTRConditionRef TRtcpWebCondition
 IDSActionRef TRtcpLimit-action
}
IDSRule TRtcp-rule
{

 TypeActions Statistics
}

#-----
IPTimeCondition
#-----
IpTimeCondition Time1
{
 TimeOfDayRange 1-22
 DayOfWeekMask 0111110
}
}
```

If you are using LDAP to define policy, see [“IDS TCP traffic regulation policy example”](#) on page 1436.

**Restriction:** LDAP policy cannot be used to define TCP traffic regulation policy that specifies IPv6 addresses.

The following traffic regulation UDP rule is defined:

- TR UDP: Defines UDP queue size for the low port range.
  - This rule provides statistics reports to determine normal traffic patterns for several applications while monitoring queue sizes.

The following example is an IDS configuration file:

```
#####
#####
TR Policies
#####

#-----
TR - IDSRule
#-----
IDSRule TRUdp-rule
{
 ConditionType TR
 Priority 2
 IDSTRConditionRef TRUdpCondition
 IDSAActionRef TRUdpLogLimit-action
}

#-----
TR - IDSTRCondition
#-----
IDSTRCondition TRUdpCondition
{
 Protocol Udp
 LocalPortRange 1-1023
 TRUdpQueueSize Long
}

#-----
TR - IDSAction
#-----
IDSAction TRUdpLogLimit-action
{
 ActionType TR LIMIT
 IDSReportSetRef LogStatReportSet
}

#-----
IDSReportSet
#-----
IDSReportSet LogStatReportSet
{
 TypeActions Log
 TypeActions Statistics
}
```

If you are using LDAP to define policy, see [“IDS UDP traffic regulation policy example”](#) on page 1438.

**Restriction:** LDAP policy cannot be used to define UDP traffic regulation policy that specifies IPv6 addresses.

## Verification

To verify that policies are correctly defined and functioning properly, consider the following points:

- Are the policies active?
- Is the expected traffic mapping to the correct policies?
- Are the IDS Policy functions working correctly?

The following subtopics provide more details about these considerations.

## Are the correct policies active?

If your policies are defined in the LDAP server, check your LDAP server log or command output for errors encountered when your policies were loaded into LDAP. Some LDAP servers treat consecutive blank lines in an LDIF file as end of file; ensure that all of the policy objects in your LDIF files are acknowledged by LDAP.

Check your Policy Agent log file for errors while processing your policy.

Use the `pasearch` command to verify that the intended policies are active and have the expected attributes for the target stack.

## Is the expected traffic mapping to the correct policies?

Use the `Netstat IDS/-k SUMmary` command to ensure that the intended policy has been mapped for each of the attack types, the Scan-Global type, the Scan-Event type for protocol ICMP, and the Scan-Event type for protocol ICMPv6. See [z/OS Communications Server: IP System Administrator's Commands](#) for more information on the Netstat command.

These IDS functions each select the single highest priority policy for their respective types at each policy change.

Use the `Netstat IDS/-k PROTOcol TCP` and `Netstat IDS/-k PROTOcol UDP` commands to ensure that the intended Scan-Event and TR policies have been mapped to the intended local sockets.

These IDS functions select the highest priority policy for the Protocol, local Port and local IP address when there is relevant activity against the socket.

For TCP this usually entails either a listen or the completion of an inbound connection handshake. For UDP this usually entails either a bind or an inbound datagram. Scan policies are also selected on some inbound error paths.

## Are the IDS policy functions working correctly?

IDS policies that include IDS actions with statistics, log, or syslog set cause the stack to make log record information available to TRMD. If TRMD is running you may run the IDS report generator `trmdstat` against the appropriate log files to produce reports on the area of interest.

## TRMD

---

TRMD runs as an APF-authorized program. The user ID associated with TRMD must be defined with a UID of 0, or must be permitted to become a superuser by having READ access to the BPX.SUPERUSER resource in the FACILITY class. See the EZARACF member of SEZAINST for sample RACF commands for TRMD.

Use the `-p` start option or the resolver configuration file to determine the stack that TRMD uses. Ensure that you specify the `-p` start option or that the `RESOLVER_CONFIG` environment variable is correctly set before starting TRMD. A separate instance of TRMD must be run for each TCP/IP stack.

The Log records written by TRMD contain two timestamps:

- A timestamp generated when the event was detected by the stack. This timestamp is generated by the stack and is always Coordinated Universal Time (UTC).
- A timestamp that is generated when the syslogd record ID is created. This timestamp is dependent on the setting of the TZ environment variable at the time that TRMD is started. If you want this timestamp to be based on UTC, then ensure that the TZ environment variable is properly set (for example, export `TZ=0`) before starting TRMD.

You can set the TZ environment variable in the following ways:

- When starting TRMD from the z/OS shell:

Export the TZ environment variable before starting TRMD; you should do this in /etc/profile or in .profile in the HOME directory. For example, if you are in the Eastern time zone in the United States:

```
export TZ=EST5EDT
```

- When starting TRMD as a started task, use either of the following methods:

- Specify TZ using the ENVAR parameter on the PARM statement in the started procedure. For example:

```
// PARM='ENVAR("TZ=EST5EDT")/'
```

- Export the TZ environment variable in a file specified with the STDENV DD statement. For example:

```
// PARM='ENVAR("_CEE_ENVFILE=DD:STDENV")/'
//STDENV DD PATH='/etc/trmd.env',PATHOPTS=(ORDONLY)
```

Place the following statement in the /etc/trmd.env file:

```
TZ=EST5EDT
```

The use of the STDENV DD statement works well when you want to specify more than one environment variable; there is a JCL limit of 100 characters on the PARM parameter. Language Environment recommends a variable record format for the STDENV file.

You can also set the TZ environment variable for all applications in the CEEPRMxx PARMLIB member. You should define the TZ environment variable for all three LE option sets (CEEDOPT, CEECOPT, and CELQDOPT). For example:

```
CEEEOPT(ALL31(ON), ENVAR('TZ=EST5EDT'))
CEEDOPT(ALL31(ON), ENVAR('TZ=EST5EDT'))
CELQDOPT(ALL31(ON), ENVAR('TZ=EST5EDT'))
```

For more information on [Using the CLER CICS transaction to display and set runtime options](#), see [z/OS Language Environment Programming Guide](#). For details on [setting the Format of the TZ environment variable](#), see [z/OS UNIX System Services Command Reference](#).

If running multiple instances of TRMD, consider using the syslogd -u option when starting syslogd. The -u option causes the jobname of the application writing the log record to be included in the log record.

The TCP/IP stack must be running before TRMD can be started.

TRMD can be started from the z/OS shell or as a started task.

## Running TRMD as a started task

A sample procedure is shipped in member EZATRMDP in SEZAINST. Follow the instructions in the sample member to define your environment.

The offset from Coordinated Universal Time (UTC) of the syslog time in the timestamp of TRMD messages is determined by the TZ environment variable. If the timestamp is required in UTC and has not been set by the TZ environment variable, specify the following definition in the TRMD procedure:

```
// PARM=('POSIX(ON) ALL31(ON)',
// 'ENVAR("LIBPATH=/usr/lib",
// '"TZ=0")/-d 1')
```

To start TRMD as a started task, use the S TRMD command from the MVS console or SDSF. TRMD issues a fork, and in some cases the job name will be the original job name with a number appended. For example, S TRMD might result in the TRMD started task running under the job name TRMD1, whereas S TRMDTASK would result in the TRMD started task running under the job name TRMDTASK. Use the D A,TRMD\* command to verify the job name that TRMD is running under.

If running as a started task, issue P *jobname* to stop TRMD.

To automatically start TRMD when the TCP/IP stack is started, add TRMD to the AUTOLOG statement in the TCP/IP profile as follows:

```
AUTOLOG
 TRMD JOBNAME TRMD
ENDAUTOLOG
```

## Running TRMD from the z/OS UNIX shell

Ensure that you specify the -p start option or that the RESOLVER\_CONFIG environment variable is correctly set before starting trmd.

The offset from Coordinated Universal Time (UTC) of the syslog time in the timestamp of TRMD messages is determined by the TZ environment variable. If the timestamp is to appear in Coordinated Universal Time (UTC), change the TZ specification in /etc/profile or export TZ="0" before starting TRMD.

After the appropriate environment is set up, issue the following command to start TRMD:

```
trmd
```

## Stopping TRMD

To stop TRMD, issue the following kill command :

```
kill -s TERM pid
```

where pid is the TRMD process ID

To obtain the TRMD process ID, issue the following z/OS UNIX command:

```
ps -A
```

Debug options can also be specified when starting TRMD. See [z/OS Communications Server: IP Configuration Reference](#) for more information.

## trmdstat

The trmdstat utility program runs from the z/OS UNIX shell. The trmdstat program reads a log file, analyzes the log records generated by TRMD, and provides summary or detailed reports based on the options specified.

The following reports can be requested:

- IDS summary of logged events
- Reports of logged connection events
- Reports of logged intrusions defined in the ATTACK policy
- Reports of logged intrusions defined in the TCP policy
- Reports of logged intrusions defined in the UDP policy
- Reports of statistics events

See [z/OS Communications Server: IP System Administrator's Commands](#) for the trmdstat command and samples of the reports generated by the trmdstat program.

## Defensive filtering

An external security information and event manager, by analyzing and correlating messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in your TCP/IP stack. A defensive filter is a rule to discard packets, and is separate from IP security filters. Filter processing matches a defensive filter rule to data traffic based on any combination of IP source

or destination address, protocol, source or destination port, or direction of flow. Filter processing checks defensive filters before IP security filters.

The z/OS UNIX **ipsec** command is used to add and manage defensive filters. Defensive filters are typically added as an automated action that results from the analysis of the external security information and event manager. However, you can also add a defensive filter by manually issuing the **ipsec** command. The Defense Manager Daemon (DMD) is an integral part of managing the defensive filters.

[Figure 44 on page 207](#) shows an overview of defensive filtering and the DMD.

For more information about defensive filters and the DMD, see [Chapter 19, “Defensive filtering,” on page 1135](#).

---

## Chapter 17. IP security

This topic contains a description of IP filtering, IPSec-protected traffic, and preparing and configuring a z/OS system for IP security. Various business configurations are explained, including host-to-host, host-to-gateway, gateway-to-gateway, and gateway-to-host.

---

### Terms and concepts for IP security

---

The following terms and concepts are used in this information:

#### **3DES**

Also known as triple DES, this encryption method uses three DES operations on a single data block with three different keys. Provides greater security than single DES.

#### **Active**

Used in three ways:

- Describes the filter policy that is in effect (default or Policy Agent).
- Describes the state of the rules or actions that are defined in Policy Agent. These rules or actions can be active or inactive due to a time condition.
- Describes the state of a manual tunnel installed in the TCP/IP stack. A manual tunnel can be active (available for use) or inactive (not available for use).

#### **Active IPSec policy**

The policy that is in effect, either the default filter policy or the IP security filter policy.

#### **Advanced Encryption Standard (AES)**

A symmetric block cipher that can encrypt (encipher) and decrypt (decipher) information. IP security for z/OS Communications Server supports AES with a 128-bit key length.

#### **AES Cipher Block Chaining (CBC) (AES\_CBC) mode**

The AES algorithm using the CBC mode. IP security for z/OS Communications Server supports AES\_CBC with a 128-bit or 256-bit key length.

#### **AES Galois Counter Mode (GCM)**

The AES algorithm using Galois Counter Mode and with a 16-byte integrity check value (ICV). Galois Counter Mode is a combined-mode algorithm that performs both encryption and authentication simultaneously. IP security for z/OS Communications Server supports AES\_GCM with a 128-bit or 256-bit key length.

#### **AES Galois Message Authentication Code (GMAC)**

The AES algorithm using Galois Counter Mode to encode authentication data in either AH or ESP headers. AES\_GMAC functions as a combined-mode algorithm; however, it provides authentication without encryption. IP security for z/OS Communications Server supports AES\_GMAC with a 128-bit or 256-bit key length.

#### **AES Extended Cipher Block Chaining (XCBC)**

The AES algorithm using the XCBC mode to encode authentication data in either AH or ESP headers, with 128-bit keys and hash truncation to 96 bits.

#### **Asymmetric encryption**

Also known as public/private key encryption, this type of encryption is performed between two parties using pairs of encryption and decryption keys.

#### **Authentication Header (AH)**

An IP protocol (51) used with an IPSec Security Association to provide authentication of IP packets.

#### **Autoactivation**

The process by which a dynamic tunnel is activated when IP security policy is installed into the TCP/IP stack, either as the result of a user action, or the result of TCP/IP or the IKED initialization.

**Certificate authority**

A trusted third party that verifies information that is contained in an X.509 digital certificate.

**Certificate revocation list (CRL)**

A time-stamped list of revoked certificates that is signed by a certificate authority.

**Child Security Association**

The IKEv2 name for a phase 2 Security Association.

**Command-line activation**

The process of activating a tunnel through the use of the **ipsec** command. Both manual and dynamic tunnels can be activated from the z/OS UNIX command line.

**CRLDistributionPoints**

An optional X.509 certificate extension that identifies one or more locations where the CRL for a certificate is.

**Data encryption standard (DES)**

A block cipher with 64-bit blocks and a 56-bit key.

**Default IP filter policy**

Used until the IP security filter policy is installed by Policy Agent. The default IP filter policy includes both the filter rules you define in the TCP/IP profile and the implicit default filter rules that the stack generates. The implicit default filter rules deny all traffic that does not match any configured filter rule.

**Dynamic tunnel**

An IPSec tunnel whose security parameters are negotiated and whose encryption keys are generated dynamically using IKE.

**Elliptic curve digital signature algorithm (ECDSA)**

The algorithm that is used to authenticate a remote security endpoint using ECDSA with either SHA2-256 on the P-256 curve, SHA2-384 on the P-384 curve, or SHA2-512 on the P-512 curve.

**Encapsulating Security Payload (ESP)**

An IP protocol (50) used with an IPSec Security Association to provide authentication and encryption of IP packets.

**Hashed message authentication code (HMAC)**

A one-way hash function that combines the contents of a message and a secret key to produce a hash value; used for authentication.

**HMAC\_MD5**

HMAC using the MD5 algorithm.

**HMAC\_SHA1**

HMAC using a SHA1 algorithm that encodes authentication data in AH or ESP headers, using a 160-bit hash value and 96-bit integrity check value (ICV).

**HMAC\_SHA2**

HMAC using a SHA2 algorithm that encodes authentication data in AH or ESP headers and that is qualified by the length of key and hash truncation. The algorithm can have 256-bit keys and hash truncation to 128 bits, 384-bit keys and hash truncation to 192 bits, or 512-bit keys and hash truncation to 256 bits.

**IKE negotiation**

A process by which two communicating IKE-enabled peers agree on a set of parameters that are used to protect traffic between them. This set of parameters is collectively known as a Security Association. One peer acts as the initiator of the negotiation, the other as the responder.

**IKE Security Association**

The IKEv2 name for a phase 1 Security Association.

**IKE tunnel**

A tunnel that protects IKE phase 2 messages.

**Internet Key Exchange (IKE)**

A protocol for the secure generation and management of encryption keys over an existing IP network. There are two versions, commonly referred to as IKE version 1.0 (IKEv1) and IKE version 2.0 (IKEv2).

**Internet Security Association and Key Management Protocol (ISAKMP)**

Defines IKEv1 procedures and packet formats to establish, negotiate, modify, and delete Security Associations.

**IP filter rule**

A configured rule that defines the action applied to an IP traffic pattern that is encompassed by the rule. The possible actions include permit, deny, and permit with IPSec protection.

**IP filter table**

An ordered list of IP filter rules. When IP filtering is active on a host, the table is consulted for each IP packet that is sent or received. The action of the matching IP filter rule is enforced by the TCP/IP stack.

**IPSec**

A suite of protocols and standards defined by the Internet Engineering Task Force (IETF) for secure communication over an existing IP network.

**IPSec tunnel**

A tunnel that protects IP traffic between two endpoints using one or both of the IPSec protocols. Manual and dynamic tunnels are both instances of an IPSec tunnel.

**IP security filter policy**

The policy that is installed by the Policy Agent. It includes the filter rules you define in the Policy Agent configuration files and an implicit deny all rule that is generated by Policy Agent.

**IP traffic pattern**

The set of IP traffic attributes that can be used as input to an IP filter table query. Typically, this includes IP source address, IP destination address, source port, destination port, protocol, and direction (inbound or outbound).

**Manual tunnel**

An IPSec tunnel whose security parameters and encryption keys are statically configured and must be manually managed by a security administrator.

**Message authentication code (MAC)**

A tag derived from the contents of a message and a secret key. The tag can be used to authenticate the integrity of a message as well as the source of the message.

**Message digest algorithm 5 (MD5)**

A MAC algorithm that produces a 128-bit hash value.

**NAT traversal (NATT)**

Traversal of IPSec traffic through a NAT device.

**Network address port translation (NAPT)**

A technique where multiple internal IP addresses are translated into a single public IP address. As part of this translation process, the TCP and UDP ports in the packets are translated. NAPT is sometimes referred to as port address translation (PAT) or IP masquerade.

**Network address translation (NAT)**

Network address translation is a broad term that encompasses both a one-to-one address translation function, translating a single internal IP address to a single public IP address, and the NAPT function.

**Network security services (NSS)**

Services performed in support of security enforcement or management.

**NSS client**

Requests network security services from an NSS server. The z/OS IKE daemon can act as an NSS client for a TCP/IP stack.

**NSS server**

Provides network security services for one or more NSS clients.

**On-demand**

The process by which a dynamic tunnel is activated by outbound traffic flow without user intervention.

**Phase 1**

The first stage of an IKE negotiation, in which an ISAKMP Security Association is established between two IKEv1-enabled peers, or in which an IKE Security Association is negotiated between two IKEv2-

enabled peers. A phase 1 Security Association refers to IKEv1 ISAKMP SAs, as well as to IKEv2 IKE SAs.

## **Phase 2**

The second stage of an IKE negotiation, in which an IPSec Security Association is established between two IKEv1-enabled peers, or in which a child Security Association is negotiated between two IKEv2-enabled peers. A phase 2 Security Association refers to IKEv1 IPSec SAs, as well as to IKEv2 child SAs.

## **Rivest Shamir Adleman (RSA)**

An asymmetric key encryption method, in which the key that is used to encrypt data is different than the key that is used to decrypt the data. RSA can be used for encryption, or to authenticate a digital signature.

## **Secure hash algorithm 1 (SHA1)**

A MAC algorithm similar to MD5, but more secure. This algorithm produces a 160-bit hash value.

## **Secure hash algorithm 2 (SHA2)**

A MAC algorithm similar to SHA1, but more secure. This algorithm produces a 256-bit, 384-bit or 512-bit hash value.

## **Security Association (SA)**

An agreement between two IPSec-enabled hosts that describes the type of data to protect and the methods that are used to protect the data. IKE creates a phase 1 Security Association to protect IKE messages (also known as the ISAKMP Security Association or the IKE Security Association), and a phase 2 Security Association to protect data traffic (also known as the IPSec Security Association or the child Security Association).

## **Symmetric encryption**

Encryption that is performed between two parties sharing the same encryption key. Also known as secret key encryption.

## **Transport mode encapsulation**

A process used to construct IPSec packets by inserting one or more additional IPSec headers between the IP header to be protected and the IP payload of the packet to be protected.

## **Tunnel**

A secure logical connection or channel that is defined by a collection of Security Associations that define the security parameters protecting traffic between two endpoints.

## **Tunnel activation**

The process by which a tunnel becomes active or usable. For dynamic tunnels, this process involves initiating an IKE negotiation.

## **Tunnel mode encapsulation**

A process used to construct IPSec packets by creating a new IP header with an IP payload consisting of the entire IP packet being protected, and then inserting one or more additional IPSec headers between the new IP header and its IP payload (that is, the original IP packet).

## **UDP encapsulation**

A process used to construct IPSec packets by first applying tunnel mode encapsulation or transport mode encapsulation to an IP packet to be protected by the ESP protocol, and then inserting a UDP header between the IP header and the ESP header.

## **Virtual private network (VPN)**

A logical network of connected network nodes that communicate through secure channels (tunnels), typically by using the IPSec protocols (AH and ESP).

## **X.500 distinguished name**

A collection of X.509 values, such as common name, host name, organization, organizational unit, and so on, that is stored in an X.509 digital certificate. An X.500 distinguished name is used as a globally unique identifier for the owner.

## **X.509 digital certificate**

A set of information in the X.509 standard containing various attributes about an entity, including identity information and a public key that is used for encrypted communications with that entity.

## Terminology conventions for IP security

---

The following terminology conventions are used throughout this information when referring to z/OS IP security:

**IP security**

The z/OS Communications Server function.

**IPSec**

The protocol suite.

**ipsec**

The action associated with an IP filter action, or the z/OS UNIX System Services command.

**IPSEC**

The statement in the TCP/IP profile.

**IPSECURITY**

The parameter on the IPCONFIG statement in the TCP/IP profile.

**NAT**

The general network address translation function. NAT encompasses both one-to-one address translation and network address port translation.

**NAPT**

Network address port translation. This term is used when information is specific only to this form of NAT.

## Commands used to administer IP security

---

The following commands are used to administer IP security. For more information on these commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

**certbundle**

Use the z/OS UNIX System Services **certbundle** command to create a certificate bundle file that contains certificate and CRL information.

**ipsec**

Use the z/OS UNIX System Services **ipsec** command to display information about active filters and Security Associations, and to control aspects of Security Association negotiation. The **ipsec** command is used to:

- Display filters that are active in the stack
- Revert to default IP filter policy, as defined in the TCP/IP profile
- Reload IP security policy, as defined in the Policy Agent configuration files
- Activate Security Association negotiations
- Display existing phase 1 Security Associations
- Display existing phase 2 Security Associations
- Display remote port mappings used with NAT traversal configurations
- Display network security configuration information for the active stacks on the local system
- Display information for each NSS IPSec client that is currently connected to the NSS server
- Refresh existing phase 1 Security Associations
- Refresh existing phase 2 Security Associations
- Deactivate existing phase 1 Security Associations
- Deactivate existing phase 2 Security Associations
- Test for a filter rule match for a given set of IP traffic characteristics

Authority to use the **ipsec** command is controlled through RACF. There are two distinct types of SERVAUTH profiles that define access to the **ipsec** command, one for display capabilities and one for control capabilities.

**Tip:** Many of the tasks, examples, and references in this information assume that you are using the z/OS Security Server (RACF). References to RACF apply to any other SAF-compliant security products that contain the required support. If you are using another security product, read the documentation for that product for instructions on task performance.

For the steps to configure access control to the **ipsec** command, see [Appendix E, “Steps for preparing to run IP security,”](#) on page 1391.

For detailed syntax and usage, and how to control access of the **ipsec** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

### **pasearch**

Use the **pasearch** command to display Policy Agent information that is defined in the Policy Agent configuration files, including IP security and other types of policies. The options that are related to IP security include the ability to view IP security policy rules and actions, both active and inactive, for any TCP/IP stack for which policies have been defined and that is IPSECURITY-enabled.

If the user of the **pasearch** command is not a superuser, authority is controlled through RACF.

For detailed syntax and usage of the **pasearch**, see [z/OS Communications Server: IP System Administrator's Commands](#).

### **MODIFY**

Use the MODIFY console command to have:

- The **MODIFY** command reread the IKED configuration file
- **MODIFY** command reread the Policy Agent configuration files

For detailed syntax and usage of the **MODIFY** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

### **Netstat**

Use the Netstat command to display the following information:

- IPSECURITY enablement for a particular stack (Netstat CONFIG/-f)
- SecurityClass (SECCLASS) for a specific interface (Netstat DEVLINKS/-d)

For detailed syntax and usage of the **Netstat** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

## **Overview of using IP security**

---

z/OS Communications Server provides the ability to control and monitor network traffic on one or more TCP/IP stacks on a z/OS system. IP security for z/OS Communications Server supports IP filtering, IPSec, and Internet Key Exchange (IKE). IP security for z/OS Communications Server supports two versions of the IKE protocol: IKEv1 and IKEv2. See [“Dynamic key management - IKE and IPSec negotiations”](#) on page 954 for more information.

IP security policy can be used for the following protection:

- Protect a secure host on an internal network from unwanted network traffic
- Provide protection for traffic between partner companies over connected networks
- Allow secure sending of data over the Internet by providing IPSec virtual private network (VPN) support

These features are implemented in the IP layer on a per packet basis, and thus are available to any network application without requiring any special modifications. Applications can also implement their own additional security features as necessary, on top of the underlying IP security.

IP security policy is enabled, enforced, managed, and monitored through a coordinated effort of several z/OS Communications Server components:

- Policy Agent

The Policy Agent is used to configure IP security on a z/OS system. It reads the configuration files that contain the IP security policy configuration statements, checks them for errors, and installs them into the IKE daemon and the TCP/IP stack.

- Internet Key Exchange daemon (IKED)

The Internet Key Exchange daemon is responsible for retrieving IP security policy from Policy Agent, and dynamically managing keys that are associated with dynamic IPSec VPNs. This daemon also provides network management capabilities for IP security aspects of local TCP/IP stacks.

- Network Security Services daemon (NSSD)

The Network Security Services daemon provides the NSS server functionality. It provides the NSS IPSec certificate service to perform digital signature creation and verification operations on behalf of NSS IPSec clients. The NSS IPSec certificate service is used by the IKED during phase 1 negotiations when digital signature authentication is required.

- TCP/IP stack

The stack maintains a list of currently active IP filters and IPSec Security Associations, actively filters network traffic, controls encryption and decryption of network data, and maintains counters that are associated with an IPSec Security Association lifetime.

- Traffic Regulation Manager daemon (TRMD)

The Traffic Regulation Manager daemon is responsible for logging IP security events that are detected by the stack, including IP filter events, updates to IP security policy, and the creation, deletion, and refresh of IPSec Security Associations.

- System logging daemon (syslogd)

The system logging daemon manages the logging of messages and events for all of the other components, including where the log messages are written.

These components provide a combination of technologies that form the basis of IP security:

- IP filtering
- IP filter logging
- Data encryption and authentication

## **FIPS 140 mode and IP security**

The Internet Key Exchange daemon (IKED), the network security services daemon (NSSD), and the TCP/IP stack components perform a wide variety of cryptographic operations for IP Security. The IKED and the NSSD manage cryptographic keys and digital signatures and perform hashes for authentication. The IKED and the TCP/IP stacks perform encryption and decryption of messages that flow over the IPSec tunnels. Architectural enhancements to the IKE protocols periodically introduce new cryptographic algorithms for performing hashes and encryption.

Federal Information Processing Standards (FIPS) document 140 (FIPS 140) provides a higher degree of assurance of the integrity of cryptographic operations by placing restrictions on the cryptographic components and the operations performed by these components. Weaker algorithms are forbidden and all the operations must be performed by cryptographic modules that are contained within a well defined cryptographic boundary.

You can configure the IKED, the NSSD, and the TCP/IP stack components to operate in FIPS 140 mode. When you do, you restrict the cryptographic algorithms they support, and you modify their interactions with each other and with the other hardware and software components of the z/OS system related to cryptography, such as Integrated Cryptographic Services Facility (ICSF) and System SSL.

In FIPS 140 mode, the IKED, the NSSD, and the TCP/IP stacks enforce the following restrictions on the cryptographic algorithms that can be used for IP security:

- You cannot use the DES encryption algorithm.

- You cannot use the HMAC-MD5, HMAC-MD5-96, AES128-XCBC, and AES128-XCBC-96 algorithms for authentication or pseudo-random function.
- You cannot use Diffie-Hellman groups 1, 2, and 5.
- You cannot use certificates for RSA signature authentication that have key lengths less than 1024 bits.
- You cannot use pre-shared keys whose length is less than half the key size of the chosen HowToAuthMsgs (IKEv1) or PseudoRandomFunction (IKEv2) algorithm.

When the FIPS 140 mode is configured for a TCP/IP stack, the Policy Agent enforces some of the FIPS 140-related restrictions when it parses the IP security policy files. Other restrictions are enforced when dynamic tunnels are being activated, after the FIPS 140 mode of all of the relevant software components (the IKED and the NSSD) is known.

You configure FIPS 140 mode independently for each of the IKED, the NSSD, and the TCP/IP stack components. ICSF and System SSL must also be configured to support FIPS 140. If you use FIPS 140 mode in some components and not others, the resulting system might not operate in FIPS 140 mode. The components that are configured to use FIPS 140 mode can use cryptographic services only from components that are also operating in FIPS 140 mode, so the FIPS 140 mode mismatch can cause functional problems.

- If a TCP/IP stack is configured to use FIPS 140 mode, but the IKED is not, the IKED does not perform any dynamic VPN tunnel activations for the stack. The IKED performs many cryptographic operations on behalf of the stack during tunnel activation.

**Rule:** Whenever the stack is configured for FIPS 140 mode, also configure FIPS 140 mode for the IKED.

- If the IKED and the TCP/IP stacks it supports are configured to use FIPS 140 mode, but the NSSD is not, the IKED cannot use the NSS IPsec certificate service for its stacks. Because the IKED must use the NSS IPsec certificate service to create and verify digital signatures for IKEv2 tunnels, this FIPS 140 mode mismatch prevents activation of any IKEv2 tunnels that use digital signature authentication.

**Rule:** Whenever the IKED is configured for FIPS 140 mode, also configure FIPS 140 mode for the NSSD.

- If you have a sysplex that is configured for Sysplex-Wide Security Associations (SWSA), and the distributor stack is not configured to use FIPS 140 mode, then it will not be able to successfully distribute tunnels to target stacks that are configured in FIPS 140 mode.

**Rule:** Whenever you have target stacks that are configured in FIPS 140 mode, first configure FIPS 140 mode for the distributing stack.

When possible, you should enable FIPS 140 mode for the IKED, the NSSD, and the TCP/IP stacks all at once. If you must implement FIPS 140 support in stages, enable FIPS 140 mode in the components in the following order:

1. Configure FIPS 140 mode in the NSSD. If the NSSD is configured in FIPS 140 mode and the IKED and the TCP/IP stacks are not, the IKED still uses the NSS IPsec certificate service provided by the NSSD. Note that the NSSD creates and verifies signatures only for certificates that conform to FIPS 140 restrictions, even if the IPsec client is not operating in FIPS 140 mode.
2. Configure FIPS 140 mode in the IKED. When the NSSD and the IKED are both in FIPS 140 mode, but the stacks are not, dynamic VPN tunnels can be activated and data can flow, as long as those tunnels follow the FIPS 140 cryptographic algorithm restrictions.
3. If you are using SWSA in a sysplex, configure FIPS 140 mode in the distributor stack of the sysplex.
4. Configure FIPS 140 mode in all other TCP/IP stacks.

Enabling FIPS 140 mode on a system can affect performance. For example, you might have to change from using a weak encryption algorithm to using one that requires more processing to perform. Even if no algorithm changes are necessary, the IKED, the NSSD, and the TCP/IP stacks perform their cryptography operations in a different way when FIPS 140 mode is enabled than when it is not enabled, because FIPS 140 imposes additional self-verification requirements and access restrictions, and because hardware accelerated implementations of some cryptographic operations might not be available in FIPS 140 mode.

## Steps for configuring IP security to support FIPS 140 mode

Configure IP security to support FIPS 140 mode on each system and stack that needs to use FIPS 140 mode. If you are using Sysplex-Wide Security Associations (SWSA), perform these steps first on your distributor and backup stacks, and then on each of your target stacks.

### Procedure

Perform the following steps to configure IP security to support FIPS 140 mode:

1. Ensure that Integrated Cryptographic Services Facility (ICSF) is started and configured to support FIPS 140.

**Requirement:** ICSF must be active before starting the IKE daemon or NSS server configured in FIPS 140 mode. For information about enabling ICSF to support FIPS 140-2, see the topic about [Operating in compliance with FIPS 140-2 in z/OS Cryptographic Services ICSF Writing PKCS #11 Applications](#).

**Tip:** You do not need to create TKDS data sets in order for IP security to use ICSF.

For more information about enabling FIPS 140 mode for ICSF, see [z/OS Cryptographic Services ICSF Administrator's Guide](#).

2. Ensure that one of the following conditions are true:

- The SAF class CRYPTOZ is not active.
- No SAF profile exists for the FIPSEXEMPT.SYSTOK-SESSION-ONLY resource in the CRYPTOZ class.
- The IKED, the NSSD, and the TCP/IP stacks that are configured in FIPS 140 mode have no access (NONE) to the SAF resource FIPSEXEMPT.SYSTOK-SESSION-ONLY in the CRYPTOZ class.

**Tip:** A single z/OS system can support multiple TCP/IP stacks, and you can configure some TCP/IP stacks with FIPS 140 support and others without FIPS 140 support. The stacks that are configured in FIPS 140 mode must not have access to the SAF resource FIPSEXEMPT.SYSTOK-SESSION-ONLY in the CRYPTOZ class.

3. Ensure that System SSL FIPS 140 support is available and configured. For more information, see the information about System SSL and FIPS 140-2 in [z/OS Cryptographic Services System SSL Programming](#).

4. If you are using network security services (NSS), configure NSS to support FIPS 140.

You can configure FIPS 140 by specifying Yes as the FIPS140 value in the NSS configuration file (for example, nssd.conf). In the IBM Configuration Assistant for z/OS Communications Server, configure the FIPS 140 option in the Advanced Server Settings for NSS in the NSS perspective.

After you have configured FIPS 140, restart the NSS daemon if it was active.

**Tip:** If TCP/IP is enabled for FIPS 140 but the NSSD is not, then the NSSD cannot provide NSS certificate services to the TCP/IP stack.

5. Configure IKE to support FIPS 140.

You can configure FIPS 140 by specifying Yes as the FIPS140 value in the IKED configuration file (for example, iked.conf). In the IBM Configuration Assistant for z/OS Communications Server, configure the FIPS 140 option in the Advanced IKE Daemon Settings in the IPsec perspective.

After you have configured FIPS 140, restart the IKE daemon if it was active.

**Tip:** If TCP/IP is enabled for FIPS 140 but the IKED is not, then the IKED will not negotiate dynamic VPN tunnels for that TCP/IP stack.

6. Configure the TCP/IP stack to support FIPS 140.

You can configure FIPS 140 by specifying FIPS140 Yes on the IpFilterPolicy statement in the IPsec policy file for the stack. In the IBM Configuration Assistant for z/OS Communications Server, configure the FIPS 140 option in the Advanced Stack Settings in the IPsec perspective.

After you have configured FIPS 140, restart the stack if it was active.

## Configuring IP security

You configure z/OS IP security using an extensive set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the set of IP security requirements for each TCP/IP stack. IBM provides two alternatives for creating the Policy Agent configuration files:

- [“Configuring IP security using the IBM Configuration Assistant for z/OS Communications Server” on page 920](#)
- [“Configuring IP security using manual configuration” on page 920](#)

### Configuring IP security using the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent and IKE daemon configuration files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create IP security configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are four types of reusable objects:

- Traffic descriptors that define the IP traffic type, such as TCP or UDP
- Security levels that define the different ways to protect data, such as the encryption level
- Requirement maps that map traffic descriptors to security levels

A single requirement map should contain a complete set of security requirements that will govern the level of security for multiple IP traffic types.

- Address groups that define a set of addresses to be used in an IP filter rule

For each TCP/IP stack, you create a set of connectivity rules that indicate the data endpoints and indicate which requirement map will govern security between the data endpoints.

The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors, security levels, and requirement maps that are easily applied to an existing network topology, or the IBM-supplied definitions can be used as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create IP security policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security, use of the GUI is encouraged to ensure that you have a consistent and easily manageable interface for implementing IP security.

This information primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and IP security function.

### Configuring IP security using manual configuration

You can manually create the IP security policy configuration files by coding all of the required statements in a z/OS UNIX file or MVS data set. There are a large number of configuration options provided by IP security policy statements that permit advanced users to carefully fine-tune IP security policy on a per-stack basis. This information describes the procedure for creating an IP security policy by manually creating and editing the configuration files. There are examples that step through the process of creating a configuration file that includes zones corresponding to various security models. For details about the

configuration statements and parameters, see the [Policy configuration files](#) topic in [z/OS Communications Server: IP Configuration Reference](#).

## Specifying the IP security configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see “[Policy types and infrastructure overview](#)” on page 813. Regardless of which option is used to configure IP security policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves IP security policies from the policy server, specify the configuration files using the `DynamicConfigPolicyLoad` statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve IP security policies from the policy server, specify the configuration files using the `IPSecConfig` statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the `IPSecConfig` statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

## IP filtering

---

IP filtering controls the flow of network traffic. An administrator can deny or allow any given network packet into or out of a z/OS system with an IP security policy.

### Filter rules and actions

The IP security policy enables a z/OS system to classify any IP packet that comes across a network interface and take specific action according to a predefined set of rules. The set of properties that identify a packet, together with the action to be performed on it, is known as an IP filter rule. The rule can be used to filter out unwanted packets from the network stream, while allowing others. The collection of all filter rules comprise the IP filter table. The IP filter table contains all of the IP filter rules in the order in which they were configured. IP filter rules are configured using the `IpFilterRule` statement in an IP security policy configuration file. For more details about the [IpFilterRule](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

For example, a simple filter table might have the following set of rules:

1. Allow Telnet traffic from IP address A.
2. Allow FTP traffic from IP address B and IP address C.
3. Allow any traffic from subnet D, but ensure that it is encrypted.
4. Allow IPsec-protected traffic from any location if the remote IKE identity is a corporate email address.
5. Allow outbound connections to anywhere.
6. Deny anything that does not match the previous rules.

This set of rules would be considered to be a filter table consisting of six rules.

The filter table that is configured for a particular installation reflects the security needs for that site. The rules can be restrictive or permissive, as the security policy allows. Normally the rules would deny anything not explicitly permitted, a configuration known as a default-deny policy, in which rules are added as necessary to allow only crucial network traffic. In a default-deny environment, the absence of any IP filter rules essentially isolates the system from the network. The alternative, a default-allow policy, allows all network traffic in the absence of any configured rules. Specific rules can be added as needed to deny unwanted or potentially malicious traffic. A default-deny policy is considered to be much more secure.

**Rule:** A z/OS Communications Server TCP/IP stack that is configured for IP security follows a default-deny policy by default, in the absence of any configured filter rules.

IP filter tables can grow very complex, and in many implementations are difficult to maintain. However, the configuration mechanism that is provided by IP security enables you to attach meaningful descriptors to rules, hosts, and other configured items, which makes keeping track of complex filter tables an easier task.

To protect data between hosts, hosts must agree on what type of traffic to protect, and how to protect that traffic. These IP traffic pattern definitions are stored in the locally configured security policy and installed in the IP filter table, which is consulted for each IP packet that enters or leaves the system. When a packet matches one of the rules in the IP filter table, the policy determines what action is taken for that packet. IP filter actions are configured using the `IpGenericFilterAction` statement in an IP security policy configuration file. For more details about the `IpGenericFilterAction` statement, see [z/OS Communications Server: IP Configuration Reference](#).

On a z/OS stack that has IPCONFIG IPSECURITY configured (and perhaps also has IPCONFIG6 IPSECURITY configured) and an active IP security policy, there are three possible actions:

- Deny the packet.
- Permit the packet.
- Permit the packet with IPSec protection.

If the action that is associated with the filter rule is an ipsec action, the packet is subject to the application of IPSec authentication and encryption before it is received or sent. Any packet that matches a filter rule with an ipsec action is processed using the IPSec protocols, either Authentication Header (AH), Encapsulating Security Payload (ESP), or both, depending on the locally configured policy. z/OS IP security requires that data authentication be done if the filter rule specifies an ipsec action.

## Filtering criteria in an IP packet

IP packets match IP filters based on a number of selection criteria. There are five primary pieces of information that are gathered from the IP packet, commonly referred to as a 5-tuple:

- Source address

An IP packet can be filtered based on the source address located in the IP header of the packet.

- Destination address

An IP packet can be filtered based on the destination address located in the IP header of the packet. For IPv6 packets that contain a type 0 or type 2 routing header, the stack performs IP filtering using the final destination address of the packet based on the routing header contents, not on the destination address in the IP header.

- Protocol

An IP packet can be filtered based on the protocol in the IP header of the packet.

- Source port

If the protocol in an IP packet is TCP or UDP, the packet can be filtered based on the source port in the TCP/UDP header of the data portion of the packet.

- Destination port

If the protocol in an IP packet is TCP or UDP, the packet can be filtered based on the destination port in the TCP/UDP header of the data portion of the packet.

## Additional filtering criteria based on protocol

The following criteria are some additional filtering criteria that are based on protocol:

- ICMP type and code

If the protocol in an IP packet is ICMP or ICMPv6, the packet can be filtered based on the ICMP type and code located in the ICMP header of the data portion of the packet.

**Guideline:** Typically, if an ICMP error is generated for a packet that arrived over a Security Association, and there is no matching rule for the ICMP error, z/OS Communications Server attempts to send the ICMP packet over the same Security Association that carried the original packet. If you want to disable this processing, you must code a rule that covers ICMP errors.

- OSPF type

If the protocol in an IP packet is OSPF, the packet can be filtered based on the OSPF type located in the OSPF header of the data portion of the packet.

- Mobility header type

If the protocol in an IP packet is IPv6 mobility header, the packet can be filtered based on the mobility header type located in the mobility header of the data portion of the packet.

## Additional filtering criteria based on network attributes

Some filtering criteria are inferred from the external characteristics of the IP traffic, rather than being found in the actual IP packet. The following additional attributes are used to distinguish IP packets:

- Direction

The direction of an IP packet is either inbound or outbound.

- Routing

The routing attribute of an IP packet is either local or routed. IP packets are considered local if either of the following conditions is true:

- The packet is inbound and the destination address in the IP packet exists on the IPSECURITY stack.
- The packet is outbound and the source address in the IP packet exists on the IPSECURITY stack.

Otherwise the IP packet is considered routed.

- Security class

Each non-virtual interface on a z/OS system is assigned a security class. The security class of an IPv4 interface is determined by the SECCLASS parameter that is coded on the LINK statement or the DYNAMICXCF parameter of the IPCONFIG statement in the TCP/IP profile. The security class of an IPv6 interface is determined by the SECCLASS parameter that is coded on the INTERFACE statement or the DYNAMICXCF parameter of the IPCONFIG6 statement in the TCP/IP profile. The value of SECCLASS is a number in the range 1-255. If SECCLASS is not specified for an interface, the interface has a default security class of 255.

Each IP packet entering or leaving the system inherits the security class of the interface that it traverses:

- For inbound traffic, this is the interface on which the packet arrived.
- For outbound traffic, this is the interface over which the packet is sent.

The value for SECCLASS has no inherent meaning. A SECCLASS of 255 is no more or less secure than a SECCLASS of 1. You can optionally assign a SECCLASS value either to uniquely identify an interface, or to group interfaces with similar security requirements, based on site policy. Consequently, this attribute can be used as an additional criterion for IP filtering. Security class can be used to define broad filter rules that encompass all of the IP traffic that uses a group of interfaces without explicit knowledge of network addressing, or to ensure that an IP packet arrived on a valid interface.

For example, as shown in [Figure 116 on page 924](#), consider a z/OS system with three physical interfaces that are assigned the following security classes:

```
I1: SECCLASS 10
I2: SECCLASS 20
I3: SECCLASS 20
```

Figure 116. Using SECCLASS to identify interfaces

All IP packets from NET1 and NET2 have the same security class (10), and all IP packets from NET3 and NET4 have the same security class (20). Even though each interface on the z/OS system can reach multiple networks, you can configure a single IP filter rule that matches all of the IP traffic from NET3 and NET4 without explicitly identifying any attributes of the IP packets, other than security class. For instance, if NET3 and NET4 are trusted internal networks in which you want to allow all network traffic, you can configure one IP filter rule permitting all traffic with a security class of 20, without regard to IP address.

An IP filter using security class as a criterion is not limited to scenarios in which the IP addresses are ignored. To counter IP address spoofing, IP filter rules can take into account both security class and IP address. IP address spoofing involves the creation of an IP packet whose source address has been modified to reflect an address other than that of the originator. Because routers ignore the source address when making routing decisions, the modified IP packet can still reach its destination. An IP packet whose source IP address has been spoofed is usually not legitimate and is often used in a malicious manner. IP filtering can counter an attempt to spoof a source IP address by ensuring that an IP packet arrived on a valid network interface. For instance, any inbound packet that has a source address of an internal network node, but entered the system though an external interface, is probably spoofed and should be denied.

**Rule:** The SecurityClass parameter cannot be used on an IpFilterRule statement with a dynamic ipsec action. The IKE protocols do not provide for the negotiation of SecurityClass, and therefore it cannot be used as a selection criterion for a Security Association. The SecurityClass parameter can be configured only for an IpFilterRule statement that has an action of permit, deny, or manual ipsec. Coding a SecurityClass parameter with a value other than 0 on a dynamic ipsec rule is considered a configuration error.

#### Guidelines:

- If there are multiple interfaces by which a packet can reach its destination, the SECCLASS values for the interfaces and the filter rules should be consistent. If a packet could reach its intended destination by traversing one of a number of interfaces, the SECCLASS values and the related filter rules should account for the possibility of alternate routing.
- If the same IPv6 link-local address exists in multiple LANs in your network and you want to define filter rules to distinguish these IP addresses, configure different SECCLASS values for the interfaces onto these LANs to make the filter rules unique. However, if you are using dynamic IPsec for link-

local addresses, you cannot use SECCLASS values to make the filter rules unique, so you must ensure that there are no overlapping or duplicate link-local addresses.

For more details about the SecurityClass parameter on the `IpService` statement, the SECCLASS parameter on the [Summary of DEVICE and LINK statements](#) and [Summary of INTERFACE statements](#), and the SECCLASS keyword on the DYNAMICXCF parameter of the `IPCONFIG` statement and `IPCONFIG6` statements, see [z/OS Communications Server: IP Configuration Reference](#).

- Remote IKE identity

For traffic that is protected by IPSec, the remote IKE identity can be used as a filtering criterion. This is particularly useful in cases where a client is roaming or mobile and does not have a fixed IP address, but has a known authenticated IKE identity.

Filter rules with a remote IKE identity often have wildcard IP addresses that are not very specific, because mobile users can connect from a variety of locations.

**Guidelines:**

- Consider placing filter rules with a remote IKE identity near the bottom of your IP filter policy, so that other traffic has optimal filter searching. Because the wildcard IP addresses are not very specific for these rules, much IP traffic needs to be compared against these rules to test whether the traffic matches the rule.
- Consider whether the mobile client's traffic might intersect with other filter rules; for example, when a mobile user occasionally brings their laptop into the office. If you choose to permit the user to continue to establish their IPSec connection while in the office, then you should order the remote identity filter rules in your IP filter policy so that they precede the office network filter rules.

## IP traffic patterns

The information that is gathered from an IP packet can be used to identify a specific type of network traffic, based on common Internet protocols. For example:

- Web traffic to a server consists of TCP packets inbound to and outbound from port 80.
- TN3270E Telnet server traffic consists of TCP packets inbound to and outbound from port 23.
- IKE traffic consists of UDP packets inbound from and outbound to port 500 or 4500.
- Ping (IPv4) consists of ICMP packets outbound with type 8, code 0 (echo request), and inbound with type 0, code 0, (echo reply).
- Ping (IPv6) consists of ICMPv6 packets outbound with type 128, code 0 (echo request), and inbound with type 129, code 0, (echo reply).

The `IpService` statement groups these attributes into definitions of common traffic patterns that can subsequently be incorporated in an IP filter rule. The sample configuration file `/usr/lpp/tcpip/samples/pagent_CommonIPSec.conf` provides definitions for many of the common traffic patterns that are seen on a typical z/OS server.

For more details about the `IpService` statement, see [z/OS Communications Server: IP Configuration Reference](#).

## Routed traffic and fragmented packets

Fragmented packets are problematic for IP security implementations because transport layer headers (UDP, TCP, and so on) are not present in every fragment. For some packet fragments, the transport layer selector values (for example, UDP ports, ICMP type and code) are indeterminate, which complicates IP packet filtering. In the case of IPv6, a fragment's IP protocol value might also be indeterminate.

**Tip:** z/OS Communications Server filters fragmented packets only for routed traffic. For all local traffic, z/OS Communications Server performs filtering on the fully assembled packet.

Because some packet fragments do not contain the transport layer header and cannot be filtered based on transport layer selector values, z/OS Communications Server enforces the following restriction for routed traffic.

**Restriction:** All routed traffic between two endpoints must be filtered in the same manner without regard to TCP or UDP port, ICMP or ICMPv6 type and code, or OSPF and MIPv6 type.

**Guideline:** To perform more granular filtering for this traffic, enforce a port-specific filtering policy, or a type-specific and code-specific filtering policy, at the final destination for this IP traffic.

z/OS Communications Server supports the specification of Opaque for matching indeterminate IPv6 protocol values in packet fragments. Packets that have an indeterminate value match filter rules only when Opaque or Any is specified.

z/OS Communications Server also supports explicit matching on fragmented packets. The IpService policy object's fragment specification can be used to match any fragmented packet, even if the packet's selector values are known. Explicit matching can be used to deny all fragmented packets in situations in which they are not part of normal traffic patterns and are considered to be a security risk.

## Conditionally controlling IP filters

When IP filters from IP security policy files are installed into the stack, they are always active by default. Depending on the business need, this might not always be desirable. For instance, you might want to restrict certain types of IP traffic to a specific time, day, or week. IP security provides this flexibility by allowing you to specify a time condition for an IP filter rule. The IpTimeCondition statement specifies when an IP filter or a manual IPSec tunnel is active. You can prescribe not only what traffic is allowed, but when that traffic is allowed, in a way that is not disruptive and without having to edit the IP security policy files.

For more details about the [IpTimeCondition](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

## Special considerations when using IP security for IPv6

---

This topic describes considerations for using IP security for IPv6.

### Neighbor discovery and multicast listener discovery

For IPv6, TCP/IP uses the neighbor discovery protocol, which provides the following functions:

- Address resolution (neighbor solicitations and neighbor advertisements to perform ARP functions for IPv6)
- Duplicate address detection (neighbor solicitations and neighbor advertisements to ensure unique IP addresses)
- Router discovery (router solicitations and router advertisements to keep track of neighboring routers)
- Neighbor unreachability detection (to keep track of the reachability of neighbors)

TCP/IP also uses multicast listener discovery (MLD), which notifies routers that nodes are ready to receive multicast packets.

Neighbor discovery and MLD are implemented using ICMPv6 packets.

When the stack is enabled for IP security for IPv6, TCP/IP performs IP filtering for these packets and denies these packets by default. You must consider these packets when configuring filter rules for IPv6. For example, if you configure permit rules for IPv6 TCP or UDP traffic over an OSA interface, but do not configure permit rules for the neighbor discovery address resolution flows over the interface, the traffic will not succeed because the stack denies the ICMPv6 neighbor solicitation and neighbor advertisement packets during address resolution. Also, you must configure permit filter rules for neighbor solicitation and neighbor advertisement packets, so that the stack can perform duplicate address detection (and learn about valid duplicate addresses).

In addition, for the stack to be able to learn about neighbors, you must configure permit filter rules for outbound router solicitations and inbound router advertisements. Similarly, for the stack to be able to perform the MLD listener function, you must configure permit filter rules for outbound MLD listener reports and inbound MLD listener query packets.

For example filter rules to permit neighbor discovery and MLD packets, see the TCP/IP sample profile and policy sample.

**Guideline:** Configure permit rules for neighbor discovery and MLD packets.

**Result:** z/OS Communications Server does not apply IPsec protection for outbound neighbor discovery or MLD packets, but does apply permit and deny actions for these packets. If such an outbound packet matches an IP filter rule that specifies an IPsec action, the stack permits the packet but does not encapsulate it.

## Stateless address autoconfiguration

If you use autoconfiguration, your IPv6 addresses might not be predictable. To configure IP filter rules for dynamic Security Associations with autoconfigured IPv6 addresses, you need to specify the IP addresses using wildcards.

Manual Security Associations typically use specific IP addresses for the endpoints. You can use wildcards for the security endpoint addresses so that the data endpoints and security endpoints are considered identical. Alternatively, you can use predictable IPv6 addresses for the security endpoints. You can obtain predictable IPv6 addresses by configuring full 128-bit IPv6 addresses on your INTERFACE statements, by specifying the INTFID keyword on your INTERFACE statements, or by using VIPAs.

## IPv6-specific protocols

The protocol number for ICMPv6 (58) is different from the protocol number for IPv4 ICMP (1); remember this when configuring IPv6 filter rules.

The handling of fragments in IPv6 is different from IPv4. For information about fragmented IPv6 packets, see [“Routed traffic and fragmented packets” on page 925](#).

## IPv6 address types

You can configure IP filter rules for any valid IPv6 address, including multicast addresses, link-local addresses, IPv4-mapped addresses, and so on.

You can configure IPsec tunnels for link-local and global addresses. For multicast addresses, you can configure manual tunnels but not dynamic tunnels. You cannot configure IPsec tunnels for IPv4-mapped addresses.

## IPv6 extension headers

If an IPv6 packet contains an extension header that is a type 0 or type 2 routing header, the stack performs IP filtering using the final destination address of the packet based on the routing header contents, rather than using the destination address in the IP header.

## Considerations for IPv6 OSPF security

IPv4 OSPF authentication is implemented within the IPv4 OSPF protocol. However, IPv6 OSPF security (both authentication and encryption) is implemented by using IPsec. Because OSPF uses both multicast messages and unicast messages, it is not possible to use dynamic tunnels for OSPF traffic. Instead, manual tunnels must be used. The IBM Configuration Assistant for z/OS Communications Server automates the process of creating IPv6 OSPF tunnels. The following information describes the process of manually creating the IPv6 OSPF tunnel definitions.

It is expected that the same manual tunnel is to be used for all link-local unicast and multicast traffic. Additional tunnels might be used for IPv6 OSPF virtual links.

Because multicast traffic is one-to-many, the manual tunnel must use the same Security Parameter Index (SPI) and keys for inbound and outbound traffic. Whatever SPI values and keys are used must be coordinated with all IPv6 OSPF peers on the LAN segment. Also, because this manual tunnel is to be used to protect traffic with various source and destination addresses, you must specify any6 for the local

and remote security endpoint locations. The following example uses AH authentication using the SHA algorithm, and ESP encryption using the DES algorithm.

```
IpManVpnAction tunnel-ipv6ospf-internal
{
 LocalSecurityEndpointAddr any6
 RemoteSecurityEndpointAddr any6
 HowToAuth AH HMAC_SHA1
 AuthOutboundSa 2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
 AuthInboundSa 2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
 HowToEncrypt DES
 EncryptOutboundSa 2701 0x3e6dcf72459ef551
 EncryptInboundSa 2701 0x3e6dcf72459ef551
 HowToEncap transport
}
```

For the filter rules, you first need to create an IP service to describe the OSPF traffic. To distinguish the traffic, you specify the OSPF protocol, and the SECCLASS of the interfaces on which the traffic will flow. For the purpose of this example, assume that the interfaces for the LAN segment that is being protected are defined with SECCLASS 10.

```
IpService service-ipv6ospf-internal
{
 Protocol ospf
 Direction bidirectional
 Routing local
 SecurityClass 10
}
```

You now need to define three filter rules to match the OSPF traffic. The first filter rule matches all link-local unicast traffic on the LAN segment:

```
IpFilterRule ipv6ospf-unicast-internal
{
 IpSourceAddr fe80::/10
 IpDestAddr fe80::/10
 IpServiceRef service-ipv6ospf-internal
 IpGenericFilterActionRef ipsec-nolog
 IpManVpnActionRef tunnel-ipv6ospf-internal
}
```

The remaining two filter rules are for the OSPF link-local multicast traffic. The first rule matches outbound multicast traffic, which has a link-local unicast source address and a link-local multicast destination address. The second rule matches inbound multicast traffic, which has a remote (destination) address that is link-local unicast, and a local (source) address that is link-local multicast. These rules are as follows:

```
IpFilterRule ipv6ospf-outbound-multicast-internal
{
 IpSourceAddr fe80::/10
 IpDestAddr ff02::/16
 IpServiceRef service-ipv6ospf-internal
 IpGenericFilterActionRef ipsec-nolog
 IpManVpnActionRef tunnel-ipv6ospf-internal
}
IpFilterRule ipv6ospf-inbound-multicast-internal
{
 IpSourceAddr ff02::/16
 IpDestAddr fe80::/10
 IpServiceRef service-ipv6ospf-internal
 IpGenericFilterActionRef ipsec-nolog
 IpManVpnActionRef tunnel-ipv6ospf-internal
}
```

## Virtual links

You can also configure IPsec protection for IPv6 OSPF virtual links. You can use the following method to configure manual tunnels for IPv6 OSPF virtual links.

**Guideline:** Because virtual links use global unicast addresses, you should use dynamic tunnels for IPv6 OSPF virtual links whenever possible. Dynamic tunnels provide numerous benefits over manual tunnels.

Because the virtual link addresses are not known beforehand, you must specify the security endpoint addresses for the manual tunnel with a wildcard value. The Security Association does not protect multicast traffic, so the inbound and outbound SPI values and keys do not need to be identical. Whatever SPI values and keys you use must be coordinated with the virtual link peer.

```
IpManVpnAction tunnel-ipv6ospfvirt-internal
{
 LocalSecurityEndpointAddr any6
 RemoteSecurityEndpointAddr any6
 HowToAuth AH HMAC_SHA1
 AuthOutboundSa 2702 0xf5c58a6e6f0761b68f424f39257f0ea89a4be3b4
 AuthInboundSa 2703 0x39a341ed1b7127b7905df2411ed0770854b54d10
 HowToEncrypt DES
 EncryptOutboundSa 2704 0xb9571d20fe98ecca
 EncryptInboundSa 2705 0xfeba84c113fb40ed
 HowToEncap transport
}
```

Only one filter rule is needed for the virtual link. For this example, the same IP service used for the link-local traffic is used, which restricts this filter rule to OSPF traffic flowing over interfaces with SECCLASS 10. Because the virtual link addresses are not known beforehand, the filter rule addresses are specified with a wildcard value to include all global unicast addresses. If you have more specific information about the address prefixes for the virtual link endpoints, you can use this to further restrict the addresses on the filter rule.

```
IpFilterRule ipv6ospf-virtual-internal
{
 IpSourceAddr 4000::/3
 IpDestAddr 4000::/3
 IpServiceRef service-ipv6ospf-internal
 IpGenericFilterActionRef ipsec-nolog
 IpManVpnActionRef tunnel-ipv6ospfvirt-internal
}
```

## Default IP filter policy and IP security policy

Policy Agent provides IP filter policy to the stack, as defined by the IP security policy configuration files. For the stack to be enabled for IP security for IPv4, the TCP/IP profile must have IPSECURITY coded. For the stack to be enabled for IP security for IPv6, the TCP/IP profile must also have IPSECURITY6 coded. For the stack to receive configured policy, the Policy Agent must be active. IP filter policy is installed when Policy Agent and the stack are active. If Policy Agent is not active when an IPSECURITY-enabled stack initializes, the stack cannot be provided with IP filter rules from that policy. Therefore, in the interest of network security, the stack provides a default IP filter policy when an IP filter policy is unavailable from Policy Agent. The default IP filter policy effectively denies all network traffic, with the exception of some select ICMP and ICMPv6 messages that are necessary for internal stack function. These deny rules are not explicitly coded, but rather are always implicitly added at any time that the default IP filter policy is in effect. The default IP filter policy can be in effect at times other than stack initialization. Default IP filter policy is in effect in all of the following cases:

- An IPSECURITY-enabled TCP/IP stack has been started but Policy Agent has not been started, or an IPSECURITY-enabled TCP/IP stack has been started but Policy Agent has not completely initialized.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but no IP security configuration file exists.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but the IP security configuration file contains errors.
- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, but no IpFilterPolicy statement exists in either IP security configuration file.

- An IPSECURITY-enabled TCP/IP stack and Policy Agent have been started, and IP filter policy has been provided to the stack, but the stack is using the default IP filter policy because the **ipsec -f default** command was issued.

This default behavior ensures that network security is not compromised in the event that IP filter policy is not installed, and is consistent with a secure default-deny policy. However, you can modify the default IP filter policy by coding an IPSECRULE statement (for IPv4) or IPSEC6RULE statement (for IPv6) in the TCP/IP profile. The IPSECRULE and IPSEC6RULE statements describe the attributes of the IP traffic that is allowed when the default policy is active. Because the default behavior is to deny all network traffic, IPSECRULE and IPSEC6RULE statements are always permit rules that denote exceptions to the default-deny policy.

It is also important to note that neither the default IP filter policy nor a modified default IP filter policy provides authentication and encryption capabilities such as those provided by a complete IP security policy; it offers the stack only the ability to perform simple IP filtering in the absence of an IP security policy.

## Modifying the default IP filter policy

The default IP filter policy is in effect when the IP security policy, as configured in the Policy Agent, is not available. The default IP filter policy denies all network traffic, unless you modify the TCP/IP profile.

Two IP filters are created by the default IP filter policy, one denying IPv4 inbound traffic and the other denying IPv4 outbound traffic. If IP security for IPv6 is also enabled, the stack also creates two similar filters, one denying IPv6 inbound traffic and the other denying IPv6 outbound traffic. For example, assuming that the default IP filter policy is active, the following sample of the **ipsec -f display** command shows that SYSDEFAULTDENYRULE was added to the filter table:

### **ipsec -f display**

8 entries selected

```

Use IPSECRULE and IPSEC6RULE for permit rules that denote exceptions to the default-deny policy. When the default IP filter policy is active, these permit rules appear in the default IP filter table before the SYSDEFAULTDENYRULE entries. Typically, these exceptions are few and are used for administrative access to the system when IP security policy is unavailable. For instance, a sample default set of permit rules might include entries to provide the following access:

- Administrative access
- Basic network services, such as DNS and OSPF routing advertisements
- Use of ping to test for server availability

IPSECRULE and IPSEC6RULE entries are coded in the IPSEC block of the TCP/IP profile. They describe the attributes of the IP traffic that is allowed when the default IP filter policy is active. These rules can specify criteria such as source address, destination address, protocol, source port, destination port, routing, direction, and security class.

IPSECRULE and IPSEC6RULE entries always have an action of permit; there is no action specification for deny or permit with IPsec protection.

Assuming the administrative machine has an IP address of 9.1.1.2 and connects through an interface whose security class is 100, the following sample IPSECRULE entries enable the z/OS system to communicate IPv4 DNS queries and OSPF routing advertisements to anyone, while giving blanket access to the administrator. The example IPSEC6RULE entry permits any ICMPv6 packets. An asterisk (\*) is the default and represents all, indicating that any packet matches this attribute.

```
IPSEC LOGENable
; Rule SrcAddr DstAddr Logging Protocol SrcPort DestPort Routing Secclass

; OSPF protocol used by Omproute
IPSECRule * * NOLOG PROTO OSPF

; IGMP protocol used by Omproute
IPSECRule * * NOLOG PROTO 2

; DNS queries to UDP port 53
IPSECRule * * NOLOG PROTO UDP SRCPort * DESTport 53

; Administrative access
IPSECRule * 9.1.1.2 LOG SECCLASS 100

; ICMPv6 protocol
IPSEC6Rule * * NOLOG PROTO ICMPv6
ENDIPSEC
```

Any IPSECRULE and IPSEC6RULE entries that are coded are given a system-generated name for purposes of display. These rules are prefixed with the string SYSDEFAULTRULE. The IPSECRULE entries that are configured in the previous example are reflected in the **ipsec -f display** command as shown in the following example. Two rules are created for each IPSECRULE or IPSEC6RULE entry configured, one for each direction. By default, IPSECRULE and IPSEC6RULE entries define bidirectional filters. If you want to limit the filter to inbound or outbound traffic, use the DIRECTION parameter to specify direction of the traffic to be filtered. Because the five rules that are configured in the example IPSEC block are bidirectional, they have been expanded into 10 IP filters. Four additional filters have been created for the default-deny behavior. Each rule is given a unique filter name comprised of SYSDEFAULTRULE.*number*, where *number* is a numerical extension that indicates the relative order of the rule in the IP filter table. Because each bidirectional IPSECRULE and IPSEC6RULE statement results in multiple filter rules with the same name (inbound and outbound), a FilterNameExtension value is assigned by the system to uniquely identify each filter.

#### **ipsec -f display**

```

14 entries selected

```

For an IP security-enabled stack, one of the two security policies is always in effect, either the default policy or the IP security policy as defined in Policy Agent. The policy that is in effect at any given time is considered to be the active policy. The source field of the report header for the **ipsec -f display** command can be used to determine which policy is currently active as follows:

#### **ipsec -f display**

```

CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 09:55:31 2010
Primary: Filter Function: Display Format: Detail
Source: Stack Profile Scope: Current TotAvail: 14
Logging: On Predecap: Off DVIPSec: No
NatKeepAlive: 0 FIPS140: No
Defensive Mode: Inactive

FilterName: SYSDEFAULTRULE.1
FilterNameExtension: 1

```

Stack Profile indicates that the default IP filter policy is active; Stack Policy would indicate that the IP security policy as defined in Policy Agent is active.

You can also choose which policy is the active policy. The **ipsec** command provides the ability to switch the active policy between the default IP filter policy in the TCP/IP profile and the IP security policy in Policy Agent. Issuing the **ipsec -f default** command causes the default policy to become the active policy, while issuing the **ipsec -f reload** command reloads the IP security policy from Policy Agent, provided that Policy Agent is active and that IP security has been correctly configured.

There are cases in which you might want to switch to the default policy. For instance, in the event of a security breach, the **ipsec -f default** command allows only the network traffic that has been explicitly coded in the TCP/IP profile IPSEC block, which typically permits only administrative access.

It is important to use the **ipsec -f default** command with discretion. Issuing **ipsec -f default** on an operational system can have a dramatic impact and cause packets to be dropped, depending on how the IPSECRULE and IPSEC6RULE entries are coded. Consider the use of **ipsec -f default** as equivalent to a shutdown, and do not use it in normal circumstances unless the following conditions are true:

- The system is in maintenance mode.
- There is no productive work being done on the system.

- The site policy for IP traffic is default-allow and the appropriate IPSECRULE and IPSEC6RULE entries were coded.

Malicious use of network resources can be identified by unusual IP traffic conditions, console messages, or log inspection. Should a security concern arise in a production environment, the following steps should be performed quickly to minimize the impact of potentially restricted flow of IP traffic.

1. To secure the system, switch to the default IP filter policy by issuing the **ipsec -f default** command.
2. Analyze system logs to determine the nature and the source of the security concern. If packet logging was active for the time period in question, then inspect the TRMD packet filtering log entries.
3. Update the IP security policy configuration to alleviate the security concern. For example, add an IpFilterRule that denies any suspicious IP address or port use, and activate IP filter logging.
4. Activate the updated IP security policy from the Policy Agent by issuing the **ipsec -f reload** command.
5. Verify that the security concern is eliminated. Monitor the network traffic and inspect the system logs, including any related IP filter log messages.

## IP filter logging

---

Monitoring network events is an important aspect of network security. Logs can be used to verify that policies have been correctly configured and enforced, or to gather statistics on any traffic of interest. For instance, traffic that is persistently denied might be suspect. With IP filter logging, you can inspect any traffic on the system and even fine tune the configuration to show only those entries of interest. Logging can be controlled at the global level or at the individual rule level, including the ability to specify whether to log permitted traffic, denied traffic, or both. The IP filter log entries provide detailed information about each packet, including the rule that the packet matched and any pertinent IPsec information.

TRMD and syslogd provide the logging service for IP security. If running in the common INET environment, you must configure one instance of TRMD for each stack on a z/OS system.

**Guideline:** Exhaustive logging of IP traffic can have a negative effect on performance. If logging is excessive, it can be turned off temporarily at the global level while the appropriate logging modifications are made to the individual IP filter rules. IP filter logging is controlled by the IpFilterLogging parameter on the IpGenericFilterAction statement. For more details, see [z/OS Communications Server: IP Configuration Reference](#).

## IP filter discard action

---

When packets are denied by IP filter policy, IP security supports sending an ICMP or ICMPv6 destination unreachable message, which indicates that a packet is administratively prohibited. You can enable this action for the implicit Policy Agent deny filter rules using the ImplicitDiscardAction parameter on the IpFilterPolicy statement, and for individual filter rules using the DiscardAction parameter on the IpGenericFilterAction statement.

**Rule:** To make a system effectively invisible to attackers, choose the discard action Silent. Choose the discard action ICMP only in cases in which doing so is a useful diagnostic aid, such as for users of internal networks.

## Data encryption and authentication - IPsec

---

To participate in a virtual private network (VPN), a host must encrypt and authenticate individual IP packets between itself and another communicating host. IPsec is one of several mechanisms for achieving this, and one of the more versatile.

IPsec is defined by the IPsec working group of the IETF. It provides authentication, integrity, and data privacy between any two IP entities. Management of cryptographic keys and Security Associations can be either manual or dynamic using an IETF-defined key management protocol called Internet Key Exchange (IKE).

IPSec provides flexible building blocks that can support a variety of configurations. Because an IPSec Security Association can exist between any two IP entities, it can protect a segment of the path or the entire path. The main advantage of using IPSec for data encryption and authentication is that IPSec is implemented at the IP layer. Consequently, any network traffic that is carried by an IP network is eligible to use IPSec services without any special changes to higher level protocols that are used by applications. However, if the system is using any of these alternate security protocols to secure specific applications, IP filtering can be used to avoid the overhead of multiple security protocols. For example, you might want to exclude web traffic (based on the well-known secure port of the web server, port 443) from IPSec coverage because you would like to use SSL.

IPSec enables the creation of VPNs. A VPN enables an enterprise to extend its network across a public network, such as the Internet, through a secure tunnel using Security Associations. IPSec VPNs enable the secure transfer of data over the public Internet for same-business and business-to-business communications, and protect sensitive data within an enterprise's internal network.

IPSec uses IP filtering to determine which traffic should be protected by IPSec. A special type of filter action specifies to permit the traffic, but only with IPSec protection. The IP filters represent IP security policy to the stack by specifying the traffic that requires IPSec protection. The filters are also used in locating the outbound IPSec Security Association, and for verifying that inbound traffic is received using the correct Security Association.

The IETF has standardized the IPSec protocol suite and key management schemes in a series of IPSec RFCs. For more information on these RFCs, see [Appendix G, “Related protocol specifications,” on page 1439](#).

IPSec has three major components:

- IP Authentication Header (AH)
- IP Encapsulating Security Payload (ESP)
- Internet Key Exchange (IKE)

## AH and ESP protocols

IPSec uses two distinct protocols, Authentication Header (AH) and Encapsulating Security Payload (ESP), which are defined by the IETF.

The AH protocol provides a mechanism for authentication only. AH provides data integrity, data origin authentication, and an optional replay protection service. Data integrity is ensured by using a message digest that is generated by an algorithm such as HMAC-MD5 or HMAC-SHA. Data origin authentication is ensured by using a shared secret key to create the message digest. Replay protection is provided by using a sequence number field with the AH header. AH authenticates IP headers and their payloads, with the exception of certain header fields that can be legitimately changed in transit, such as the Time To Live (TTL) field.

The ESP protocol provides data confidentiality (encryption) and authentication (data integrity, data origin authentication, and replay protection). ESP can be used with confidentiality only, authentication only, or both confidentiality and authentication. When ESP provides authentication functions, it uses the same algorithms as AH, but the coverage is different. AH-style authentication authenticates the entire IP packet, including the outer IP header, while the ESP authentication mechanism authenticates only the IP datagram portion of the IP packet.

Either protocol can be used alone to protect an IP packet, or both protocols can be applied together to the same IP packet. The choice of IPSec protocol is determined by the security needs of your installation, and is configured by the administrator. It does not have to be applied system-wide, and can be configured differently for each set of connection endpoints. For a dynamic tunnel, the choice of IPSec protocol is configured using the `IpDataOffer` statement in an IP security policy configuration file. For a manual tunnel, the choice of IPSec protocol is configured using the `IpManVpnAction` statement in an IP security policy configuration file. For more details about the [IpDataOffer statement](#) and the [IpManVpnAction statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

z/OS IP security requires authentication due to potential security exposures when encryption is used alone. Authentication can be provided by the ESP or AH protocol. The complete list of combinations for authentication and encryption that are provided by z/OS IP security and that can be used for a specific connection are shown in [Table 50 on page 949](#).

| <i>Table 50. Possible authentication and encryption combinations for a connection</i> |                                                                                                                                                                            |                                |                                                                                                                                                                                                                                                                                     |

**Guideline:** RFC 4835 discourages the use of DES. Use the AES encryption algorithms wherever possible for better security and interoperability.

**Restriction:** The combination of ESP protocol for encryption and AH protocol for authentication is not supported by IKEv2. If you are using IKEv2 and require both encryption and authentication, you should use ESP for both.

## Encapsulation

In the process of applying either AH or ESP to an IP packet, the original IP packet is modified. Outbound packets are rebuilt with additional IPSec headers in a process known as encapsulation, while inbound packets are stripped of their IPSec headers in a process known as decapsulation. Before leaving a host, outbound packets are encapsulated using a cryptographic key that is known to both communicating hosts. Inbound packets are decapsulated on the receiving side using the same cryptographic key, thereby recovering the original datagram. If encryption is used, any packet that is intercepted on the IP network is unreadable to anyone without the encryption key. Any modifications to the IP packet while in transit are detected by authentication processing at the receiving host and discarded.

## Transport mode and tunnel mode

The manner in which the original IP packet is modified depends on the encapsulation mode used. There are two encapsulation modes used by AH and ESP, transport and tunnel.

Transport mode encapsulation retains the original IP header. Therefore, when transport mode is used, the IP header reflects the original source and destination of the packet. Transport is most often used in a host-to-host scenario, where the data endpoints and the security endpoints are the same. A transport mode encapsulated datagram is routed, or transported, in the same manner as the original packet.

Figure 117 on page 950 shows an IPv4 packet that is encapsulated using AH in transport mode:

Figure 117. IPv4 packet encapsulated using AH in transport mode

Figure 118 on page 950 shows an IPv4 packet that is encapsulated using ESP in transport mode:

Figure 118. IPv4 packet encapsulated using ESP in transport mode

Figure 119 on page 950 shows an IPv6 packet that is encapsulated using AH in transport mode:

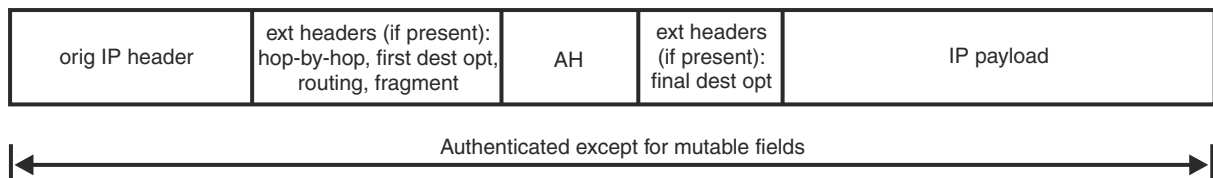

Figure 119. IPv6 packet encapsulated using AH in transport mode

For a description of the IPv6 mutable fields, see RFC 2402. For information about accessing RFCs, see Appendix G, “Related protocol specifications,” on page 1439.

Figure 120 on page 950 shows an IPv6 packet that is encapsulated using ESP in transport mode:

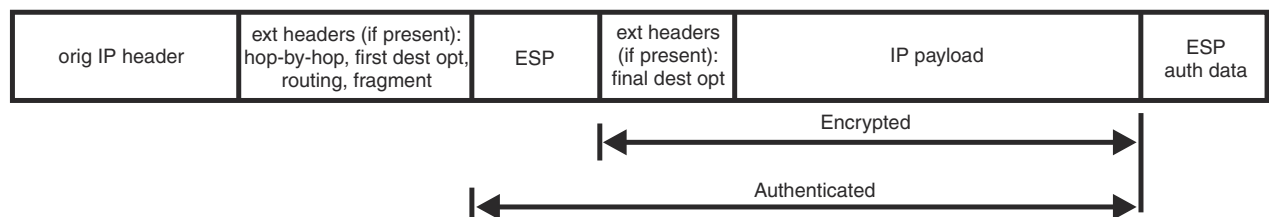

Figure 120. IPv6 packet encapsulated using ESP in transport mode

Tunnel mode encapsulation builds a new IP header containing the source and destination address of the security endpoints. When tunnel mode is used, the outer IP header reflects the source and destination of the security endpoints, which might or might not be the same as the original source and destination IP address of the data connection. The choice of transport or tunnel mode depends on the structure of the network and relies heavily on logical connections between the endpoints. Tunnel mode is required if

one of the IKE peers is a security gateway that is applying IPSec on behalf of another host or hosts. A datagram that is encapsulated in tunnel mode is routed, or tunneled, through the security gateways, with the possibility that the secure IPSec packet will not flow through the same network path as the original datagram. To successfully encapsulate and send an outbound packet, the route table must contain a route that can be used to reach the security gateway, as well as a route that can be used to reach the data endpoint. If policy-based routing is being used on a TCP/IP stack where IP security is active, it is important to understand how the two functions interact. For more information, see [“Considerations for using policy-based routing with IP security”](#) on page 384.

Figure 121 on page 951 shows an IPv4 packet that is encapsulated using AH in tunnel mode:

Figure 121. IPv4 packet encapsulated using AH in tunnel mode

Figure 122 on page 951 shows an IPv4 packet that is encapsulated using ESP in tunnel mode:

Figure 122. IPv4 packet encapsulated using ESP in tunnel mode

Figure 123 on page 951 shows an IPv6 packet that is encapsulated using AH in tunnel mode:

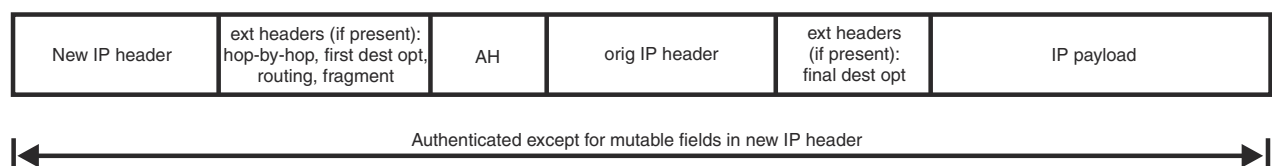

Figure 123. IPv6 packet encapsulated using AH in tunnel mode

For a description of the IPv6 mutable fields, see RFC 2402.

Figure 124 on page 951 shows an IPv6 packet that is encapsulated using ESP in tunnel mode:

Figure 124. IPv6 packet encapsulated using ESP in tunnel mode

Do not confuse tunnel mode encapsulation with IKE tunnel or IPSec tunnel. In this context, tunnel refers only to the method by which IPSec packets are constructed, while IKE and IPSec tunnels are conceptually defined as secure logical connections between hosts. IPSec tunnels can use transport mode or tunnel mode encapsulation.

For a dynamic tunnel, the choice of encapsulation mode is configured using the `IpDataOffer` statement in an IP security policy configuration file. For a manual tunnel, the choice of IPSec protocol is configured using the `IpManVpnAction` statement in an IP security policy configuration file. For more details about the `IpDataOffer` statement and the `IpManVpnAction` statement, see [z/OS Communications Server: IP Configuration Reference](#).

**Guideline:** In host-to-host scenarios, transport mode is commonly used because it does not incur the overhead of having to build an additional IP header. However, tunnel mode is equally valid.

**Tip:** Any configurations that include a secure gateway as an IKE endpoint require tunnel mode; however, if IKEv2 is used, then the selection of encapsulation mode is performed automatically. The IKED will use transport mode if it determines that the connection is host-to-host; otherwise the IKED will use tunnel mode encapsulation. This behavior can be overridden by using the `HowToEncapIKEv2` parameter on the associated `KeyExchangeAction` statement; see the [KeyExchangeAction](#) statement in [z/OS Communications Server: IP Configuration Reference](#) for details.

**Rule:** If you are using Sysplex-Wide Security Associations, a dynamic Security Association cannot use a subnet or range that encompasses a DVIPA address. For takeover to work consistently, Security Associations must be negotiated for single IP addresses only. If two DVIPAs that are covered by the same Security Association are subsequently taken over by two different backup stacks, the coverage of the Security Association is ambiguous because it is then linked to two DVIPAs on two different stacks.

## UDP encapsulation of IPSec ESP packets

When building an ESP packet, it can be further encapsulated by placing a UDP header in front of the ESP header. This is known as UDP encapsulation. UDP encapsulation is used to allow IPSec traffic to successfully traverse a NAT device. For more information on NAT traversal (NATT), see [“IPSec and network address translation devices”](#) on page 960. [z/OS Communications Server](#) supports NAT traversal for IPv4 traffic only.

[z/OS Communications Server](#) supports both tunnel and transport modes of UDP encapsulation.

As shown in [Figure 125](#) on page 952, UDP-encapsulated transport mode inserts a UDP header in between the IP header and the ESP header of a normal transport mode ESP packet.

*Figure 125. UDP-encapsulated transport mode*

As shown in [Figure 126](#) on page 952, UDP-encapsulated tunnel mode inserts a UDP header in between the new IP header and the ESP header of a normal tunnel mode ESP packet.

*Figure 126. UDP-encapsulated tunnel mode*

When an IPSec UDP-encapsulated packet is built, the source and destination port values in the UDP header are set to the IKE port value of 4500.

Configure the choice of transport or tunnel mode using the `IpDataOffer` statement in the IP security policy configuration file. For more details about the `IpDataOffer` statement, see [z/OS Communications Server: IP Configuration Reference](#).

The decision to use a UDP-encapsulated mode is not configured, but instead inferred, when a NAT is detected between two IKE daemons.

## IPSec and symmetric key management

At the center of encryption and authentication is the notion of a cryptographic key. Security endpoints use keys to encrypt and decrypt data. The IPSec protocols create Security Association keys that are directional. As shown in [Figure 127 on page 953](#), the key that is used to encrypt outbound data on one host is used to decrypt the same data on the remote host, while the key that is used to encrypt data on the remote host is used to decrypt data on the local host.

Figure 127. Symmetric encryption

This type of encryption is known as symmetric, because it requires that both hosts use the same keys on the same data.

## Manual key management

IPSec keys and values can be configured manually. Manual management of keys was the only non-proprietary option for implementing IPSec before the standardization of the IKE protocols. In a manual IPSec configuration, the keys that are used to encrypt data, and the Security Parameter Index (SPI) values that are used to uniquely identify a Security Association, are determined by the administrator and configured beforehand on both hosts. However, the steps that you must take to manually generate encryption keys can become quite cumbersome, as shown in the following examples:

- A single IPSec connection requires two keys, because encryption keys are unidirectional (one for inbound traffic, one for outbound traffic).
- A single IPSec connection can require up to four SPI values, depending on the type of IPSec protection required.
- The keys and SPI values must be individually installed on both the local and remote system.
- To help ensure that the keys are not compromised, they need to be changed periodically and updated on both hosts. Manual IPSec has no key refresh capabilities unless the Security Associations are deactivated, reconfigured with the new key, and then reactivated.
- During the refresh maintenance period, IPSec functionality is unavailable, disrupting any IP traffic requiring IPSec protection.
- Because of the disruptive nature of key refresh with manual IPSec, key lifetimes are frequently defined with much larger values, thus increasing the security exposure.
- These steps must be carried out for each remote host that communicates with IPSec, with different keys for each of them.

In a small installation with minimal security concerns, this manual process can work quite well, and might actually be preferable. However, given the large number of communicating hosts in a typical

network, this manual process quickly becomes unwieldy, error prone, maintenance intensive, and not scalable. Nevertheless, z/OS IP security does support manual IPSec configuration for compatibility with systems that use it. If an IP filter rule specifies a manual ipsec action, the corresponding action is consulted to determine all aspects of the encryption and authentication policy for that data, including the identities of the communicating hosts, the keys that are used for encryption and authentication of outbound and inbound packets, and the SPI values. Manual IPSec protection is configured using the `IpManVpnAction` statement in an IP security policy configuration file. For more details about the `IpManVpnAction` statement, see [z/OS Communications Server: IP Configuration Reference](#).

## Dynamic key management - IKE and IPSec negotiations

The primary role of the IKE daemon in an IP security environment is the automatic management of cryptographic keys. Dynamic key management, as provided by the IKE daemon, removes much of the administrative burden that is associated with the creation, distribution, and maintenance of cryptographic keys. IKE provides the following services:

- Host authentication (ensuring that both hosts are certain of the other's identity)
- The negotiation of a Security Association as follows:
  - Agreeing on the type of traffic to be protected
  - Agreeing on the authentication and encryption algorithms to be used
  - Generating cryptographic keys
- Nondisruptive periodic refresh of keys
- The deletion of Security Associations whose lifetimes have expired

There are two versions of the IKE protocol: IKEv1 and IKEv2. The architectural differences between IKEv1 and IKEv2 are as follows:

- IKEv2 requires fewer network flows for Security Association establishment.
- IKEv2 provides a mechanism for re-keying an IKE Security Association without reauthentication, which reduces the CPU cost.
- IKEv2 allows each peer to manage its own values for lifetime and lifetimesize, whereas in IKEv1 Security Association lifetimes and lifetimesizes are negotiable attributes. This reduces coordination of configuration parameters between the peer nodes and avoids potential race conditions when the SAs expire.
- IKEv2 supports the hash and URL certificate encoding types, but IKEv1 does not.

The following difference between IKEv1 and IKEv2 is specific to the z/OS implementation:

- To use any authentication method for IKEv2 based on a digital signature, the certificate service must be provided by an NSS server. You cannot use the IKED native certificate service.

IKE operates at the application layer. IKE negotiations are communicated between two IKE peers by a series of UDP messages. Ports 500 and 4500 are used by the IKE daemon. For both IKEv1 and IKEv2, Security Association negotiation proceeds in phases. In each phase, IKE negotiates a Security Association with a remote host. During the initial phase, IKE negotiates a phase 1 Security Association, which establishes a secure channel over which the IKE peers communicate. The phase 2 Security Association is negotiated to provide data authentication and encryption for subsequent IP traffic. The distinction between a phase 1 Security Association and a phase 2 Security Association is what the Security Associations protect:

- Phase 1 Security Associations are used to protect IKE messages that are exchanged between two IKE peers, or security endpoints.
- Phase 2 Security Associations are used to protect IP traffic, as specified by the security policy for a specific type of traffic, between two data endpoints.

Every Security Association that the IKE daemon negotiates contains information about the type of traffic it is to protect, the IP addresses of the two endpoints, the type of encryption or authentication that is provided, the keys that are used to protect data, how often the keys are refreshed, and an identifier called a Security Parameter Index (SPI) that is used to uniquely identify the Security Association.

An IPsec configuration contains separate policies governing each phase. Although many of the same attributes apply for phase 1 and phase 2 negotiations and keys, there are two major differences:

- The phase 1 Security Association can specify only a single IP address for the security endpoints, while the phase 2 Security Association can specify a contiguous range or subnet as the data endpoint.
- The phase 1 Security Association must specify an encryption method, while encryption is optional for the phase 2 Security Association. An authentication method must be specified for both the phase 1 and phase 2 Security Association.

The exact specifications for each phase 1 Security Association and each phase 2 Security Association are configured in the IP security configuration file. The specific IP security policy statements that apply to the phase 1 and phase 2 specifications are the `KeyExchangeOffer` statement (phase 1) and the `IpDataOffer` statement (phase 2). For more details about the `KeyExchangeOffer` statement and the `IpDataOffer` statement, see [z/OS Communications Server: IP Configuration Reference](#).

Because the IKE protocols deal with initializing keys, they must be capable of running over links where no security is assumed to exist. IKE addresses the problem of secure key distribution by automatically deriving the keying material using a Diffie-Hellman exchange during the IKE phase 1 negotiation. This automatic creation and distribution of the key during phase 1 eliminates the need to manually distribute the session key between remote sites. Besides the obvious administrative advantage of IKE, the manual method of key distribution is prone to key compromise.

In addition, IKE non-disruptively refreshes the session keys based on the security policy of the installation. IKE specifies that this can be based on time (lifetime) and bytes transmitted (life size). IKE provides a property called perfect forward secrecy (PFS), and if PFS is used, each phase 2 key is derived independently through a separate Diffie-Hellman exchange. With PFS, if a single key is compromised, the integrity of subsequently generated keys is not affected.

## Phase 1

Before IKE can negotiate the security parameters and generate the keys that are used to protect data between the two hosts, it must have a way of protecting the negotiation itself. The IKE phase 1 negotiation provides this protection by performing two tasks:

- Authenticating the IKE peer

Peer authentication is performed either by the pre-shared key method or a digital signature method. For details of peer authentication, see [“Peer authentication” on page 956](#).

- Generating cryptographic keys

A Diffie-Hellman exchange is performed to create a shared secret between the two IKE peers. This shared secret is then used in the generation of keying material. Keys to encrypt and authenticate messages sent during phase 2 are produced from this keying material. Cryptographic keys used by phase 2 Security Associations are generated from this keying material. The creation of the Diffie-Hellman shared secret is secure, but computationally expensive.

The phase 1 Security Association contains the following information:

- The key that is used to encrypt IKE messages
- The key that is used to authenticate IKE messages
- Keying material used to generate keys produced during phase 2
- The security endpoints (single IP addresses)
- The type of protection that is required (authentication and encryption)
- How often the keys should be renewed
- A Security Parameter Index (SPI) value, which is used together with the remote security endpoint IP address to uniquely identify the Security Association
- The Diffie-Hellman group, which is an attribute of the public key cryptography algorithm

Because the tasks of authentication and master key generation are so resource intensive, a phase 1 Security Association is usually refreshed less often than a phase 2 Security Association.

## **Peer authentication**

Peer authentication is a critical part of a phase 1 negotiation. Before two hosts can participate in the negotiation of a Security Association, each must be authorized to negotiate with the other. IKE does not allow negotiation with a host that cannot be properly identified. IP addresses are not a guarantee of identity (an IP packet can be spoofed), and the IP address from an inbound packet alone is insufficient to prove the identity of a remote host. Therefore, the IKE daemon needs a more reliable method for determining the remote host's identity. This proof of identity is first presented during the phase 1 negotiation.

z/OS IP security implements two methods of host authentication as follows:

- Digital signature (RSA or ECDSA)
- Pre-shared key

Each of these authentication methods provides a way for hosts to verify the identity of the other, and while the pre-shared key mechanism is easier to configure, the digital signature methods are more versatile, secure, and scalable. The choice of authentication method is configured in an IP security policy configuration file for each IPSec connection, using the `KeyExchangeOffer` statement for IKEv1 and the `KeyExchangeAction` statement for IKEv2. For more details about the `KeyExchangeOffer` statement and `KeyExchangeAction` statements, see [z/OS Communications Server: IP Configuration Reference](#).

Peer authentication is not the same as data authentication. Data authentication uses IPSec to authenticate an IP packet after an IPSec Security Association has been negotiated by two IKE daemons. Peer authentication is used during an IKE phase 1 negotiation to identify two IKE peers to each other before the establishment of any phase 2 Security Associations.

**Guideline:** As a matter of security, pre-shared keys should not be shared among multiple remote IKE peers. If the pre-shared key method of authentication is used, each remote host should have its own unique key and `KeyExchangeRule` specific to that host. If multiple remote hosts are identified by the same `KeyExchangeRule`, digital signature methods of peer authentication should be used.

**Rule:** For IKEv2, if digital signatures are used as the authentication method, then the IKED must be configured to use the certificate services of the NSSD. For more details about the configuring the IKED and the NSS IPSec client, see [Chapter 18, "Network security services," on page 1111](#).

### *Identity information*

Multiple identities can be assigned down to the level of individual IP addresses for each IKE negotiation, or for ease of configuration, a single identity can be assigned to represent the IKE daemon for the TCP/IP stack. With either method, the identity that is assigned must be an identity that is known to the remote IKE peer. Similarly, the local server must know the identity of any remote IKE peer with which it is to negotiate.

**Guideline:** Do not use the same identity on more than one TCP/IP stack or z/OS system image. IKED assumes that an identity is not used by any other stack, and this assumption can lead to a disruption of IPSec service for other stacks when identities are shared between stacks.

The identity can be one of the following types:

- X500dn (the host's X.500 distinguished name)
- IpAddr (an IP address)
- Fqdn (a fully qualified domain name)
- UserAtFqdn (an email address)
- KeyID (EBCDIC, ASCII or hexadecimal string)

**Restriction:** An identity of KeyID is valid only when using preshared key authentication.

If a digital signature method of peer authentication is used, the local identity must be in an X.509 digital certificate on the IKE daemon's key ring for an IKEv1 negotiation, or on the NSS server's key ring for an IKEv1 or IKEv2 negotiation that uses the NSS certificate service. If the pre-shared key method of peer authentication is used, any of the identity types can be used to identify this IKE peer. Because digital

certificates are not used in the pre-shared key method, the only requirement for the use of an identity type is that it be known to both hosts.

Identity information is configured using the `LocalSecurityEndpoint` and `RemoteSecurityEndpoint` statements in an IP security policy configuration file. For more details about the `LocalSecurityEndpoint` statement and `RemoteSecurityEndpoint` statement statements, see [z/OS Communications Server: IP Configuration Reference](#).

### *Digital signatures*

Digital signature authentication methods include RSA and ECDSA. They use X.509 digital certificates. An X.509 digital certificate contains information that was verified by a certificate authority to uniquely identify a host. IKE peers exchange certificates during the phase 1 negotiation to identify each other. Of the information that is typically included in an X.509 digital certificate, there are four fields that are relevant to an IKE exchange:

#### **Subject Name**

A certificate's subject name is the unique name by which the host is known. The subject name is used to extract the host's X.500 distinguished name (X.500dn). IKE can use the X.500dn as an identifier for the remote host, or use one of the certificate's Subject Alternative Names.

#### **Subject Alternative Name**

An optional field, X.509 extensions, can contain a Subject Alternative Name field. Although the X.500dn is the most specific way to identify a certificate, the Subject Alternative Name can be used as well, often acting as a simple alias to identify the certificate. If the certificate includes optional X.509v3 extensions, the certificate can contain any or all of the following information:

- `IpAddr` - an IP address
- `Fqdn` - a fully qualified domain name
- `UserAtFqdn` - an email address

#### **Subject Public Key Info**

The public key is used for encrypting information that can be decrypted only with the certificate's private key. Likewise, information that is encrypted using the certificate's private key can be decrypted only with the public key. Using this scheme, information from the owner can be encrypted, digitally signed, and authenticated. IKE uses the public key to assist in verifying a host's identity.

#### **Issuer Name**

Certificate signing is a method by which a certificate is verified by a trusted third party. A signed certificate contains the subject name and key identifier of the certificate authority that signed it, known as the issuer.

Because there are many commercial and private certificate authorities, it is possible for a host to own multiple certificates that are signed by different certificate authorities. Depending on a site's policy, only certain certificate authorities might be trusted. Therefore, a z/OS IP security host might request that a peer use only certificates that are signed by a specific trusted certificate authority. Two configuration parameters refer to certificate authorities, the `SupportedCertAuth` parameter of the `IkeConfig` statement in the `iked.conf` file, and the `CaLabel` parameter of the `RemoteSecurityEndpoint` statement. The `SupportedCertAuth` parameter names a specific certificate authority that is recognized by the IKE daemon. The `CaLabel` parameter identifies a portion of a certificate authority hierarchy that is preferred by the local security endpoint.

For more information about the `IkeConfig` statement and `RemoteSecurityEndpoint` statement statements, see [z/OS Communications Server: IP Configuration Reference](#).

### *Pre-shared key*

The pre-shared key method of authentication enables a remote host to authenticate itself by providing a secret key, which is known to both hosts. This key is pre-configured by the administrator, and is used along with the Diffie-Hellman shared secret to derive cryptographic keys used to protect and authenticate data that flows during the phase 1 negotiation. The pre-shared key is a shared secret between the two IKE peers, and any host that does not know the shared key cannot enter into negotiation. IKE maintains

a list of all the remote hosts that are authorized to negotiate. This list contains the identity of the remote host and the pre-shared key known to that host.

### *Negotiation modes for phase 1*

For IKEv1, the phase 1 negotiation that takes place between two IKE peers happens in one of two modes, Main mode or Aggressive mode.

Main mode is more secure because it encrypts the identities of the two hosts that are contained in the IKE messages, but somewhat slower because more message exchanges are required. Main mode requires a total of six messages, three from the initiator and three from the responder.

Aggressive mode is faster, in that fewer messages are exchanged. Aggressive mode requires only three messages, two from the initiator and one from the responder. However, the identity of the two hosts is not protected in Aggressive mode. An IKE implementation is not required to support Aggressive mode.

The choice of mode depends in part on the security needs of the installation. If it is important that the identities of either host are not to be in clear text on the network, use Main mode. Otherwise, if both hosts support it, you can use Aggressive mode for faster, more efficient key exchange. One limitation of Aggressive mode is that the initiator can specify only a single Diffie-Hellman group because the key exchange data is sent in the first message. If you need to allow the initiator to send multiple offers with different Diffie-Hellman groups, use Main mode.

For IKEv2, there is only one set of network flows defined for phase 1 negotiation. The set requires four messages, two from the initiator and two from the responder. The first two of these four messages flow in the clear on the network; the other two messages are encrypted. The negotiation of the first phase 2 Security Association is accomplished within these four flows; when the fourth message flows, both phase 1 and phase 2 Security Associations are activated. Either the initiator or the responder can subsequently activate additional phase 2 Security Associations using this phase 1 Security Association.

You configure the choice of negotiation mode using the `KeyExchangeAction` statement and the Diffie-Hellman group using the `KeyExchangeOffer` statement in an IP security policy configuration file. For more details about the [KeyExchangeAction](#) and [KeyExchangeOffer](#) statements, see [z/OS Communications Server: IP Configuration Reference](#).

## **Phase 2**

The purpose of phase 2 negotiation is to establish a set of parameters that are known as a Security Association, which is used to protect specific types of IP traffic. The phase 2 Security Association contains the keys that are used to encrypt and decrypt IPSec packets on the host, authenticate IPSec packets on the host, or both. The phase 2 Security Association is negotiated for a specific set of data endpoints for a specific type of traffic, and contains the following information:

- The keys that are used to encrypt, if encryption is being used
- The keys that are used to authenticate
- The data endpoints, either a single IP address or range of IP addresses
- The protocol of the traffic to be protected, either a single protocol or all protocols
- The ports of the traffic to be protected, either a single port, a range of ports if the IKEv2 protocol is used to negotiate the phase 2 Security Association, or all ports
- The IPSec protocol that is used to protect the data: AH or ESP, or both if the IKEv1 protocol is used for the negotiation
- The type of authentication algorithm to be used
- The type of encryption algorithm to be used, if encryption is being used
- How to build the IPSec packets (tunnel, transport, UDP-encapsulated tunnel, or UDP-encapsulated transport)
- How often the keys should be refreshed, if the IKEv1 protocol is used for the negotiation
- A security parameter index (SPI) value, used together with the remote security endpoint IP address to uniquely identify the Security Association

- The Diffie-Hellman group for perfect forward secrecy (PFS)

A phase 2 negotiation can begin only after the completion of a corresponding phase 1 Security Association. The encryption methods that are agreed upon during the phase 1 negotiation are used to protect the data that is exchanged during the phase 2 negotiation. For instance, if the KeyExchangeRule between two security endpoints specified SHA1 and 3DES, the IKE data that is exchanged during the phase 2 negotiation is authenticated using HMAC-SHA and encrypted using 3DES encryption. Although both phase 1 and phase 2 Security Associations might use the same authentication and encryption methods, this is not required. For instance, a phase 1 Security Association can specify SHA1 authentication and 3DES encryption, while a phase 2 Security Association might use ESP with HMAC-MD5 authentication and DES encryption.

The keys that are generated during the phase 2 negotiation can be derived from the phase 1 master key to amortize the cost of the phase 1 key generation. As an alternative, you can configure the phase 2 negotiation to use perfect forward secrecy (PFS) for stronger security. Each has its advantage as follows:

- If PFS is used, phase 2 negotiation does not derive its keys from the master key, but instead generates new keying material using the Diffie-Hellman algorithm. Because it is independently derived, the resultant phase 2 key is more secure.
- If PFS is not used, phase 2 negotiation is completed much more quickly, but the resultant phase 2 key is less secure.

In either case, phase 2 does not incur the same degree of processing overhead that is involved in phase 1 negotiation with the remote IKE peer.

For IKEv2, the negotiation of the first phase 2 Security Association on a given phase 1 is a special case because it is performed during activation of the phase 1. In this case, the phase 1 Diffie-Hellman group is used for the phase 2 negotiation, regardless of what was defined on the IpDataOffer statement that corresponds to the phase 2.

When phase 2 negotiation has completed, the Security Association is available for use by the stack. Now, any traffic that is mapped to this Security Association by an IP filter rule is IPSec-protected. Because each phase 2 Security Association corresponds to a single unique phase 1 Security Association, the identity of the remote peer is implicitly authenticated when the phase 2 Security Association is used.

Policy for phase 2 Security Associations is defined by referencing an IpDynVpnAction statement on an IpFilterRule statement. For more details on referencing an [IpDynVpnAction statement](#) on an [IpFilterRule statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

You can specify only tunnel or transport mode encapsulation on the IpDataOffer statement. The decision to use UDP-encapsulated transport or tunnel mode is made heuristically by the z/OS IKE daemon. If a NAT device is detected in the process of creating a phase 1 Security Association, all phase 2 Security Associations negotiated under the protection of that phase 1 Security Association are negotiated using UDP encapsulation. In this case, all IpDataOffer statements that contain ESP refer to UDP-encapsulated tunnel or transport mode, as applicable. Any IpDataOffer statements that are configured to use AH authentication are ignored, because the IPSec protocols do not allow for AH authentication when UDP encapsulation is used.

The phase 2 parameter values supported can differ between IPSec implementations. For example, z/OS provides configuration to negotiate a phase 2 Security Association for specific port and specific protocol values. Many implementations of IPSec support negotiating only a wide Security Association, covering all ports and protocols.

## Refreshing phase 1 Security Associations

Refreshing a Security Association is the process of creating a new Security Association to replace an existing Security Association. The IKED automatically refreshes Security Associations when they are about to expire.

When an IKEv1 phase 1 Security Association is refreshed, the IKED performs the following actions:

- It creates a new Security Association using a main mode or aggressive mode exchange.
- It negotiates new keys and it reauthenticates the identity of the IKE peer.

When an IKEv2 phase 1 Security Association is refreshed, the IKED performs the following actions:

- It creates a new Security Association by using a create child exchange process.
- It negotiates new keys but does not reauthenticate the identity of the IKE peer.

You can use the `ReauthInterval` parameter on the `KeyExchangeAction` statement to cause the IKED to periodically reauthenticate an existing IKEv2 phase 1 Security Association. For more information about the `KeyExchangeAction` statement, see the [KeyExchangeAction statement in z/OS Communications Server: IP Configuration Reference](#).

You can use the `refresh` option on the **ipsec** command to refresh an existing phase 1 Security Association. When you use the **ipsec** command to refresh an existing IKEv1 or IKEv2 phase 1 Security Association, new keys are negotiated and the identity of the IKE peer is reauthenticated. For more information about the **ipsec** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

## IPSec and network address translation devices

There are inherent incompatibilities between IPSec and network address translation (NAT) functions. RFC 3715, *IPsec-Network Address Translation (NAT) Compatibility Requirements*, describes the problems that arise when IPSec is used to protect traffic that traverses a NAT. One basic problem is that when IPSec Security Associations traverse a NAT, the NAT is unable to update IP addresses and checksums that are part of the encapsulated data (encrypted, authenticated, or both). See “NATT support level” on page 961 for descriptions of the RFCs that define mechanisms to enable specific uses of IPSec to traverse one or more NAT devices.

When IPSec traverses one or more NAT devices, it is known as NAT traversal (NATT). z/OS Communications Server supports NAT traversal for IPv4 traffic only. NAT traversal is supported for IKEv1 and IKEv2 dynamic tunnels; it is not supported for manual tunnels.

There are several reasons why network address translation might be used. One reason is to economize on the use of public addresses within the internal network, using a public address only when data must be globally routed. A second reason is to hide internal IP addresses from network segments outside the internal IP address domain.

It should be noted that the NAT traversal support, as defined by the IETF, transmits internal IP addresses to its IPSec peer. These internal addresses are not exposed on the external network. However, the internal addresses are available for display at the remote security endpoint. If you are considering using this support, evaluate whether transmitting internal IP addresses to an IPSec peer is acceptable from a security policy perspective.

NAT encompasses the following IP address mapping techniques:

- One technique performs a one-to-one address translation. An internal-external IP address mapping is maintained by the NAT device. IP addresses are translated, but ports are unchanged. The mapping can be static or dynamic. For a static mapping, there is a definition in the NAT that always translates IP address `x.x.x.x` to IP address `y.y.y.y`. An outbound packet is not needed to establish the mapping. For a dynamic mapping, the NAT has a pool of IP addresses that are assigned as needed, so IP address `x.x.x.x` might be mapped to IP address `y.y.y.y` one time, and to IP address `z.z.z.z` at another time. The mapping is established when an outbound packet is processed.
- The network address port translation (NAPT) technique uses multiple internal IP addresses that are translated into a single public IP address. As part of this translation process, the TCP and UDP ports in the packets are translated. NAPT is sometimes referred to as port address translation (PAT) or IP masquerade. The mapping is typically dynamic and established in the NAPT when an outbound packet is processed. For example, the NAPT might create a mapping for internal address `x.x.x.x` port `y` to external address `a.a.a.a` port `b` and a mapping for internal address `z.z.z.z` port `v` to external address `a.a.a.a` port `c`.

When only one client behind a NAPT has negotiated a Security Association, it is not always possible for the remote peer to detect whether the public address is being used for one-to-one address translation

or for NAPT. When multiple clients have active Security Associations, the remote peer can detect when port translation is being performed.

The terms *in front of* and *behind* are used to convey which IP address a NAT is translating. When a NAT is said to be in front of a client, it means the client's address will be translated by the NAT. When a server is said to be behind a NAT, it means that server's address will be translated by the NAT.

## NATT support level

z/OS Communications Server supports NAT traversal as defined in RFCs 3947, 3948, and 5996; they define mechanisms that enable IPsec to traverse one or more NAT devices. Platforms that have implemented their NAT traversal support using pre-RFC drafts might not interoperate with implementations that are compliant with RFCs 3947, 3948, and 5996.

- RFC 3947, *Negotiation of NAT-Traversal in the IKE*, allows an IKEv1 daemon to detect when one or more NATs are being traversed.
- RFC 3948, *UDP Encapsulation of IPsec ESP Packets*, defines two IPsec encapsulation modes, UDP-encapsulated tunnel mode and UDP-encapsulated transport mode. These modes facilitate the traversal of IPsec traffic through a NAT by encapsulating ESP packets within a UDP packet.
- RFC 5996, *Internet Key Exchange (IKEv2) Protocol*, specifies how to detect when IKEv2 peers are traversing one or more NATs

z/OS Communications Server does provide limited support for the following pre-RFC implementations:

- draft-ietf-ipsec-nat-t-ike-02 (pre-RFC draft of RFC 3947), and draft-ietf-ipsec-udp-encaps-02 (pre-RFC draft of RFC 3948)
- draft-ietf-ipsec-nat-t-ike-03 (pre-RFC draft of RFC 3947), and draft-ietf-ipsec-udp-encaps-03 (pre-RFC draft of RFC 3948)

## Dynamic structures used to map Security Associations

The negotiation of a phase 2 Security Association results in the dynamic creation of new filters used to map the Security Association to a specific type of traffic. These dynamic filters are then added to the filter table and remain as long as the Security Association is available for use. Additional structures are added to the filter table when the remote security endpoint is behind a NAT.

### Anchor filters and dynamic filters

Filters with ipsec actions are flagged as anchor filters. Anchor filters are neither permit or deny rules, but rather serve as place holders for dynamic filters in the ordered list of filter rules. A dynamic filter is an extension of an anchor filter and is created when a phase 2 Security Association is created. Each phase 2 Security Association that is negotiated is associated with two dynamic filters, an inbound filter and an outbound filter. When an IP packet matches an anchor filter rule, there is a secondary search for a matching dynamic filter rule. If one is not found, the packet is denied, unless the packet is an outbound packet and on-demand negotiations are allowed. In that case, an IKE negotiation ensues to create a Security Association and the matching dynamic filter. If a dynamic filter already exists, the action taken is to permit with IPsec processing applied. The dynamic filter rule indicates which Security Association should be used when applying IPsec processing, because there is a one-to-one correspondence between dynamic filter pairs (inbound and outbound) and phase 2 Security Associations. For a sample display of anchor and dynamic filters, see [“Displaying active filters with the ipsec command” on page 1079](#).

### NATT anchor and NATT dynamic filters

When the remote peer is behind a NAT, the dynamic anchor still serves as a place holder in the ordered list of filter rules. However, the dynamic filters that are created when a phase 2 Security Association is created are handled differently. When the phase 2 negotiation is successful, the dynamic filter pair that is created contains the 5-tuple information for which the Security Association was negotiated:

- The data endpoints, either a single IP address or range of IP addresses

- The protocol of the traffic to be protected, either a single protocol or all protocols
- The ports of the traffic to be protected, either a single port or all ports

In cases when the remote peer is behind a NAT, this 5-tuple might not be unique for a Security Association. An additional structure, a NATT anchor, is generated to anchor dynamic filters that share the same 5-tuple information. The dynamic filter is then an extension to the NATT anchor and is flagged as a NATT dynamic. For a sample display of NATT anchor and NATT dynamic filters, see [“Displaying active filters with the ipsec command”](#) on page 1079.

## NAT resolution filters

When the remote peer is behind a NAT, a connection level filter structure is also created for TCP and UDP connections, the NAT resolution filter (NRF). Unlike the NATT anchor and NATT dynamic filters, which are created when the phase 2 Security Association is created, the NRF is created when the first inbound packet is received for the connection over the phase 2 Security Association. The NRF contains a single source and destination IP address, a single source and destination port value, and a single protocol. This connection-level filter is needed to determine the phase 2 Security Association that will be used for outbound data. For a sample display of NAT resolution filters, see [“Displaying active filters with the ipsec command”](#) on page 1079.

## Remote port translation

When the remote peer is a security gateway behind a NAT, the remote data endpoint of the client is represented by the security gateway's public IP address. From the z/OS server's perspective, multiple clients that are behind the security gateway are all identified by the IP address of their corresponding security gateway, not the client's private IP address. Consequently, if two clients behind the security gateway were to open a connection to the same service (FTP, for example) from the same ephemeral port (1024, for example), the two connections could not be uniquely identified.

Similarly, when the remote peer is a host behind a NAPT, the remote data endpoint of the host is represented by the public address assigned by the NAPT. Typically, multiple hosts that are behind the NAPT are all assigned the same public IP address, with port translation distinguishing the hosts. The port that is being translated by the NAPT is the port found in the UDP header of the IKE packet and the UDP-encapsulated ESP packet, not the connection port. Consequently, if two hosts behind the NAPT open a connection to the same service (FTP, for example) from the same ephemeral connection port (1024, for example), the two connections cannot be uniquely identified.

Traditionally, the combination of local and remote IP addresses and ports is enough to distinguish the connections; in these instances, because the connection requests appear to be coming from the same IP address, they look identical. To avoid such conflicts, Communications Server provides remote port translation for TCP and UDP connections when needed. Without remote port translation, the first inbound TCP connection request for a unique 5-tuple would succeed. However, a subsequent inbound connection request using the same 5-tuple would fail. Communications Server's remote port translation allows subsequent inbound connections using the same 5-tuple to succeed by translating the remote port value to a different ephemeral port.

Remote port translation does not need to be configured or enabled. It is built into Communications Server's NAT traversal support and is always in effect when the remote peer is behind a NAT. When a remote port is translated, message EZD0827I, remote port translated, is logged. Remote port translation determines whether the source port in an inbound packet represents a duplicate port. If it does, an attempt is made to assign an unused ephemeral port value. If the inbound packet matches a configured filter rule that covers all ports, any unused ephemeral port value can be assigned. If the configured filter rule applies only to a range of ports, the remote port is translated only to an unused ephemeral port in that range. If an unused port cannot be found, the connection request fails. When a remote port value is translated, there is both an original remote port and translated remote port for a connection. Various commands, such as Netstat, enable you to view connection information including the port, or even to select display data based on port. For connection data, if only one remote port is being provided, the translated port is displayed or used for a selection, if remote port translation has been done.

The **ipsec -o display** command provides a display of port mappings in effect. For a sample display of remote port translation, see [“Displaying remote port translation with the ipsec command” on page 1093](#).

## Steps for preparing the z/OS system for IP security

---

Establish the security needs for your installation. Set up key required applications, modify default IP filter policy if necessary, configure the IKE daemon, configure the NSS daemon and additional encryption products as needed, and create IP security policy configuration files.

### Before you begin

You need to be familiar with the concepts of IP filter logging and IPSec protection. See [“Overview of using IP security” on page 916](#). You also need to be familiar with the commands used to administer IP security. See [“Commands used to administer IP security” on page 915](#).

### Procedure

Perform the following steps to prepare the z/OS system for IP security.

1. Develop a site policy to address the security needs of your installation.

Consider the following questions before beginning to build a robust IP security policy:

- Do you want a default-allow or default-deny policy?
- If you want a default-deny policy, what traffic is allowable as critical to the correct functioning of the system?
- What hosts are allowed to send data to the secure host?
- Do you understand the network topology, and where the communicating hosts are located within the network?
- Are there network address translation (NAT) devices in the network topology?
- What type of traffic is allowable from those hosts?
- What general network services that rely on well-known ports do you want to allow?
- Will you forward any packets you receive that are not destined for you?
- Who is allowed to configure the IP security policy?
- Are you running with one TCP/IP stack, or more than one TCP/IP stack?
- Are you running IPv6 traffic?
- Will all TCP/IP stacks share the same policy definitions, or will they have unique differences?
- Will traffic that is sent or received by the secure host traverse the Internet?
- Do you want to participate in a VPN? (If so, IPSec is required.)
- If IPSec is required:
  - What are the IPSec capabilities of the remote endpoints?
  - How do you want to authenticate participating hosts:
    - Pre-shared key?
    - Digital signature? (requires digital certificates)
  - What type of authentication is needed for the data that is involved?
  - Is encryption needed for the data that is involved, and how strong should the encryption algorithms be?
  - Will all participating hosts use the same level of data encryption and authentication, or do you need to define unique policies for individual hosts?

2. Identify the resources to be secured.

Create a worksheet for each TCP/IP stack you will enable for IP security. This information aids in determining which interfaces and connected networks are secured. You can later use the information

from the worksheets to provide values for IP security policy configuration statements. [Figure 128 on page 964](#) includes a sample worksheet:

```
Host name of z/OS system _____

Complete for each TCP/IP stack on this host:
TCP/IP stack name _____ IPSECURITY-enabled (Y/N) _____
Network interface(s)
IPv4 address/Mask _____ Security Class _____
IPv4 address/Mask _____ Security Class _____
IPv4 address/Mask _____ Security Class _____
IPv4 address/Mask _____ Security Class _____
IPv6 address/Prefix _____ Security Class _____
IPv6 address/Prefix _____ Security Class _____
Virtual IPv4 address/Mask _____
Virtual IPv4 address/Mask _____
Virtual IPv4 address/Mask _____
Virtual IPv4 address/Mask _____
Virtual IPv6 address/Prefix _____
Virtual IPv6 address/Prefix _____

Identities, other than IP address, by which the IKE daemon will be known
(e.g., X500dn, Fqdn, UserAtFqdn, KeyID)

```

*Figure 128. Sample worksheet for stack security*

Security class is an optional designation for a network interface. You can assign network interfaces a security class (1-255) that is used to group interfaces with similar security requirements. This concept is an extension of the traditional notion of secure and nonsecure interfaces, to allow for more than two classes. The secure and nonsecure model can still apply if only two security classes are defined.

Complete a table of remote hosts and subnetworks with which this host needs to transfer data, as shown in [Table 51 on page 964](#). The remote hosts can optionally be grouped in a user-defined zone to simplify the number of IP filter rules that are required. For instance, you might want to define an internal, external, trusted, Internet, partner company, or other zone that has meaning to your site.

**Rule:** If the remote IKE peer is on a security gateway to the remote host, the IP address of the remote host might not match the IP address of the remote IKE peer. If this is the case, tunnel-mode encapsulation of IPSec traffic is required.

| Table 51. Table of remote hosts and subnetworks |                                   |                                                                          |                               |                                                                |                                       |                                     |
|-------------------------------------------------|-----------------------------------|--------------------------------------------------------------------------|-------------------------------|----------------------------------------------------------------|---------------------------------------|-------------------------------------|
| Remote IP address or subnet                     | User-defined zone of remote hosts | Identity of remote IKE peer (IpAddr, X500dn, KeyID, Fqdn, or UserAtFqdn) | IP address of remote IKE peer | Allowed list of services (Telnet, FTP, web, EE, ALL, or other) | Security action (permit, deny, ipsec) | IPSec security level, if applicable |
|                                                 |                                   |                                                                          |                               |                                                                |                                       |                                     |
|                                                 |                                   |                                                                          |                               |                                                                |                                       |                                     |

### 3. Modify the default IP filter policy (optional).

After the site policy is established, you can modify the default IP filter policy if necessary. For a description and examples of how to modify the default IP filter policy, see [“Default IP filter policy and IP security policy” on page 929](#).

**Guideline:** You should define IPSECRULE and IPSEC6RULE statements that permit access from at least one administrative machine. In the event that Policy Agent is unavailable, or the IP security configuration files contain errors, the active default policy would deny access to the IP security-enabled stack. Should this situation occur, if you have added the appropriate IPSECRULE and

IPSEC6RULE statements to the default policy, you can still access the secure z/OS host and make the necessary administrative changes to correct the problem.

#### 4. Set up the key required applications:

- TCP/IP

To enable IP security on a z/OS stack, make the following changes in the TCP/IP profile:

- Add IPCONFIG IPSECURITY.
- To also enable IP security for IPv6, add IPCONFIG6 IPSECURITY.
- Reserve ports 500 and 4500 for IP security. If the IKE daemon is running on this system, reserve the ports for the user ID under which the IKE daemon is running. In this example, the IKE daemon is running under the IKED user ID:

|      |     |      |
|------|-----|------|
| 500  | UDP | IKED |
| 4500 | UDP | IKED |

If the IKE daemon is not running on this system, reserve the ports by specifying RESERVED:

|      |     |          |
|------|-----|----------|
| 500  | UDP | RESERVED |
| 4500 | UDP | RESERVED |

- To direct IPsec's AH and ESP protocol processing to zIIPs, add GLOBALCONFIG ZIIP IPSECURITY.

For information on the [IPCONFIG](#) statement, [IPCONFIG6](#), [GLOBALCONFIG](#) statement, and [PORT](#) statement statements, see [z/OS Communications Server: IP Configuration Reference](#).

- Policy Agent

For information on configuring the Policy Agent, see [Chapter 14, “Policy-based networking,” on page 813](#).

- TRMD

For information on configuring TRMD, see [“TRMD” on page 906](#).

- Syslogd

For information on configuring the syslog daemon, see [“Configuring the syslog daemon” on page 235](#).

- IKED

The IKED can be started from a z/OS UNIX command line or as an MVS procedure. The iked.conf file controls the overall function of the IKE daemon, such as the following settings:

- The logging level of the IKE daemon
- The logging level of the Policy Agent when performing IP security-related tasks on behalf of the IKE daemon
- The name of the RACF key ring that is owned by the IKE daemon
- Whether IKE messages are echoed to STDOUT when the daemon is started for the UNIX System services shell
- How long to wait when attempting to connect to the Policy Agent
- The list of certificate authorities that are acceptable for RSA signature negotiation when the IKED is using the native certificate service (when the Network Security Services (NSS) server is providing the certificate service, this list is not used)

Most of the configuration parameters have a default value and do not require modification.

**Rule:** If the RSA signature method is to be used in any IKE phase 1 negotiation and the IKED is using the native certificate service, the name of the IKE key ring must be included in the iked.conf file. If the NSS server is providing the certificate service, the IKE key ring name is not needed.

**Tip:** If the RSA signature method is used and the IKED is using the native certificate service, including a list of supported certificate authorities enhances the performance of certificate searches.

**Guideline:** You should not change the logging levels of the IKE daemon (IkeSyslogLevel) and Policy Agent (PagentSyslogLevel) from their default values for normal day-to-day operation. Higher logging levels can affect performance and should be used for temporary diagnostic purposes only. The default PagentSyslogLevel value 0 prevents the IKE daemon from logging diagnostic information about its interactions with Policy Agent. The default IkeSyslogLevel value 1 provides basic informational and error messages. You can set the IkeSyslogLevel value to 0 to disable IKE syslog messages entirely (for both the IKE daemon and Policy Agent; to collect PagentSyslogLevel tracing, the IkeSyslogLevel value must also be a nonzero value). You can set the IkeSyslogLevel value to a higher value to identify the source of an error; for example, if you experience problems with Security Association negotiations that are caused by a configuration error, you might enable IkeSyslogLevel 4 (debugging information for Security Association negotiations).

For detailed syntax and a description of the `iked.conf` file, and details on starting the IKE daemon as an MVS procedure, see z/OS Communications Server: IP Configuration Reference.

5. Define access controls for key required applications:

- TRMD

TRMD runs as an authorized program and requires RACF setup. TRMD must be able to run as a started task and have superuser authority. For sample RACF commands, see the EZARACF member of SEZAINST.

- Policy Agent

Policy Agent runs as an authorized program and requires RACF setup. Policy Agent must be able to run as a started task and have superuser authority. For sample RACF commands, see the EZARACF member of SEZAINST and “Step 1: Configure general information” on page 834.

- IKED

For the steps to prepare for running the IKE daemon, see Appendix E, “Steps for preparing to run IP security,” on page 1391.

6. Configure the IKE daemon.

See Appendix E, “Steps for preparing to run IP security,” on page 1391.

7. (Optional) Configure the NSS daemon.

If the IKED is using the NSS certificate service for any IKEv1 or IKEv2 Security Association negotiation, then configure the NSS daemon. The IKED must use the NSS certificate service for any IKEv2 negotiation that uses certificates for authentication. The IKED can use either the native certificate service or the NSS certificate service for an IKEv1 negotiation that uses certificates for authentication.

For more information about the NSS daemon, see Chapter 18, “Network security services,” on page 1111.

8. (Optional) Configure additional encryption products.

- 3DES support

For 3DES (triple DES), the Communications Server Security Level 3 feature, is required.

- AES support (including AES-CBC, AES-GCM and AES-GMAC)

For AES, the Communications Server Security Level 3 feature and the z/OS Security Level 3 feature are required and ICSF must be started.

- FIPS 140

For IKED, NSSD, and TCP/IP to run in FIPS 140 mode, you must first choose one of several modes of FIPS operation for ICSF and start ICSF.

**Requirement:** ICSF must be active before starting the IKE daemon or NSS server configured in FIPS 140 mode. For information about enabling ICSF to support FIPS 140-2, see the topic about Operating in compliance with FIPS 140-2 in z/OS Cryptographic Services ICSF Writing PKCS #11 Applications.

- ICSF

There are several options available on z/OS to perform encryption in hardware. The ICSF product is required to support these various options. For a description and information about how to configure these options, see [z/OS Cryptographic Services ICSF Administrator's Guide](#).

For the RACF commands that authorize ICSF, see [Appendix E, “Steps for preparing to run IP security,”](#) on page 1391.

- SHA2 support (including SHA2-256, SHA2-384, and SHA2-512, as well as all corresponding HMAC-SHA2 algorithms) and AES authentication (AES-XCBC)

For SHA2 and AES-XCBC authentication, ICSF must be started.

#### 9. Create IP security policy configuration files.

After the security needs of your installation are established, the next step is to create one or more IP security policy configuration files. There are two main configuration files in which IP security policy configuration is stored:

##### **Stack-specific IP security configuration file**

Configured on a per-stack basis and contains only IP security policy configuration that applies to the stacks for which it is configured.

##### **Common IP security configuration file**

Contains IP security policy configuration that applies to every stack on the system and can be used to hold shared definitions.

The stack-specific file can refer to various definitions in the common file, and can override policy definitions in the common file.

Although Policy Agent uses LDAP to store policy for some other policy types, IP security policy configuration is stored exclusively in human-readable text files, either in the z/OS UNIX file system or in an MVS data set. These configuration files are then read by Policy Agent when it initializes and before being installed into the stack.

## **IP security policy configuration**

---

This topic describes the general steps for creating IP security policy configuration files for the most common configurations. Configuring a complete and specific IP security policy that meets the needs of any installation is beyond the scope of this text, but guidance for more advanced configurations is provided.

[“Overview of configuring IP security policy”](#) on page 967 describes the common IP security configuration file, the stack-specific IP security configuration file, and the general content, structure, and use of these files.

[“Component policies of IP security policy configuration files”](#) on page 974 describes the types of policies contained in IP security policy configuration files.

[“Steps for configuring IP security policy”](#) on page 1000 describes the steps for manually creating IP security policy configuration files.

[“Quick start using IP filtering and IPsec host-to-host”](#) on page 985 describes a complete IP security policy allowing connections from a secure server to an administrative machine on an internal network, and represents the minimum configuration needed to provide IPsec protection with dynamic key management between two hosts. This topic also describes the use of the **ipsec** command to display filters and Security Associations.

[“Configuring specific security models”](#) on page 1002 provides more examples and describes the configuration needed for common security models.

## **Overview of configuring IP security policy**

There are three options for IP security policy configuration for a system:

- Use a common IP security configuration file that applies to all stacks on the system, enforcing a consistent policy. In this instance, a stack-specific IP security configuration file is not necessary.

- Use a unique and separate stack-specific IP security configuration file for each stack on the system. In this instance, a common IP security configuration file is not necessary.
- Use both a common and a stack-specific IP security configuration file.
  - The common IP security configuration file can be used as a common repository for frequently used definitions, which can be referenced by any stack-specific IP security configuration file.
  - The stack-specific IP security configuration file can contain unique statements that apply only to the stack for which it is configured, and can reference statements that are defined in the common IP security configuration file.

Although not an error, note that when using the last approach, it is possible for duplicate statements to exist in the common and the stack-specific IP security configuration files (for example, two `IpFilterRule` statements with the same name). In this case, the statement in the stack-specific IP security configuration file is honored. Statements in the stack-specific IP security configuration file always take precedence over the common IP security configuration file.

## Structure of an IP security configuration file

The common IP security configuration file and the stack-specific IP security configuration file have exactly the same structure. They are comprised of a number of statements that define items that are used to define policy, such as policies, rules, actions, groups, and objects. Statement names and attribute names are not case sensitive, though they appear in mixed case in this information for readability. Only user-defined names are case sensitive. For the complete syntax of all [IPSec policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

An IP security policy configuration statement has the following generic form:

```
StatementType user-defined name
{
 Attribute1 value1
 Attribute2 value2
 .
 .
}
```

Statements often contain other inline statements in a recursive form:

```
StatementType1 user-defined name
{
 Attribute1 value1
 StatementType2 optional user-defined name
 {
 Attribute1 value1
 Attribute2 value2
 }
 Attribute2 value2
}
```

There are three main sections in an IP security configuration file, identified by the following three statements:

- `IpFilterPolicy`
- `KeyExchangePolicy`
- `LocalDynVpnPolicy`

Additional statements that define rules, actions, groups, and objects are found both in the main body of the configuration file and within any of these other three policy blocks. A high-level view of an IP security configuration file follows. Although the statement blocks are shown in a specific order, the ordering is arbitrary.

```
IpFilterPolicy #(required)
{
 <local statements>
}
```

```

KeyExchangePolicy #(optional)
{
 <local statements>
}

LocalDynVpnPolicy #(optional)
{
 <local statements>
}

 <global statements>

```

## ***Groups***

Groups provide a method to combine related objects in a meaningful way into sets. The following IP security policy configuration statements can be used as groups:

- IpAddrGroup
- IpFilterGroup
- IpServiceGroup
- KeyExchangeGroup
- LocalDynVpnGroup

## ***Reference statements***

A reference statement can be recognized by the suffix `Ref`. References provide a convenient way to reuse definitions, eliminating the need to repeatedly specify things such as host addresses and common services. Nearly all statements in the IP security configuration file can be referenced, and all action statements must be referenced. To be referenced, an IP security policy configuration statement must be given a user-defined name. Names of statements can be up to 32 characters. The following IP security policy configuration statements can be referenced, and therefore reused:

- IpAddr
- IpAddrSet
- IpDataOffer
- IpDynVpnAction
- IpFilterGroup
- IpFilterRule
- IpGenericFilterAction
- IpLocalStartAction
- IpManVpnAction
- IpService
- IpServiceGroup
- IpTimeCondition
- KeyExchangeAction
- KeyExchangeGroup
- KeyExchangeOffer
- KeyExchangeRule
- LocalDynVpnGroup
- LocalDynVpnRule
- LocalSecurityEndpoint
- RemoteIdentity
- RemoteSecurityEndpoint

## Steps for configuring local IP security policy using only a common IP security configuration file

You can configure local IP security policy for all stacks on the system using only a common IP security configuration file. In this instance, a stack-specific IP security configuration file is not necessary.

### Procedure

Perform the following steps to configure local IP security policy using only a common IP security configuration file.

1. In the main Policy Agent configuration file, include a CommonIpSecConfig line that identifies the common IP security configuration file, as follows:

```
CommonIpSecConfig /etc/common.ipsecpol
```

2. In the main Policy Agent configuration file, include a line with the TcpImage statement for each IP security stack to be configured:

```
TcpImage TCPCS /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
:
```

3. In each configuration file that was identified on the TcpImage statement shown in step “2” on [page 970](#), include a line that contains IpSecConfig with no file name, as follows:

```
In /etc/TCPCS.image:
IpSecConfig

In /etc/TCPCS2.image:
IpSecConfig
```

### Results

All stacks on the z/OS system will adhere to the policy that is specified in the /etc/common.ipsecpol file.

## Steps for configuring remote IP security policy using only a common IP security configuration file

You can configure remote IP security policy for all stacks on the z/OS policy client system using only a common IP security configuration file. In this instance, a stack-specific IP security configuration file is not necessary.

### Procedure

Perform the following steps to configure remote IP security policy using only a common IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

```
ServerConnection
{
 ...
}
TcpImage TCPCS /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
:
```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.

For example, in /etc/TCPCS.image:

```

PolicyServer
{
 ClientName IPSecClientTCPCS
 PolicyType IPSec
 {
 ...
 }
 ...
}

```

In /etc/TCPCS2.image:

```

PolicyServer
{
 ClientName IPSecClientTCPCS2
 PolicyType IPSec
 {
 ...
 }
 ...
}

```

3. In the main configuration file on the policy server, include a DynamicConfigPolicyLoad statement, as follows:

```

DynamicConfigPolicyLoad IPSecClient.*
{
 PolicyType IPSec
 {
 CommonPolicyLoad /etc/common.ipsecpol
 }
 ...
}

```

## Results

All stacks on the z/OS policy client system will adhere to the policy that is specified in the /etc/common.ipsecpol file on the policy server.

## Steps for configuring local IP security policy using only a stack-specific IP security configuration file

You can configure local IP security policy using only a unique and separate stack-specific IP security configuration file for each stack on the system. In this instance, a common IP security configuration file is not necessary.

## Procedure

Perform the following steps to configure local IP security policy using only a stack-specific IP security configuration file.

1. In the main Policy Agent configuration file, include a line with the TcpImage statement for each stack to be configured, as follows:

```

TcpImage TCPCS /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
:

```

2. In each configuration file that was identified on the TcpImage statement shown in step “1” on [page 971](#), include an IPSecConfig line that identifies the stack-specific IP security configuration file, as follows:

```

In /etc/TCPCS.image:
IpSecConfig /etc/TCPCS.ipsecpol

In /etc/TCPCS2.image:
IpSecConfig /etc/TCPCS2.ipsecpol

```

## Results

Each stack on the z/OS system will adhere to the policy that is specified by its unique policy file. Stack TCPCS uses the policy that is configured in /etc/TCPCS.ipsecpol, and stack TCPCS2 uses the policy that is configured in /etc/TCPCS2.ipsecpol.

## Steps for configuring remote IP security policy using only a stack-specific IP security configuration file

You can configure remote IP security policy using a unique and separate stack-specific IP security configuration file for each stack on the z/OS policy client system. In this instance, a common IP security configuration file is not necessary.

### Procedure

Perform the following steps to configure remote IP security policy using only a stack-specific IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

```
ServerConnection
{
 ...
}
TcpImage TCPCS /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
:
```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.

For example, in /etc/TCPCS.image:

```
PolicyServer
{
 ClientName IPSecClientTCPCS
 PolicyType IPSec
 {
 ...
 }
 ...
}
```

In /etc/TCPCS2.image:

```
PolicyServer
{
 ClientName IPSecClientTCPCS2
 PolicyType IPSec
 {
 ...
 }
 ...
}
```

3. In the main configuration file on the policy server, include DynamicConfigPolicyLoad statements, as follows:

```
DynamicConfigPolicyLoad IPSecClientTCPCS
{
 PolicyType IPSec
 {
 PolicyLoad /etc/TCPCS.ipsecpol
 }
 ...
}
DynamicConfigPolicyLoad IPSecClientTCPCS2
{
 PolicyType IPSec
 {
```

```

 PolicyLoad /etc/TCPSCS2.ipsecpol
 }
 ...
}

```

## Results

Each stack on the z/OS policy client system will adhere to the policy that is specified by its unique policy file. Stack TCPSCS uses the policy that is configured in /etc/TCPSCS.ipsecpol on the policy server, and stack TCPSCS2 uses the policy that is configured in /etc/TCPSCS2.ipsecpol on the policy server.

## Steps for configuring local IP security policy using both a stack-specific file and a common file

You can configure local IP security policy using both a stack-specific file and a common file. If there are duplicate statements, the stack-specific file always takes precedence over the common file.

### Procedure

Perform the following steps to configure local IP security policy using both a stack-specific IP security configuration file and a common IP security configuration file.

1. In the main Policy Agent configuration file, include a CommonIpSecConfig line that identifies the common IP security configuration file, as follows:

```
CommonIpSecConfig /etc/common.ipsecpol
```

2. In the main Policy Agent configuration file, include a line with the TcpImage statement for each stack to be configured, as follows:

```
TcpImage TCPSCS /etc/TCPSCS.image
TcpImage TCPSCS2 /etc/TCPSCS2.image
:
```

3. In each configuration file that was identified on the TcpImage statement in step “2” on page 973, include an IPsecConfig line that identifies the stack-specific IP security configuration file, as follows:

```
In /etc/TCPSCS.image:
IpSecConfig /etc/TCPSCS.ipsecpol

In /etc/TCPSCS2.image:
IpSecConfig /etc/TCPSCS2.ipsecpol
```

## Results

Any statements in the common IP security configuration file are added to the policy for each stack when the policy is initialized. Either file, /etc/TCPSCS.ipsecpol or /etc/TCPSCS2.ipsecpol, can refer to statements in /etc/common.ipsecpol. In the case of duplicate names, any named statement in the stack-specific IP security configuration file overrides a statement with the same name in the common IP security configuration file.

## Steps for configuring remote IP security policy using both a stack-specific file and a common file

You can configure remote IP security policy using both a stack-specific file and a common file. If there are duplicate statements, the stack-specific file always takes precedence over the common file.

### Procedure

Perform the following steps to configure remote IP security policy using both a stack-specific IP security configuration file and a common IP security configuration file.

1. In the main Policy Agent configuration file on the policy client, include the ServerConnection statement, and a line with the TcpImage statement for each IP security stack to be configured:

```
ServerConnection
{
 ...
}
TcpImage TCPCS /etc/TCPCS.image
TcpImage TCPCS2 /etc/TCPCS2.image
:
```

2. In each configuration file that was identified on the TcpImage statement shown in step 1, include a PolicyServer statement.

For example, in /etc/TCPCS.image:

```
PolicyServer
{
 ClientName IPSecClientTCPCS
 PolicyType IPSec
 {
 ...
 }
 ...
}
```

In /etc/TCPCS2.image:

```
PolicyServer
{
 ClientName IPSecClientTCPCS2
 PolicyType IPSec
 {
 ...
 }
 ...
}
```

3. In the main configuration file on the policy server, include DynamicConfigPolicyLoad statements, as follows:

```
DynamicConfigPolicyLoad IPSecClientTCPCS
{
 PolicyType IPSec
 {
 CommonPolicyLoad /etc/common.ipsecpol
 PolicyLoad /etc/TCPCS.ipsecpol
 }
 ...
}
DynamicConfigPolicyLoad IPSecClientTCPCS2
{
 PolicyType IPSec
 {
 CommonPolicyLoad /etc/common.ipsecpol
 PolicyLoad /etc/TCPCS2.ipsecpol
 }
 ...
}
```

## Results

Any statements in the common IP security configuration file are added to the policy for each stack when the policy is initialized. Either file, /etc/TCPCS.ipsecpol or /etc/TCPCS2.ipsecpol, can refer to statements in /etc/common.ipsecpol. In the case of duplicate names, any named statement in the stack-specific IP security configuration file overrides a statement with the same name in the common IP security configuration file.

## Component policies of IP security policy configuration files

There are three types of policies in IP security policy configuration files:

- IP filter policy (IpFilterPolicy statement)
- Key exchange policy (KeyExchangePolicy statement)
- Local dynamic VPN policy (LocalDynVpnPolicy statement)

## IP filter policy

An IP filter policy can stand alone to provide IP filtering and IPSec protection with manual key management. Used in conjunction with the two other policies, it is also required to provide IPSec protection with dynamic key management (IKE). Because filtering is crucial to secure traffic on a host, an IP security policy that contains no IpFilterPolicy statement block or an empty IpFilterPolicy statement block is considered an error, leaving the default policy that is provided by the stack in effect.

The IpFilterPolicy statement block consists of:

- A set of global configuration options
- An ordered list of IP filter rules (IpFilterRule statements)

The purpose of the global configuration options is to control global policy items, such as whether logging is active or whether on-demand Security Association negotiations are allowed, and so forth. These global options apply to all of the IP filter rules that are contained in the policy. Each IP filter rule, in turn, contains data endpoints, traffic descriptions, and actions. When a packet entering or leaving the system matches the data endpoints and traffic description in an IP filter rule, the associated action is taken. If the action is an ipsec action, additional action statements are coded that define the parameters of the IPSec Security Association.

The following sample IpFilterRule statement allows web traffic on an internal server, and references a description of each line in the sample:

```

1 IpFilterRule InternalNetWeb
2 {
3 IpSourceAddr 9.1.1.1
4 IpDestAddrSet 9.1.1.0/24
5 IpService
6 {
7 SourcePortRange 80
8 DestinationPortRange 1024 65535
9 Protocol tcp
10 Direction bidirectional InboundConnect
11 Routing local
12 SecurityClass 0
13 }
14 IpGenericFilterActionRef permit-nolog
15 }
```

### Line

#### Description

**1**

The IpFilterRule keyword, followed by a required user-defined name for this rule.

**2**

An open brace ({}) marks the start of an IpFilterRule statement block.

**3**

The source address of the rule. Outbound IP packets that match this rule must have 9.1.1.1 as the source address in the IP header.

**4**

The destination address of the rule. Outbound IP packets that match this rule must have an address in the range of 9.1.1.0 - 9.1.1.255 as the destination address in the IP header.

**5**

The IpService statement block describes the type of traffic that is allowed between the two data endpoints. The IpService block in this rule is inline to the rule, meaning that the entire definition of the IP service is included within the rule. Many policy statements, including the IpService statement, can be referenced rather than included inline.

- 6** An open brace ({} marks the start of the IpService statement block.
- 7** The range of source ports that is allowed for outbound packets. The value can be a single number, or a range of ports.
- 8** The range of destination ports that is allowed for outbound packets. The value can be a single number, or a range of ports.
- 9** The specific protocol that is allowed by this rule.
- 10** The direction specification for the IP packet.
- Bidirectional indicates that this rule allows outbound traffic from local address 9.1.1.1 on local port 80 to any address in subnet 9.1.1.0/24 using any ephemeral port (that is, 1024-65535), and inbound traffic from any address in subnet 9.1.1.0/24 using any ephemeral port to local address 9.1.1.1 on local port 80. Without the use of the bidirectional keyword, it would be necessary to create two filter rules, one for outbound traffic and one for inbound traffic.
- InboundConnect indicates that the rule will match inbound TCP connection attempts as well as bidirectional data on an established connection, but it will not match outbound TCP connection attempts.
- 11** The routing information for a packet matching this rule. For a packet to match this rule, the traffic must be local. In other words, this rule does not allow any packets that must be forwarded to another network node. Possible values are local, routed, or either.
- 12** The security class of the interface on which the packet must arrive or leave. The security class of an interface is defined using the SECCLASS parameter on the statement that is used to define the interface in the TCP/IP profile (that is, the LINK, INTERFACE, IPCONFIG DYNAMICXCF, or IPCONFIG6 DYNAMICXCF statement). Each interface on the system can be assigned a SECCLASS in the range 1 – 255. If the SECCLASS parameter is not coded in the TCP/IP profile for an interface, by default the interface is SECCLASS 255. In the SecurityClass parameter in this example, the value 0 indicates that a packet that matches this rule is not restricted and can traverse any interface (1 – 255).
- 13** A close brace (}) marks the end of the IpService block.
- 14** The action that is taken on a packet that matches this rule. In this case, permit the packet and log all occurrences of a match. All IP filter rules must include an IpGenericFilterActionRef statement. The IpGenericFilterAction statement itself should be defined elsewhere, outside of the IpFilterRule block, either in the common or the stack-specific IP security configuration file:
- ```
IpGenericFilterAction    permit-nolog
{
  IpFilterAction         permit
  IpFilterLogging        no
}
```
- 15** A close brace (}) marks the end of the IpFilterRule statement block.

Rule: Do not include policy action statements inline. They must be referenced.

Example 1

Permit rule allowing outbound FTP client connections from the local host (9.1.1.1) to a remote FTP server (9.1.1.2):

```
IpFilterRule      FTP-client
{
    IpSourceAddr    9.1.1.1
    IpDestAddr      9.1.1.2
    IpService
    {
        SourcePortRange 1024 65535
        DestinationPortRange 21
        Protocol         tcp
        Direction        bidirectional OutboundConnect
        Routing          local
        SecurityClass    0
    }
    IpService
    {
        SourcePortRange 1024 65535
        DestinationPortRange 20
        Protocol         tcp
        Direction        bidirectional InboundConnect
        Routing          local
        SecurityClass    0
    }
    IpGenericFilterActionRef permit
}
```

Normal (non-passive mode) FTP requires that the FTP client be allowed to initiate outbound connections to port 21, and be able to receive inbound connections from port 20. The `IpGenericFilterAction permit` block must be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```
IpGenericFilterAction permit
{
    IpFilterAction      permit
}
```

Example 2

Deny rule that blocks all traffic from all private address spaces that is inbound to a public interface:

```
IpFilterRule      deny-private
{
    IpSourceAddrGroupRef PrivateAddrs
    IpDestAddr      all
    IpService
    {
        SourcePortRange 0
        DestinationPortRange 0
        Protocol         all
        Direction        inbound
        Routing          either
        SecurityClass    0
    }
    IpGenericFilterActionRef deny-log
}
```

The `IpSourceAddrGroupRef` parameter references an IP address group that is presumed to be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```
IpAddrGroup PrivateAddrs
{
    IpAddrSet
    {
        Prefix 10.0.0.0/8
    }
    IpAddrSet
    {
        Prefix 172.16.0.0/12
    }
    IpAddrSet
```

```

    {
      Range 192.168.0.0-192.168.255.255
    }
  }
}

```

The `IpGenericFilterActionRef` parameter references an `IpGenericFilterAction` statement that is presumed to be defined elsewhere, in either the common or the stack-specific IP security configuration file:

```

IpGenericFilterAction    deny-log
{
  IpFilterAction          deny
  IpFilterLogging         yes
}

```

Example 3

An ipsec rule that requires IPSec protection for all traffic between the secure server and an administrative machine on the internal network:

```

IpFilterRule              Rule2Admin
{
  IpSourceAddrRef          InternalServerAddressA1
  IpDestAddrRef            AdminClient
  IpServiceRef             All-traffic-local
  IpGenericFilterActionRef ipsec
  IpDynVpnActionRef        Silver-TransportMode
}

```

The use of multiple references in this example makes the IP filter rule easier to read. For each referenced object or action, there should be a corresponding definition elsewhere, in either the common or the stack-specific IP security configuration file:

```

IpAddr                    InternalServerAddressA1
{
  Addr                    9.1.1.1
}

IpAddr                    AdminClient
{
  Addr                    9.1.1.2
}

IpService                 All-traffic-local
{
  Protocol                all
  Direction               bidirectional
  Routing                 local
  SecurityClass           0
}

IpGenericFilterAction     ipsec
{
  IpFilterAction          ipsec
  IpFilterLogging         yes LogDeny
}

IpDynVpnAction            Silver-TransportMode
{
  Initiation              either
  InitiateWithPfs         None
  AcceptablePfs           None
  IpDataOfferRef          SHA-DES-Transport
}

IpDataOffer               SHA-DES-Transport
{
  HowToEncap              transport
  HowToEncrypt            DES
  HowToAuth               ESP HMAC_SHA1
}

```

IP filter rule order

“Example 1” on page 977, “Example 2” on page 977, and “Example 3” on page 978 show individual IP filter rules. A complete IP filter policy contains any number of IP filter rules, configured in much the same manner. It is important to remember that IP filter rules in an IP filter policy are searched in the order listed. Because it is possible for a packet to match more than one rule, a search for a matching filter rule stops after the first match is found, even if there are additional matches further down in the list. Use the **ipsec** command traffic test option (**ipsec -t**) as an aid in determining which IP filter rule an IP packet matches.

The command-line arguments to the **ipsec -t** command are a set of characteristics that describe a particular IP packet. The existing set of filter rules are searched for potential matches. Unlike normal filter processing, which stops the search after a match is found, the **ipsec -t** command displays all matching filter rules. Input to the **ipsec -t** command does not have to specify all possible filtering criteria from an IP packet. The output of the **ipsec -t** command must be inspected to determine which of the returned rules match for a given case.

For instance, an IP filter rule for ICMP can be configured for a specific type and code value, while the traffic test does not provide ICMP type and code as inputs. If more than one IP filter rule matches on the ICMP protocol, they are all displayed. You must determine, from among those listed, which rule applies for a specific IP packet.

For a complete description of the **ipsec** command, including the **ipsec -t** option, see [z/OS Communications Server: IP System Administrator's Commands](#).

Key exchange policy

A key exchange policy is required by IKE to provide dynamic key management. The policy contains the definitions about how the negotiation of keys is to be performed (using IKEv1 or IKEv2), how the negotiations are to be protected, and which hosts are allowed to negotiate keys. The absence of a key exchange policy is not considered an error, but without it, the IKE daemon is unable to provide dynamic key management.

A key exchange policy consists of an ordered list of key exchange rules. A key exchange rule consists of a set of security endpoints, and an action to be taken when the two security endpoints engage in an IKE phase 1 negotiation.

Optionally, a key exchange rule can contain a shared key known only to the two negotiating entities that are described in the rule. When an IKE negotiation is initiated, the current list of key exchange rules is searched for a match, based on four criteria:

- The identity of the local IKE peer, if known
- The identity of the remote IKE peer, if known
- The location (IP address) of the local IKE peer, if needed to distinguish it or if local identity is not known
- The location (IP address) of the remote IKE peer, if needed to distinguish it or if remote identity is not known

The following sample KeyExchangeRule block allows an IKE negotiation between IKE daemons at 9.2.2.2 and 9.4.4.4. A description of each line in the sample follows the sample.

```
1  KeyExchangeRule           ZoneB_KeyExRule1
2  {
3      LocalSecurityEndpoint
4      {
5          Identity           IpAddr 9.2.2.2
6          Location           9.2.2.2
7      }
8      RemoteSecurityEndpoint
9      {
10         Identity           X500dn CN=ZoneB Cert,T=IKE
11         ServerB,OU=endicott,O=ibm,C=US
12         Location           9.4.0.0/16
13         CaLabel            CA4endicott
```

```

13     }
14     KeyExchangeActionRef      Gold-RSA
15     SharedKey                 Ascii TheEagleHasLanded
16 }

```

Line

Description

1

The KeyExchangeRule keyword, followed by a required user-defined name.

2

An open brace ({) marks the beginning of the KeyExchangeRule statement block.

3

The LocalSecurityEndpoint statement identifies a local security endpoint, or local IKE peer.

4

An open brace ({) marks the beginning of the LocalSecurityEndpoint statement block.

5

The identity of the local security endpoint that must match this rule. This can be one of five types:

- Fqdn
- IpAddr
- KeyID
- UserAtFqdn
- X500dn

In the example, an IP address is used as the identity value.

6

The IP address of the local IKE peer.

7

A close brace (}) marks the end of the LocalSecurityEndpoint statement block.

8

The RemoteSecurityEndpoint statement identifies a remote security endpoint, or remote IKE peer. The RemoteSecurityEndpoint statement can also be used to define a related group of remote IKE peers by using wildcard values for identity and location.

9

An open brace ({) marks the beginning of the RemoteSecurityEndpoint statement block.

10

The identity of the remote security endpoint that must match this rule. This can be one of five types:

- Fqdn
- IpAddr
- KeyID
- UserAtFqdn
- X500dn

In the example, an X.500 distinguished name is used as the identity value.

11

The IP subnetwork that defines a group of remote IKE peers.

12

Used only for digital signature peer authentication. Specifies the certificate authority that is advertised to the remote security endpoint as an acceptable authority. The value for this parameter must be the label of a certificate authority that is defined in RACF. The CaLabel parameter can be specified multiple times.

13

A close brace (}) marks the end of the RemoteSecurityEndpoint statement.

14

A reference to a key exchange action that has been defined elsewhere, in either the common or the stack-specific IP security configuration file, as follows:

```
KeyExchangeAction      Gold-RSA
{
    HowToInitiate       main
    HowToRespondIKEv1   main
    KeyExchangeOffer    {
        HowToEncrypt    3DES
        HowToAuthMsgs   SHA1
        HowToAuthPeers  RsaSignature
    }
}
```

The KeyExchangeAction statement specifies the detailed parameters that govern a phase 1 negotiation between these two security endpoints, such as who can begin the negotiation and what type of encryption is used.

15

An optional shared key used only for pre-shared key host authentication.

16

A close brace (}) marks the end of the KeyExchangeRule statement block.

Example 1

The following key exchange rule for an IKEv1 Aggressive-mode phase 1 negotiation uses pre-shared key authentication:

```
KeyExchangeRule      Admin_KeyExRule1
{
    LocalSecurityEndpointRef  Internal_IKED
    RemoteSecurityEndpointRef Admin_IKED
    KeyExchangeActionRef     Bronze-PSK
    SharedKey                 Ascii TheEagleHasLanded
}
```

This rule defines the parameters for the IKEv1 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and Admin_IKED (presumed to be defined elsewhere in the policy file). The specifics of the negotiation are covered by the Bronze-PSK action as follows:

```
KeyExchangeAction      Bronze-PSK
{
    HowToInitiate       Aggressive
    HowToRespondIKEv1   Aggressive
    KeyExchangeOffer    {
        HowToEncrypt    DES
        HowToAuthMsgs   SHA1
        HowToAuthPeers  PreSharedKey
    }
}
```

The optional SharedKey parameter is required only when the pre-shared key authentication method is used for the phase 1 negotiation.

Example 2

The following KeyExchangeRule statement for an IKEv1 Main-mode phase 1 negotiation uses digital signature authentication:

```
KeyExchangeRule      ZoneA_KeyExRule1
{
    LocalSecurityEndpointRef  Internal_IKED
    RemoteSecurityEndpointRef ZoneA_IKED
}
```

```

KeyExchangeActionRef      Silver-RSA
}

```

The referenced objects are presumed to be defined elsewhere in the policy file. This rule defines the parameters for the IKEv1 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and ZoneA_IKED. The specifics of the negotiation are covered by the Silver-RSA action as follows:

```

KeyExchangeAction      Silver-RSA
{
    HowToInitiate        main
    HowToRespondIKEv1    main
    KeyExchangeOffer     {
        HowToEncrypt      DES
        HowToAuthMsgs     SHA1
        HowToAuthPeers    RsaSignature
    }
}

```

Example 3

The following key exchange rule for an IKEv2 phase 1 negotiation uses digital signature authentication:

```

KeyExchangeRule          IKEv2_Example
{
    LocalSecurityEndpointRef  Internal_IKED
    RemoteSecurityEndpointRef ZoneA_IKED
    KeyExchangeActionRef     IKEv2-DigitalSignature
}

```

This rule defines the parameters for the IKEv2 phase 1 negotiation between two hosts that are identified by the security endpoints Internal_IKED and ZoneA_IKED (presumed to be defined elsewhere in the policy file). The specifics of the negotiation are covered by the IKEv2-DigitalSignature action as follows:

```

KeyExchangeAction          IKEv2-DigitalSignature
{
    HowToInitiate           IKEv2
    HowToAuthMe             DigitalSignature
    ReauthInterval          0
    BypassIpValidation       Yes
    KeyExchangeOffer        {
        HowToEncrypt         AES_CBC KeyLength 128
        HowToVerifyMsgs      HMAC_SHA1_96
        PseudoRandomFunction HMAC_SHA1
        HowToAuthPeers       RsaSignature
    }
}

```

Key exchange rule order

“[Example 1](#)” on page 981 and “[Example 2](#)” on page 981 show individual key exchange rules. A complete key exchange policy contains any number of key exchange rules. Key exchange rules in a key exchange policy are searched in the order listed. In the process of an IKE negotiation, Policy Agent searches the list of active key exchange rules to locate a best match. It is possible for more than one key exchange rule to match a pending IKE negotiation. For this reason, the list of key exchange rules in the key exchange policy should be ordered from most specific to least specific in much the same way as the IP filter rules. If the key exchange policy contains key exchange rules with both unique and wildcard security endpoints, the most specific definitions should be placed higher in the list than the wildcard definitions.

For instance, there might be one key exchange rule governing a connection from an internal administrative machine, and another key exchange rule governing all other hosts on the internal network, as follows:

```

KeyExchangeRule          Admin_KeyExRule1
{
    LocalSecurityEndpointRef  Internal_IKED
    RemoteSecurityEndpointRef Admin_IKED
    KeyExchangeActionRef     Bronze-PSK
}

```

```

    SharedKey                Ascii TheEagleHasLanded
  }
  KeyExchangeRule            ZoneA_KeyExRule1
  {
    LocalSecurityEndpointRef  Internal_IKED
    RemoteSecurityEndpointRef ZoneA_IKED
    KeyExchangeActionRef      Silver-RSA
  }

```

In this case, because the remote IKE peer that is defined by the remote security endpoint Admin_IKED matches both the Admin_KeyExRule1 and ZoneA_KeyExRule1 rules, the Admin_KeyExRule1 rule should be placed ahead of the ZoneA_KeyExRule1 rule in the key exchange policy as follows:

```

KeyExchangePolicy
{
  KeyExchangeRuleRef      Admin_KeyExRule1
  KeyExchangeRuleRef      ZoneA_KeyExRule1
  KeyExchangeRuleRef      ZoneB_KeyExRule1
  KeyExchangeRuleRef      ZoneC_KeyExRule1
}

```

Local dynamic VPN policy

A local dynamic VPN policy is required only if the IPSec negotiation is started through command-line activation using the **ipsec** command, or through automatic activation due to a local dynamic VPN policy update. IPSec negotiations can be initiated in one of four ways:

- On-demand

The negotiation initiates when an outbound IP packet matches a filter rule with an ipsec action.

- Remotely

The remote peer initiates the request, and the local IKE daemon responds.

- Command-line activation

The **ipsec** command enables you to manually initiate an IPSec negotiation. (Not to be confused with manual tunnels, which do not use the IKE daemon at all.)

- Autoactivation

The negotiation begins when either the stack or the IKE daemon initializes and both are active, or when the local dynamic VPN policy is updated.

A local dynamic VPN policy is required only in the last two cases.

A local dynamic VPN policy consists of an unordered list of local dynamic VPN rules. The negotiation for a phase 2 Security Association requires that the two communicating hosts agree on two data endpoints that the Security Association covers, the protocols the Security Association covers, and the ports that the Security Association covers. This information is then stored in the phase 2 Security Association, which is consulted each time relevant IPSec traffic needs to be encapsulated or decapsulated. The purpose of the local dynamic VPN rule is to define these requirements for each Security Association that is configured.

The following sample LocalDynVpnRule statement defines the parameters for the negotiation of a phase 2 Security Association for TN3270E Telnet server traffic between a server (9.1.1.1) and a client (9.4.4.100). A description of each line follows the sample.

```

1 LocalDynVpnRule      TelnetSA
2 {
3     LocalIP            9.1.1.1
4     RemoteIP           9.4.4.100
5     LocalDataPort      23
6     RemoteDataPort     0
7     Protocol           tcp
8     Autoactivate       yes
9 }

```

Line	Description
------	-------------

- 1 The LocalDynVpnRule keyword and user-defined name.
- 2 An open brace ({}) marks the start of the LocalDynVpnRule statement block.
- 3 The local address of IP traffic that this Security Association is to protect. The address can be either a single address or a range of addresses. However, if the address is not a single address, this Security Association must be negotiated for tunnel mode.
- 4 The remote address of IP traffic that this Security Association is to protect. The address can be either a single address or a range of addresses. However, if the address is not a single address, this Security Association must be negotiated for tunnel mode.
- 5 The local ports for IP traffic that this Security Association is to protect. The port must be either a single port or all ports. A range of ports is not allowed. A value of 0 indicates all ports.
- 6 The remote ports for IP traffic that this Security Association is to protect. The port must be either a single port or all ports. A range of ports is not allowed. A value of 0 indicates all ports.
- 7 The protocol that this Security Association is to protect. This value can be numeric. It must define a single protocol or all protocols.
- 8 Indicates that this Security Association is to be activated when the stack and IKE daemon are active. No user intervention is required.
- 9 A close brace (}) marks the end of the LocalDynVpnRule statement block.

An on-demand Security Association does not require a local dynamic VPN rule definition. All of the parameters for the negotiation of an on-demand phase 2 Security Association can be inferred from one of two places, either the packet that began the on-demand activation or the filter rule on which the packet matched. The packet always provides a single value for address, protocol, port, type, and code. The filter rule, however, can allow for a range of values for IP address, protocol, port, type, or code. The granularity setting of the `IpLocalStartAction` statement determines whether the information is taken from the packet or from the matching filter rule. For more information regarding the `IpLocalStartAction` statement, see [z/OS Communications Server: IP Configuration Reference](#).

Security Associations can be defined as wide or narrow with respect to IP addresses or ports and protocols. If a Security Association is wide with respect to IP address, the same Security Association is used to protect data between multiple endpoints. If a Security Association is wide with respect to ports and protocols, the same Security Association is used to protect multiple traffic types. Conversely, a narrowly defined Security Association can be used to protect specific data endpoints (based on IP address) or specific traffic types (based on commonly used ports and protocols for network services). Security Associations negotiated with IKEv2 can also be narrow with respect to types and codes.

Example 1 - wide Security Association

The following rule allows any type of traffic to flow between `PublicServerAddressA1` and `SubnetC` using the same Security Association. `PublicServerAddressA1` and `SubnetC` can be defined in either the common or the stack-specific IP security configuration file. The `AutoActivate` parameter causes the IKE negotiation to initiate when the stack or IKE initializes.

```
LocalDynVpnRule      ZoneC_VPN-All-traffic
{
    LocalIpRef         PublicServerAddressA1
    RemoteIpSetRef      SubnetC
    Protocol            all
    AutoActivate        yes
}
```

```

IpAddr          PublicServerAddressA1
{
  Addr          9.3.3.3
}

IpAddrSet       SubnetC
{
  Prefix        9.6.0.0/16
}

```

Example 2 - narrow Security Association

If narrow Security Associations are used for IPSec-protected FTP traffic, two VPN definitions are required, one for the data connection and one for the control connection. The following rules are from the server's perspective. The FTP client connecting from BranchOfficeAddressC1 to the PublicServerAddressA1 ports 20 and 21 uses the respective ZoneC FTP VPNs.

```

LocalDynVpnRule      ZoneC_VPN-FTP-Data
{
  LocalIpRef          PublicServerAddressA1
  RemoteIpRef         BranchOfficeAddressC1
  LocalDataPort       20
  RemoteDataPort      0
  Protocol            tcp
}

LocalDynVpnRule      ZoneC_VPN-FTP-Control
{
  LocalIpRef          PublicServerAddressA1
  RemoteIpRef         BranchOfficeAddressC1
  LocalDataPort       21
  RemoteDataPort      0
  Protocol            tcp
}

IpAddr              PublicServerAddressA1
{
  Addr              9.3.3.3
}

IpAddr              BranchOfficeAddressC1
{
  Addr              9.5.5.5
}

```

Quick start using IP filtering and IPSec host-to-host

The following sample shows a complete IP security policy allowing connections from a secure server (9.1.1.1) to an administrative machine (9.1.1.2) on an internal network. It represents the absolute minimum number of items that need to be configured for the IKED to provide IPSec protection with dynamic key management between two hosts.

Tip: You can modify the quick start sample for IPv6 by replacing all IPv4 addresses with IPv6 addresses.

This IP security policy allows IKE negotiations in the clear (UDP, port 500 traffic), while authenticating and encrypting all other traffic using the ESP IPSec protocol. The policy relies almost exclusively on the z/OS IP security policy defaults, including MD5 and DES for the phase 1 Security Association and ESP/MD5 ESP/DES for the phase 2 Security Association. For a complete description of [IPSec policy statements](#) and their defaults, see [z/OS Communications Server: IP Configuration Reference](#).

```

#-----
# Quick-Start IP Security policy
#-----
IpFilterPolicy

        IpService
        {
            Direction         bidirectional
            Routing            local
        }
        IpGenericFilterActionRef ipsec
        IpDynVpnActionRef      TransportMode
    }
}

KeyExchangePolicy
{
    KeyExchangeRule          QuickStart_KeyExRule
    {
        LocalSecurityEndpoint
        {
            Identity           IpAddr 9.1.1.1
            Location            9.1.1.1
        }
        RemoteSecurityEndpoint
        {
            Identity           IpAddr 9.1.1.2
            Location            9.1.1.2
        }
        KeyExchangeActionRef   QuickStart_KeyExAction
        SharedKey              Ascii TheEagleHasLanded
    }
}

#-----
# Reusable actions
#-----
IpGenericFilterAction      permit
{
    IpFilterAction          permit
}

IpGenericFilterAction      ipsec
{
    IpFilterAction          ipsec
    IpFilterLogging          yes LogDeny
}

KeyExchangeAction          QuickStart_KeyExAction
{
    KeyExchangeOffer
    {
        HowToAuthPeers        PreSharedKey
    }
}

IpDynVpnAction             TransportMode
{
    IpDataOffer
    {
        HowToEncap            transport
    }
}

```

For all IKE negotiations, there must be a corresponding and consistent configuration on the remote host. In this case, if the remote system is running with z/OS IP security, the corresponding policy for the remote system can be generated merely by transposing all instances of local and remote IP addresses.

Displaying filters, rules, and actions

To display the filter rules for the quick start policy after they have been installed in the stack, enter the following UNIX System Services command:

```
ipsec -f display -r detail -c current
```

```

Each IP service in the example uses the bidirectional keyword. Therefore, two rules are created for each IP service, one outbound and one inbound. When the IP filter rules are expanded in this way, the specific filter rules are distinguished from each other by a unique numeric value in the FilterNameExtension field.

Note that the last four deny rules are not explicitly coded in the IP security configuration file, but are added by the system in keeping with a default-deny policy.

For more information on displaying active filters with the **ipsec** command, see [“Displaying active filters with the ipsec command” on page 1079](#).

To view the quick start filter rules using the **pasearch** command, issue the following command:

```

pasearch -v f

TCP/IP pasearch CS V1R12          Image Name: TCPCS

Activating the quick start Security Association

The quick start policy enables on-demand activation of a Security Association between the two endpoints. The Security Association is a wide Security Association allowing any type of traffic. Therefore, it can be activated by sending any type of traffic from the local host at 9.1.1.1 to the remote host at 9.1.1.2 as follows:

```

ping -s 9.1.1.1 9.1.1.2
CS V2R5: Pinging host 9.1.1.2
sendto(): EDC5111I Permission denied. (errno2=0x74420291)

```

Because the Security Association does not exist, the initial **ping** attempt fails. After the negotiation for the Security Association has activated and the Security Association is established, a subsequent **ping** attempt succeeds as follows:

```

ping -s 9.1.1.1 9.1.1.2
CS V2R5: Pinging host 9.1.1.2
Ping #1 response took 0.001 seconds.(1.378 milliseconds)

```

Displaying the quick start Security Associations

Use the **ipsec** command to display both the phase 1 and phase 2 Security Associations between 9.1.1.1 and 9.1.1.2. The following command displays the phase 1 Security Associations:

```

ipsec -k display -r detail

Steps for configuring IP security policy

These steps are used to configure the specific security models.

Procedure

Perform the following steps to configure IP security policy.

1. Determine the number of zones to be protected. A zone typically equates to a subnetwork that is reachable by the host server, but can be any group of IP addresses that are conceptually related. The internal network can be defined in one or several zones, while any external network or group of networks can be placed in separate zones. Each zone should have meaning related to the site's security policy. If a zone maps to a physical interface, optionally assign a security class to all interfaces in that zone.
2. For each zone, determine what services are allowed and define an IpService statement for each wanted service. Services are defined by the protocols and well-known ports that they use.
3. Determine the data endpoints to be protected. Typically, this is both a local and remote IP address, or subnetwork.
4. Determine what level of security is needed between each set of data endpoints. The level of security can be deny, permit, or ipsec.
5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged.
6. If IPSec is required between any two endpoints:
 - a) Configure a KeyExchangePolicy statement that defines the parameters of the phase 1 negotiation:
 - i) Determine the required type and strength of protection for the phase 1 Security Association.
 - ii) Decide what type of peer authentication will be used:
 - If digital signature, set up RACF certificates and certificate authority information.
 - If pre-shared key, create a secret key that is known to both peers.
 - iii) Decide whether NAT traversal will be allowed. If the network topology contains one or more NAT devices that must be traversed by the phase 1 Security Association, NAT traversal should be allowed.

- iv) Configure a KeyExchangeOffer statement.
 - v) Determine negotiation mode, IKEv1 Main, IKEv1 Aggressive, or IKEv2.
 - vi) Configure a KeyExchangeAction statement.
 - vii) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement.
 - viii) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action.
 - ix) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block.
 - b) Configure an IpDynVpnAction statement that defines the control of the phase 2 negotiation:
 - i) Determine the required type and strength of IPSec protection for the phase 2 Security Association.
 - ii) Determine whether tunnel or transport mode is required. For an IKEv2 negotiation, the appropriate mode is chosen based on topology.
 - iii) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation.
 - iv) Determine which peer should be allowed to initiate the negotiation.
 - c) Decide how the Security Association is to be activated:
 - i) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.
 - ii) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.
 - iii) Either create an IpFilterRule statement that allows IPSec traffic (AH and ESP), or set the global PreDecap parameter of the IpFilterPolicy statement to off.
7. Define an IpFilterRule statement for each set of data endpoints.
- The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500.
- Rule:** To allow IKE negotiations for Security Associations, IKE traffic (port 500, and optionally port 4500 for NAT traversal) must be permitted in the clear.
8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.
9. Include the IpFilterRule statements in the IpFilterPolicy block.
10. Include all configured statements in the IP security configuration file.
- For more information, see:
- [“Steps for configuring local IP security policy using only a common IP security configuration file” on page 970](#)
 - [“Steps for configuring remote IP security policy using only a common IP security configuration file” on page 970](#)
 - [“Steps for configuring local IP security policy using only a stack-specific IP security configuration file” on page 971](#)
 - [“Steps for configuring remote IP security policy using only a stack-specific IP security configuration file” on page 972](#)
 - [“Steps for configuring local IP security policy using both a stack-specific file and a common file” on page 973](#)
 - [“Steps for configuring remote IP security policy using both a stack-specific file and a common file” on page 973](#)

Results

For examples of the use of these steps, see [“Configuring specific security models” on page 1002](#).

Configuring specific security models

Setting up IP security configuration files can be a complex task, as there are many powerful features, options, and controls. However, after the security needs of the business are identified, implementing an IP security policy becomes a matter of translating the requirements to a Policy Agent configuration file.

The choice of protection model primarily depends on the network topology. Although it is perfectly permissible to follow a single model when configuring IP security policy, the z/OS IP security function enables any number of models to be installed concurrently. Commonly, one set of rules governs internal network traffic, another protects traffic from connected networks, and a third provides security for traffic that is routed over the Internet. The following scenarios presume that you are configuring a secure server that is a multihomed host that is connected to an internal, an external, and a wide-area network that traverses the Internet. The configuration guidelines that are presented in the following subtopics are based on three business models:

- Trusted internal network (permit, deny)

In the trusted internal network model, the server is protecting traffic that originates from hosts inside a privately controlled network. IP packets on the internal network are not generally subject to the stringent restrictions that are placed on traffic that is generated from outside the business. This model is usually more tolerant, given that users inside the company need access to internal network resources and services, such as the web, FTP, and Telnet.

- Partner company (permit, deny, strong IPSec protection)

The partner company model consists of two interconnected networks, with the server protecting traffic that originates from hosts outside the internal network. Typically, two separate networks are physically connected to the z/OS server. Because the traffic is not restricted to internal hosts, security is usually somewhat tighter than in the trusted internal network model. Each partner company has no physical control over the machine of the other partner company. The services that are provided are determined by the needs of the business, but typically include many of the same services that are provided to the internal network, such as access to a web server, FTP, and Telnet. Though many services might be allowed between partner companies, the need for confidentiality and authentication of data is more stringent than in the trusted internal network model, because there is little to no control over the other network. IPSec is often specified to authenticate and optionally encrypt data that flows between the two networks.

- Branch office (permit, deny, strong tunnel-mode IPSec protection)

The branch office model consists of two networks whose IP connectivity relies on the Internet. The server is protecting traffic that originates from hosts outside the internal network, which at some point is routed over the Internet. Because there is no control over any data that traverses the Internet, the need for security is greatest in this model. The services that are provided are based on business need, but typically include a subset of what is available internally. All traffic that traverses the Internet carrying vital information should be secured using some form of authentication and encryption.

[Figure 129 on page 1003](#) shows a sample network for all three security models.

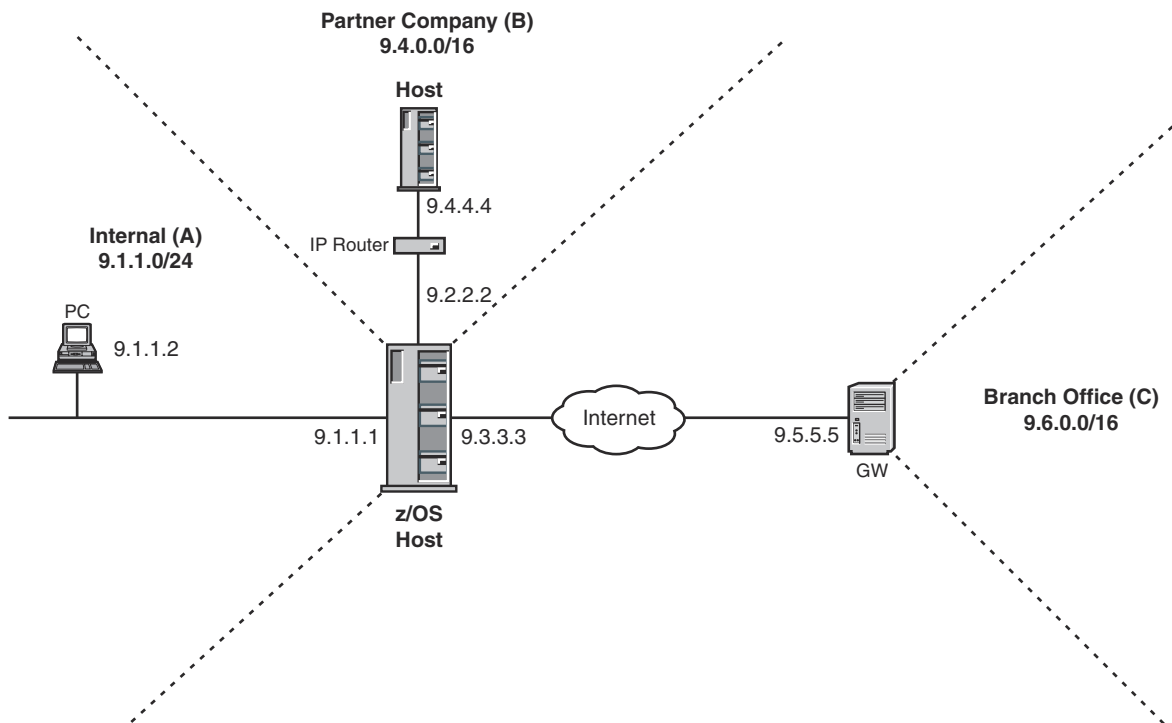

Figure 129. Security model network

The following subtopics describe how to configure these models using the steps described in [“Steps for configuring IP security policy”](#) on page 1000. The policy examples assume that a default-deny policy is in place. Any traffic not explicitly permitted is blocked.

Steps for configuring the trusted internal network model (simple IP filtering)

In the trusted internal network model, the server is protecting traffic that originates from hosts inside a privately controlled network.

Before you begin

The following statements, concepts, and files are covered in the discussion of this model:

- IpFilterRule
- IpService
- IpGenericFilterAction
- References
- Groups
- Stack-specific IP security configuration file
- Common IP security configuration file

[Figure 130 on page 1004](#) shows the trusted internal network portion of the security model network.

Internal (A) 9.1.1.0/24

Figure 130. Trusted internal network model

For this example, assume that the following requirements must be met to control traffic on the internal network:

- Give FTP access to an administrator from a host inside the internal network (9.1.1.2) to the secure server (9.1.1.1). Log any traffic that matches this traffic pattern.
- Allow web access (HTTP, port 80) to the secure server from any host on the internal network (9.1.1.0/24). Do not log any traffic that matches this traffic pattern.
- Deny all other traffic.

Procedure

Perform the following steps to meet these requirements and configure the trusted internal network model.

1. Determine the number of zones to be protected.

There is only one zone for this example, the internal network 9.1.1.0/24.

2. For each zone, determine what services are allowed and define an IpService block for each wanted service. Optionally, assign a security class to all interfaces in each zone.

There are two services stated in the example requirements, HTTP and FTP. The traffic is local to this host and, therefore, the routing is designated as local. No forwarding of these services is allowed.

Because the entire internal network is defined in one zone, you can define a unique security class for the interface with address 9.1.1.1. For this example, the SECCLASS parameter of all internal network interfaces is assigned the arbitrary value of 1, which can be interpreted to mean a trusted network. If you specify the SecurityClass parameter in the IpService block, the related interface must be assigned the same value on the SECCLASS parameter of the LINK or INTERFACE statement in

the TCP/IP profile. In this example, the traffic is allowed only over an interface with a SECCLASS parameter value of 1, presumed to be the interface connected to the internal network.

```
IpService
{
  SourcePortRange      80
  DestinationPortRange 1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         1
}
```

Because normal FTP uses two well-known ports, two services are required, one for the control connection and one for the data connection:

```
IpService
{
  SourcePortRange      21
  DestinationPortRange 1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         1
}

IpService
{
  SourcePortRange      20
  DestinationPortRange 1024 65535
  Protocol              tcp
  Direction             bidirectional OutboundConnect
  Routing               local
  SecurityClass         1
}
```

The InboundConnect keyword is used for services that are not allowed to initiate a TCP connection. The OutboundConnect keyword is used for services that are not allowed to receive a TCP connection request. If neither keyword is specified, either side can initiate a TCP connection.

3. Determine the data endpoints to be protected.

There are two sets of data endpoints to be protected in this example, representing the connection from the administrative machine, and all the other hosts on the subnetwork:

```
Local  Address of secure server: 9.1.1.1
Remote Address of administrative machine: 9.1.1.2

Local  Address of secure server: 9.1.1.1
Remote Address of all hosts on internal network: 9.1.1.0/24
```

4. Determine what level of security is needed between each set of data endpoints.

In this example, only permit is required. Therefore, no IPsec information is needed. Because z/OS IP security policy implicitly provides a default-deny policy, all other traffic is denied.

5. Configure an IpGenericFilterAction statement for the level of security (permit, deny, ipsec) that is required, including whether the connection is logged.

Because the example requirement is to permit two types of traffic with different logging requirements, two actions are needed as follows:

```
IpGenericFilterAction    permit-log
{
  IpFilterAction          permit
  IpFilterLogging          yes
}

IpGenericFilterAction    permit-nolog
{
  IpFilterAction          permit
  IpFilterLogging          no
}
```

6. If IPSec is required between any two endpoints, configure a KeyExchangePolicy statement that defines the parameters of the phase 1 negotiation, configure an IpDynVpnAction statement that defines the control of the phase 2 negotiation, and decide how the Security Association is to be activated.

IPSec is not required in this example. If there was sensitive data flowing through the internal network that needed to be confidential, IPSec could be specified to encrypt some IP packets, thereby effectively securing information that travels between two hosts on the internal network.

7. Define an IpFilterRule block for each set of data endpoints.

Each rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500.

In this example, the source address refers to an address on the secure host. The destination address refers to remote hosts. The IpService statements are the ones defined in step “2” on [page 1004](#). Note that the IpGenericFilterAction statement must reference a previously defined action.

```

IpFilterRule      AdminFTP
{
  IpSourceAddr    9.1.1.1
  IpDestAddr      9.1.1.2
  IpService
  {
    SourcePortRange 21
    DestinationPortRange 1024 65535
    Protocol         tcp
    Direction        bidirectional InboundConnect
    Routing          local
    SecurityClass    1
  }
  IpService
  {
    SourcePortRange 20
    DestinationPortRange 1024 65535
    Protocol         tcp
    Direction        bidirectional OutboundConnect
    Routing          local
    SecurityClass    1
  }
  IpGenericFilterActionRef permit-log
}
IpFilterRule      InternalNetWeb
{
  IpSourceAddr    9.1.1.1
  IpDestAddrSet   9.1.1.0/24
  IpService
  {
    SourcePortRange 80
    DestinationPortRange 1024 65535
    Protocol         tcp
    Direction        bidirectional InboundConnect
    Routing          local
    SecurityClass    1
  }
  IpGenericFilterActionRef permit-nolog
}
IpGenericFilterAction permit-log
{
  IpFilterAction    permit
  IpFilterLogging    yes
}
IpGenericFilterAction permit-nolog
{
  IpFilterAction    permit
  IpFilterLogging    no
}

```

Because IPSec is not required in this example, no filters for IKE traffic are needed.

8. Include the IpFilterRule statements in the IpFilterPolicy block.

The IP filter rules and their relative placement within the IpFilterPolicy block should be from most specific to least specific. Because the AdminFTP rule controls traffic from a specific host, it should be placed before the InternalNetWeb rule. Note that to enable logging of the individual rules, filter logging must be enabled at the global level of the IP filter policy with the FilterLogging parameter.

```
IpFilterPolicy
{
  FilterLogging          on

  IpFilterRule           AdminFTP
  {
    IpSourceAddr         9.1.1.1
    IpDestAddr           9.1.1.2
    IpService
    {
      SourcePortRange    21
      DestinationPortRange 1024 65535
      Protocol            tcp
      Direction           bidirectional InboundConnect
      Routing             local
      SecurityClass       1
    }
  }
  IpService
  {
    SourcePortRange      20
    DestinationPortRange 1024 65535
    Protocol              tcp
    Direction             bidirectional OutboundConnect
    Routing               local
    SecurityClass         1
  }
  IpGenericFilterActionRef permit-log
}
IpFilterRule           InternalNetWeb
{
  IpSourceAddr         9.1.1.1
  IpDestAddrSet        9.1.1.0/24
  IpService             WebServer
  {
    SourcePortRange      80
    DestinationPortRange 1024 65535
    Protocol              tcp
    Direction             bidirectional InboundConnect
    Routing               local
    SecurityClass         1
  }
  IpGenericFilterActionRef permit-nolog
}
}
```

9. Include all configured statements in the stack-specific IP security configuration file.

The IpFilterPolicy statement and the IpGenericFilterAction statements are placed in the file in no particular order, although the file is easier to read if logically related items are placed close together. For further ease of reading and maintenance, document the file with comments, which begin with the number sign (#).

The completed stack-specific IP security configuration file for the internal network with two filter rules follows:

```
# IP Security policy for Secure Server
#####
# IpFilterPolicy block #
#####
IpFilterPolicy
{
  FilterLogging          on
  #Allow admin FTP; log traffic
  IpFilterRule           AdminFTP
  {
    IpSourceAddr         9.1.1.1
    IpDestAddr           9.1.1.2
    IpService
    {
      SourcePortRange    21
```

```

        DestinationPortRange 1024 65535
        Protocol             tcp
        Direction             bidirectional InboundConnect
        Routing               local
        SecurityClass         1
    }
    IpService
    {
        SourcePortRange       20
        DestinationPortRange 1024 65535
        Protocol              tcp
        Routing               local
        SecurityClass         1
        Direction             bidirectional OutboundConnect
    }
    IpGenericFilterActionRef permit-log
}
#Allow LAN Web traffic; don't log
IpFilterRule InternalNetWeb
{
    IpSourceAddr      9.1.1.1
    IpDestAddrSet     9.1.1.0/24
    IpService
    {
        SourcePortRange       80
        DestinationPortRange 1024 65535
        Protocol              tcp
        Direction             bidirectional InboundConnect
        Routing               local
        SecurityClass         1
    }
    IpGenericFilterActionRef permit-nolog
}

#####
# Generic Filter Actions #
#####
IpGenericFilterAction permit-log
{
    IpFilterAction      permit
    IpFilterLogging      yes
}

IpGenericFilterAction permit-nolog
{
    IpFilterAction      permit
    IpFilterLogging      no
}

```

10. Define an IP filter group for each zone, and include the IP filter rules that belong to that zone.

In step “9” on page 1007, both `IpFilterRule` statements include a reference to statements defined outside of the `IpFilterRule` block, the `IpGenericFilterAction` statements. Some other information, such as IP addresses and services, is undoubtedly to be needed more than once. Changing these occurrences to reference objects eliminates repeated typing of the same information and adds clarity to the configuration file. To take advantage of references, the reusable statements must be given a name.

- Single IP addresses are defined by the `IpAddr` statement, which contains one parameter, `Addr`:

```

IpAddr      InternalNetServerAddress
{
    Addr      9.1.1.1
}

IpAddr      InternalNetAdminAddress
{
    Addr      9.1.1.2
}

```

- Ranges or subnetworks are defined by the `IpAddrSet` statement, which contains either a `Range` or `Prefix` attribute:

```

IpAddrSet   InternalNet
{
    Prefix    9.1.1.0/24
}

```

- To be referenced, each IpService statement needs a name:

```

IpService      WebServer
{
    SourcePortRange      80
    DestinationPortRange 1024 65535
    Protocol              tcp
    Direction             bidirectional InboundConnect
    Routing               local
    SecurityClass         1
}

IpService      FTPServer-Control
{
    SourcePortRange      21
    DestinationPortRange 1024 65535
    Protocol              tcp
    Direction             bidirectional InboundConnect
    Routing               local
    SecurityClass         1
}

IpService      FTPServer-Data
{
    SourcePortRange      20
    DestinationPortRange 1024 65535
    Protocol              tcp
    Direction             bidirectional OutboundConnect
    Routing               local
    SecurityClass         1
}

```

- FTP is composed of two individual services, and both can be condensed into an IpServiceGroup that references the two FTP services:

```

IpServiceGroup  FTPServer
{
    IpServiceRef  FTPServer-Control
    IpServiceRef  FTPServer-Data
}

```

- The IP filter rules can be grouped as well. Because the filter rules that apply to the internal network naturally relate to each other in the sense that they apply to the same security zone, they can be combined into an IpFilterGroup statement:

```

IpFilterGroup  InternalNetZoneA
{
    IpFilterRef  AdminFTP
    IpFilterRef  InternalNetWeb
}

```

Notice that just as the list of IpFilterRule statements in the IpFilterPolicy block is ordered, the list of IpFilterRef statements in the IpFilterGroup block is also ordered. The InternalNetWeb rule applies to all of the IP addresses in the network, including the administrative machine. However, the AdminFTP rule is more specific because it applies only to a specific address within that network. The more specific rule is placed first in the list.

Now that all reusable statements have been identified and separately defined, they can be incorporated into any statement that requires that reusable statement type. The modified stack-specific IP security configuration file using references follows. Note that by adding names and organizing related statements, the purpose of the IpFilterPolicy statement is clarified.

```

# IP Security policy for Secure Server
#####
# IpFilterPolicy block  #
#####
IpFilterPolicy
{
    FilterLogging      on
    IpFilterGroupRef   InternalNetZoneA
}

#####
# Security Zones      #
#####

```

```

IpFilterGroup      InternalNetZoneA
{
    IpFilterRuleRef    AdminFTP
    IpFilterRuleRef    InternalNetWeb
}

#####
# Filter rules          #
#####
#Allow admin FTP; log traffic
IpFilterRule      AdminFTP
{
    IpSourceAddrRef      InternalNetServerAddress
    IpDestAddrRef        InternalNetAdminAddress
    IpServiceGroupRef    FTPServer
    IpGenericFilterActionRef  permit-log
}

#Allow LAN Web traffic; don't log
IpFilterRule      InternalNetWeb
{
    IpSourceAddrRef      InternalNetServerAddress
    IpDestAddrSetRef      InternalNet
    IpServiceRef          WebServer
    IpGenericFilterActionRef  permit-nolog
}

##### All reusable reference statements defined below #####

#####
# Generic Filter Actions  #
#####
IpGenericFilterAction  permit-log
{
    IpFilterAction      permit
    IpFilterLogging      yes
}

IpGenericFilterAction  permit-nolog
{
    IpFilterAction      permit
    IpFilterLogging      no
}

#####
# Reusable Services      #
#####
IpService      WebServer
{
    SourcePortRange      80
    DestinationPortRange  1024 65535
    Protocol              tcp
    Direction              bidirectional InboundConnect
    Routing                local
    SecurityClass          1
}

IpService      FTPServer-Control
{
    SourcePortRange      21
    DestinationPortRange  1024 65535
    Protocol              tcp
    Direction              bidirectional InboundConnect
    Routing                local
    SecurityClass          1
}

IpService      FTPServer-Data
{
    SourcePortRange      20
    DestinationPortRange  1024 65535
    Protocol              tcp
    Direction              bidirectional OutboundConnect
    Routing                local
    SecurityClass          1
}

#####
# Reusable Service Groups  #
#####
IpServiceGroup      FTPServer

```

```

{
  IpServiceRef    FTPServer-Control
  IpServiceRef    FTPServer-Data
}

#####
# Reusable IP Addresses      #
#####
IpAddr           InternalNetServerAddress
{
  Addr           9.1.1.1
}

IpAddr           InternalNetAdminAddress
{
  Addr           9.1.1.2
}

IpAddrSet        InternalNet
{
  Prefix         9.1.1.0/24
}

```

This stack-specific IP security configuration file gives FTP access to the administrator and web access to everyone in the internal network. By relying heavily on the abstracted use of references, the policy is not only more self-explanatory, but changes to any referenced object are propagated to any statement that references it. So, if the IP address of the administrative machine or internal subnetwork changes, you merely have to make one change to an `IpAddr` or `IpAddrSet` statement, rather than modify a large number of instances in multiple rules.

Using a common IP security configuration file for reusable statements

The stack-specific IP security configuration file should be tailored to the specific stack to which it belongs. However, as the policy files for IP security are being constructed, a large number of statements can be reused. Reusable statements can be placed in a common file, which is available to all stacks. Statements in the common IP security configuration file are read by all stacks on the system, providing a convenient way to store common definitions that they can all share. If you are operating in a sysplex, you can also place a common IP security configuration file on shared DASD or in a shared z/OS File System directory so that stacks in a multiple sysplex image have access to the same common configuration file.

Assuming that all statements that might be used later are placed in a common IP security configuration file, the stack-specific IP security configuration file from step 10 now reads as follows:

```

# IP Security policy for Secure Server
#####
# IpFilterPolicy block      #
#####
IpFilterPolicy
{
  FilterLogging      on
  IpFilterGroupRef   InternalNetZoneA
}

#####
# Security Zones          #
#####
IpFilterGroup       InternalNetZoneA
{
  IpFilterRuleRef    AdminFTP
  IpFilterRuleRef    InternalNetWeb
}

#####
# Filter rules            #
#####
#Allow admin FTP; log traffic
IpFilterRule        AdminFTP
{
  IpSourceAddrRef    InternalNetServerAddress
  IpDestAddrRef      InternalNetAdminAddress
  IpServiceGroupRef  FTPServer
  IpGenericFilterActionRef  permit-log
}

```

```
#Allow LAN Web traffic; don't log
IpFilterRule      InternalNetWeb
{
    IpSourceAddrRef      InternalNetServerAddress
    IpDestAddrSetRef     InternalNet
    IpServiceRef         WebServer
    IpGenericFilterActionRef  permit-nolog
}
```

This stack-specific IP security configuration file references the following reusable statements:

- InternalNetServerAddress
- InternalNetAdminAddress
- InternalNet
- FTPServer
- FTPServer-Control
- FTPServer-Data
- permit-log
- permit-nolog
- WebServer

IpFilterRule statements can also be placed in the common IP security configuration file, because some IP filter rules apply to all addresses. If certain IpFilterRule statements are to apply globally to all stacks on the system, they can go into the common file. Use a value of `all` for the `IpSourceAddr` and `IpDestAddr` attributes. For instance, if all stacks on a z/OS system need rules permitting dynamic routing traffic (OSPF or RIP, for example), the statements that define this type of traffic can be placed in the common file and referenced in the stack-specific file:

```
IpFilterRule      AllowOmprouteLocalNolog
{
    IpSourceAddr      all
    IpDestAddr        all
    IpServiceGroupRef  Omproute-local
    IpGenericFilterActionRef  Permit-nolog
}

IpServiceGroup     Omproute-local
{
    IpServiceRef      OSPF-local
    IpServiceRef      RIP-local
}

IpService           OSPF-local
{
    Protocol          OSPF
    Direction         bidirectional
    Routing           local
}

IpService           RIP-local
{
    Protocol          UDP
    SourcePortRange   520
    DestinationPortRange 520
    Direction         bidirectional
    Routing           local
}
```

With these definitions in the common IP security configuration file, any stack needing global permission to send and receive routing information merely needs to include the following statement in the `IpFilterPolicy` block of its stack-specific IP security configuration file:

```
IpFilterRuleRef  AllowOmprouteLocalNolog
```

Steps for configuring the partner company model (host-to-host with IPSec)

The partner company model consists of two interconnected networks, with the server protecting traffic that originates from hosts outside the internal network.

Before you begin

The following statements and concepts are covered in the discussion of this model:

- Dynamic host-to-host IKE negotiations
- Key exchange rules
- Local and remote security endpoints
- Use of wildcards in Location and Identity
- IpLocalStartAction
- Granularity
- RSA signature peer authentication
- Certificates and certificate authorities
- On-demand activation
- Remote activation

Figure 131 on page 1013 shows the partner company portion of the security model network.

Figure 131. Partner company model

The partner company model is similar to that of the internal network, but an increased need for security means that a greater number of connections rely on data authentication and encryption. Although some services are allowed in the clear, sensitive data needs IPSec protection. To apply IPSec to a connection, the traffic that flows over that connection must match an IP filter rule that has an ipsec action.

For this example, assume you must meet the following requirements to allow network communications from a partner company in an untrusted zone B over a connected network (9.4.0.0/16) to a public IP address (9.2.2.2) on this host:

- Allow IKE traffic from untrusted zone B to this host.
- Allow secure FTP traffic (using TLS/SSL) from untrusted zone B to a secure FTP server running on this host.

Secure FTP has its own security mechanism. Although IPSec can be used together with TLS/SSL, using both adds processing expense. For this example, secure FTP is allowed without IPSec protection.

- Allow Enterprise Extender (EE) traffic from untrusted zone B to an EE service running on this host using a dynamic IPSec tunnel with strong encryption and authentication.

Because there is no encryption mechanism used in this example for EE, IPSec provides the secure service.

- Allow FTP traffic from untrusted zone B to an FTP server running on this host using a dynamic IPSec tunnel with strong AH authentication.

- The dynamic IPSec tunnel for EE comes up when outbound EE traffic is detected (on-demand activation).
- A dynamic IPSec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPSec tunnel for normal FTP data activates for each outbound data connection to a remote host (local activation).
- Peers authenticate themselves using the RSA signature method.

Procedure

Perform the following steps to meet these requirements and configure the partner company model.

1. For each zone, determine what services are allowed:
 - IKE traffic
 - Normal FTP traffic
 - Secure FTP traffic
 - Enterprise Extender traffic
2. Define an IpService statement for each wanted service.
 - IKE uses UDP, port 500 for message exchanges:

```
IpService                               IKE-local
{
  SourcePortRange                       500
  DestinationPortRange                  500
  Protocol                              UDP
  Direction                             bidirectional
  Routing                               local
  SecurityClass                          0
}
```

- For normal FTP traffic, allow inbound connections but do not allow outbound connection requests, other than data. Two services are required, one for the control connection and one for the data connection:

```
IpService                               FTPServer-Control
{
  SourcePortRange                       21
  DestinationPortRange                  1024 65535
  Protocol                              tcp
  Direction                             bidirectional InboundConnect
  Routing                               local
  SecurityClass                          0
}

IpService                               FTPServer-Data
{
  SourcePortRange                       20
  DestinationPortRange                  1024 65535
  Protocol                              tcp
  Direction                             bidirectional OutboundConnect
  Routing                               local
  SecurityClass                          0
}
```

- For secure FTP traffic, allow inbound connections but do not allow outbound connection requests, other than data. Two services are required, one for the control connection and one for the data connection.

```
IpService                               SecureFTPServer-Control
{
  SourcePortRange                       990
  DestinationPortRange                  1024 65535
}
```

```

    Protocol      tcp
    Direction     bidirectional InboundConnect
    Routing       local
    SecurityClass 0
}

IpService        SecureFTPServer-Data
{
    SourcePortRange 989
    DestinationPortRange 1024 65535
    Protocol      tcp
    Direction     bidirectional OutboundConnect
    Routing       local
    SecurityClass 0
}

```

- For Enterprise Extender traffic, allow both inbound and outbound traffic:

```

IpService        Enterprise-Extender
{
    SourcePortRange 12000 12004
    DestinationPortRange 12000 12004
    Protocol      UDP
    Direction     bidirectional
    Routing       local
    SecurityClass 0
}

```

IP services can be grouped together for convenience, flexibility, and reuse of configuration. Any IP filter rule that includes an IP service group will be expanded to include all of the services from that group. The following IP service groups include the IP services that define the FTPServer and the SecureFTPServer:

```

IpServiceGroup FTPServer
{
    IpServiceRef FTPServer-Control
    IpServiceRef FTPServer-Data
}
IpServiceGroup SecureFTPServer
{
    IpServiceRef Secure-FTPServer-Control
    IpServiceRef Secure-FTPServer-Data
}

```

3. Determine the data endpoints to be protected.

In this example, the local data endpoint is the public address of the server, and the remote data endpoint is the entire subnet in zone B:

```

Local public IP address: 9.2.2.2
Remote subnet: 9.4.0.0/16

```

4. Determine what level of security is needed between each set of data endpoints:

```

IKE traffic - permit
Secure FTP traffic - permit
EE traffic - IPSec encryption and authentication
FTP traffic - IPSec authentication

```

5. Configure an IpGenericFilterAction statement for the level of security that is required.

The requirements stated that IKE and secure FTP should be allowed, and that EE and normal FTP traffic required IPSec protection. Notice that the parameters of the IpGenericFilterAction statement include ipsec as well as permit and deny. Because no logging requirements were specified, two actions are needed, permit and ipsec:

```

IpGenericFilterAction  permit-nolog
{
    IpFilterAction      permit
}

```

```

    IpFilterLogging      no
  }

  IpGenericFilterAction  ipsec-nolog
  {
    IpFilterAction       ipsec
    IpFilterLogging      no
  }
}

```

6. If IPsec is required between any two endpoints, take the following actions:

a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

- i) Determine the required type and strength of protection for the phase 1 Security Association. Phase 1 Security Associations must use both authentication and encryption. Because strong encryption was specified for phase 2, use strong encryption for phase 1:

```

Authentication, SHA1 algorithm
Encryption, 3DES algorithm
DHGroup, Diffie-Hellman Group2

```

Tip: The greater the Diffie-Hellman group specified, the greater the protection provided.

ii) Decide what type of peer authentication is used:

```

RSA signature

```

Because the remote data endpoint represents multiple hosts in this example, RSA signature is used. RSA signature authentication provides greater flexibility, scalability, and security than pre-shared key authentication. Because there are potentially multiple remote peers in the partner company's subnet, RSA signature is a reasonable choice.

The use of RSA signature requires setup of RACF certificates and certificate authority information. Both IKE peers need access to a key ring with at least one X.509 digital certificate to identify itself. To set up the IKE daemon for certificates, see [Appendix E, "Steps for preparing to run IP security,"](#) on page 1391. The site should decide what certificate authorities are recognized. A certificate authority can be an outside commercial entity, or it can be defined locally in RACF. For information about installing certificate authorities in RACF, see [z/OS Security Server RACF Security Administrator's Guide](#).

In this example, the IKEv1 protocol is used and the IKE daemon is using the native certificate service. A certificate authority with label CA4PartnerCompany is used, which is presumed to have been defined as a certificate authority in the RACF database. The label CA4PartnerCompany should be added to the iked.conf file as a recognized certificate authority as follows:

```

SupportedCertAuth CA4PartnerCompany

```

Guideline: For more efficient processing of certificates when the IKED is using the native certificate service, you should code SupportedCertAuth for each acceptable certificate authority that will be used to sign certificates for remote IKE peers.

iii) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation, including type of peer authentication, strength of encryption, and how often the phase 1 keys are refreshed. Because KeyExchangeOffer statements are reusable, give it a descriptive name as follows:

```

KeyExchangeOffer RSA-SHA1-3DES-DH2
{
  HowToEncrypt      3DES
  HowToAuthMsgs     SHA1
  HowToAuthPeers    RsaSignature
  DHGroup           Group2
  RefreshLifetimeProposed 480
  RefreshLifetimeAccepted 240 1440
  RefreshLifesizeProposed none
}

```

```
RefreshLifesizeAccepted none
}
```

- iv) Decide whether NAT traversal will be allowed.

In this example, the following parameter is used:

```
AllowNat No
```

- v) Determine the negotiation mode. Main mode is used for phase 1, providing added security by encrypting the identities of the two IKE peers during the phase 1 negotiation.
- vi) Configure a KeyExchangeAction statement that defines the control information for the phase 1 negotiation. The key exchange action determines the mode of the phase 1 negotiation and the parameters that are included in the KeyExchangeOffer statement. Although multiple KeyExchangeOffer statements are acceptable, only one is required. Both peers must agree on the parameters. Use the KeyExchangeOffer statement that was configured in step “7.a.iii” on [page 1016](#):

```
KeyExchangeAction Main-RSA-SHA1-3DES-DH2
{
    HowToInitiate      main
    HowToRespondIKEv1  main
    KeyExchangeOfferRef RSA-SHA1-3DES-DH2
}
```

- vii) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement. In this example, the local security endpoint is the local host. An identity and IP address of the local IKE peer is required as follows:

```
LocalSecurityEndpoint Public_IKED
{
    Identity      IpAddr 9.2.2.2
    Location      9.2.2.2
}
```

Similarly, the same information is needed for remote hosts. Notice that in the RemoteSecurityEndpoint statement, an IP address range is specified for both identity and location. Although it is possible to configure a RemoteSecurityEndpoint statement for every host in the remote subnetwork, unless they have unique key exchange requirements, it is not necessary. Wildcards can be used for the Identity and Location parameters. Any of the identity types can potentially contain wildcards to include a group of remote hosts with similar identities.

```
RemoteSecurityEndpoint ZoneB_IKED
{
    Identity      IpAddr 9.4.0.0/16
    Location      9.4.0.0/16
    CaLabel       CA4PartnerCompany
}
```

The use of an IPv4 address on the Identity parameter for the Local_IKED security endpoint requires that the X.509 digital certificate for the local IKE daemon include the IPv4 address in the Subject Alternative Name field of the certificate. The use of an IPv4 subnet on the Identity parameter for the ZoneB_IKED security endpoint requires that an IPv4 address within that subnet (9.4.0.0/16) appear in the Subject Alternative Name field of the X.509 digital certificate for the remote IKE daemon.

The inclusion of the CaLabel parameter in the ZoneB_IKED security endpoint emphasizes the fact that the local host requests that the remote host use only certificates that are signed by the certificate authority that is identified by the label CA4PartnerCompany.

Rule: For RSA signature mode authentication, the identity of a security endpoint must be contained in its X.509 digital certificate, either in the Subject Name field or the Subject Alternative Name field.

For detailed specifications on the use of wildcards in the `RemoteSecurityEndpoint` statement, see [z/OS Communications Server: IP Configuration Reference](#).

- viii) Configure a `KeyExchangeRule` statement that includes the two endpoints and the key exchange action:

```
KeyExchangeRule      ZoneB_KeyExRule1
{
  LocalSecurityEndpointRef  Public_IKED
  RemoteSecurityEndpointRef ZoneB_IKED
  KeyExchangeActionRef     Main-RSA-SHA1-3DES-DH2
}
```

- ix) Include the key exchange rule in the `KeyExchangePolicy` statement:

```
KeyExchangePolicy
{
  KeyExchangeRuleRef  ZoneB_KeyExRule1
}
```

- b) Configure an `IpDynVpnAction` statement that defines the parameters of the phase 2 negotiation as follows:

- i) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, there is a unique requirement for each traffic type. Therefore, there are two types of IPSec protection for each type of traffic as follows:

```
EE traffic - strong encryption: ESP, 3DES
             strong ESP authentication: Hmac SHA1
Normal FTP traffic - strong AH authentication, Hmac SHA1
```

This information eventually translates into two `IpDataOffer` statements.

- ii) Determine whether tunnel or transport mode is required.

Tunnel mode is required only if either endpoint of the Security Association is a secure gateway. The choice is optional in a host-to-host configuration, but transport mode is typically used.

- iii) Configure `IpDataOffer` statements that define the parameters of the phase 2 negotiation.

- Authenticated offer for FTP:

```
IpDataOffer TRAN-AHSHA-NOENCR
{
  HowToEncap Transport
  HowToEncrypt DoNot
  HowToAuth    AH HMAC_SHA1
  RefreshLifetimeProposed 240
  RefreshLifetimeAccepted 120 480
  RefreshLifesizeProposed none
  RefreshLifesizeAccepted none
}
```

- Encrypted and authenticated offer for EE:

```
IpDataOffer TRAN-ESPSHA-3DES
{
  HowToEncap Transport
  HowToEncrypt 3DES
  HowToAuth    ESP HMAC_SHA1
  RefreshLifetimeProposed 240
  RefreshLifetimeAccepted 120 480
  RefreshLifesizeProposed none
}
```

```
RefreshLifesizeAccepted none
}
```

- iv) Determine which peer is allowed to initiate the negotiation.

Because the EE VPN activates when outbound EE traffic is detected, you need to be able to start the negotiation locally. The remote host initiates the negotiation of the Security Association for the FTP control connection, so local initiation is not required. The FTP data connection is initiated from the local host, so to activate the Security Association, local initiation is required.

- v) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation.

The IpDynVpnAction statement can control which host is allowed to initiate the negotiation. You must allow the IPsec VPN for the FTP control connection to be initiated by the remote peer, and the data connection by the local host. EE should be allowed to initiate an IKE negotiation locally.

- Authenticated VPN action for FTP:

```
IpDynVpnAction FTP-vpnaction
{
    Initiation            either
    InitiateWithPfs       group2
    AcceptablePfs         group2
    VpnLife               1440
    IpDataOfferRef        TRAN-AHSHA-NOENCR
}
```

- Encrypted and authenticated VPN action for EE traffic:

```
IpDynVpnAction EE-vpnaction
{
    Initiation            localonly
    InitiateWithPfs       group2
    AcceptablePfs         group2
    VpnLife               1440
    IpDataOfferRef        TRAN-ESPSHA-3DES
}
```

- c) Decide how the Security Association is to be activated as follows:

- i) Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.

Neither the EE nor FTP VPNs require a LocalDynVpnPolicy statement, because neither is command-line activated or autoactivated.

- ii) Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

Before a phase 2 negotiation can initiate, the IKE daemon needs to know the IP addresses, ports, and protocols that the Security Association covers. In most cases, these can be inferred from the filter rule, or from the packet that started the on-demand activation. An IpLocalStartAction statement explicitly defines where these parameters are obtained. The granularity setting determines whether the information comes from the matching filter rule, or from the packet. By explicitly specifying packet, you can guarantee that a new Security Association is created for each connection request.

```
IpLocalStartAction          ZoneB-Start-Action
{
    AllowOnDemand            yes
    LocalPortGranularity     packet
    RemotePortGranularity    packet
}
```

```

ProtocolGranularity      packet
LocalIpGranularity       packet
RemoteIpGranularity      packet
LocalSecurityEndpointRef Public_IKED
RemoteSecurityEndpointRef ZoneB_IKED
}

```

In this example, specifying packet is not required. IKE detects that the filter rule has a range of ports specified and resorts to packet granularity instead of the default of rule. Specifying packet is required, however, if the EE and FTP rules had all ports specified. In that case, one Security Association is negotiated for all ports, not a single port. To avoid confusion, it is better to specify your intention.

- iii) Set the global PreDecap parameter of the IpFilterPolicy statement to off, or create an IpFilterRule statement that allows IPSec traffic (AH and ESP).

When the system begins to process encapsulated traffic, the encapsulated packets are subject to filtering. The encrypted and authenticated packets are denied unless they are explicitly allowed. There are two options to configure this that are subtly different. The first is less restrictive, allowing AH and ESP packets from anywhere and not subjecting them to filtering until after the packets have had their IPSec headers removed. The second method is to add an IpFilterRule statement that explicitly permits the IPSec-encapsulated traffic. This option adds an additional layer of security, in that you can control exactly who is allowed to send encrypted traffic. This protects system resources by preventing the processing of IPSec packets unnecessarily, such as might happen in the case of a malicious attack of IPSec packets. Although more secure, this solution is less efficient because it requires additional processing resources to filter all IPSec-encapsulated traffic.

For the first option, in the main IpFilterPolicy block, code PreDecap off as follows:

```

IpFilterPolicy
{
    PreDecap off
    :
}

```

For the second option, configure a filter rule in the IpFilterPolicy block that explicitly allows AH and ESP traffic as follows:

```

IpFilterRule      Allow-IPSec-traffic
{
    IpSourceAddr    9.2.2.2
    IpDestAddrSet   9.4.0.0/16
    IpService
    {
        Protocol      AH
        Direction     bidirectional
        Routing        local
        SecurityClass  0
    }
    IpService      ESP-traffic
    {
        Protocol      ESP
        Direction     bidirectional
        Routing        local
        SecurityClass  0
    }
    IpGenericFilterRef  permit-nolog
}

```

Tip: In most cases, unless the extra security is deemed a necessity, use the PreDecap off global option to allow IPSec packets to flow with minimum overhead.

7. Define an IpFilterRule statement for each set of data endpoints.

The secure host and subnetwork B represent the data endpoints. The IpService statements were defined in step “2” on page 1014. Place the IpDynVpnAction statements that were created in step “6” on page 1016 with the appropriate rule.

```

IpFilterRule      ZoneB-Permitted-traffic
{
    IpSourceAddrRef      PublicServerAddress
    IpDestAddrSetRef     ZoneB-subnet
    IpServiceRef         IKE-local
    IpServiceGroupRef    SecureFTPServer
    IpGenericFilterActionRef  permit-nolog
}

IpFilterRule      FTPServer-ZoneB
{
    IpSourceAddr      9.2.2.2
    IpDestAddrSet     9.4.0.0/16
    IpServiceGroupRef FTPServer
    IpGenericFilterActionRef ipsec-nolog
    IpDynVpnAction    FTP-vpnaction
    IpLocalStartActionRef ZoneB-Start-Action
}

IpFilterRule      EE-ZoneB
{
    IpSourceAddr      9.2.2.2
    IpDestAddrSet     9.4.0.0/16
    IpService
    {
        SourcePortRange      12000 12004
        DestinationPortRange 12000 12004
        Protocol              udp
        Direction             bidirectional
        Routing               local
        SecurityClass         0
    }
    IpGenericFilterActionRef ipsec-nolog
    IpDynVpnAction          EE-vpnaction
    IpLocalStartActionRef   ZoneB-Start-Action
}

```

Because both IKE and Secure FTP need to be permitted without IPSec protection, an IpFilterRule statement for both is not needed. The two services can be combined into one rule.

Tip: Any services that share the same data endpoints and the same security requirements can be placed together in one IpFilterRule statement.

8. Include the IpFilterRule statements in the IpFilterPolicy block.

The IpFilterRule statement allowing IKE traffic should always be at the top of the list. The rest of the IpFilterRule statements are disjointed, and their relative placement within the IpFilterPolicy is irrelevant.

Tip: If it is known that one particular type of traffic is the most frequent, placing that rule near the top of the list results in faster filter lookups.

9. Define an IP filter group for each zone and include the IpFilterRule statements that belong to that zone.

Although the creation of reference objects and groups is not mandatory, they provide for ease of maintenance as the IP security policy grows more complex.

A completely configured policy, including all objects and their references, is as follows:

```

# IpFilterPolicy for secure public server

IpFilterPolicy
{
    PreDecap      off
    IpFilterGroupRef ZoneB
}

```

```

KeyExchangePolicy
{
    KeyExchangeRuleRef    ZoneB_KeyExRule1
}

##### All reusable statements follow #####

10. Include all configured statements in the stack-specific IP security configuration file.

Steps for configuring the partner company with NAT model (host-to-host with IPSec)

In the partner company with NAT model, the partner company model topology is modified to include private addressing in the private network of each partner company, with a NAT device in front of each private network.

Before you begin

The following statements and concepts are covered in the discussion of this model:

- AllowNat and NatKeepAliveInterval parameters on the KeyExchangePolicy and KeyExchangeAction statements
- IKE traffic on UDP port 4500, in addition to port 500
- NAT implications for host-to-host dynamic IKE negotiations:
 - Local and remote data endpoints
 - Local and remote security endpoints
 - IKE initiator and responder roles
 - Restriction on HowToAuth protocol (AH not supported)
- Using wildcards for location and identity
- RSA signature peer authentication
- Certificates and certificate authorities
- CaLabel
- SupportedCertAuth

“Steps for configuring the partner company model (host-to-host with IPSec)” on page 1013 assumed a network topology with both partner companies using public IP addresses in their internal networks. Often one or both businesses have an internal network that uses IETF-defined private IP addresses (10.0.0.0/8, 172.16.0.0/12, and 192.168.0.0/16). Private IP addresses cannot be routed outside an internal network. Network address translation (NAT) is used to create a mapping of private addresses to public addresses and perform the necessary translation as packets traverse the NAT device.

When IPSec Security Associations traverse a NAT, there are problems because the NAT is unable to update IP addresses and checksums that are part of the encapsulated data (encrypted, authenticated, or both). The IETF has defined a solution known as NAT traversal (NATT) that allows IPSec Security Associations to successfully traverse a NAT device.

Figure 132 on page 1027 shows the partner company with NAT topology when the partner company model topology has been modified to include private addressing in each partner company's private network with a NAT device in front of each private network.

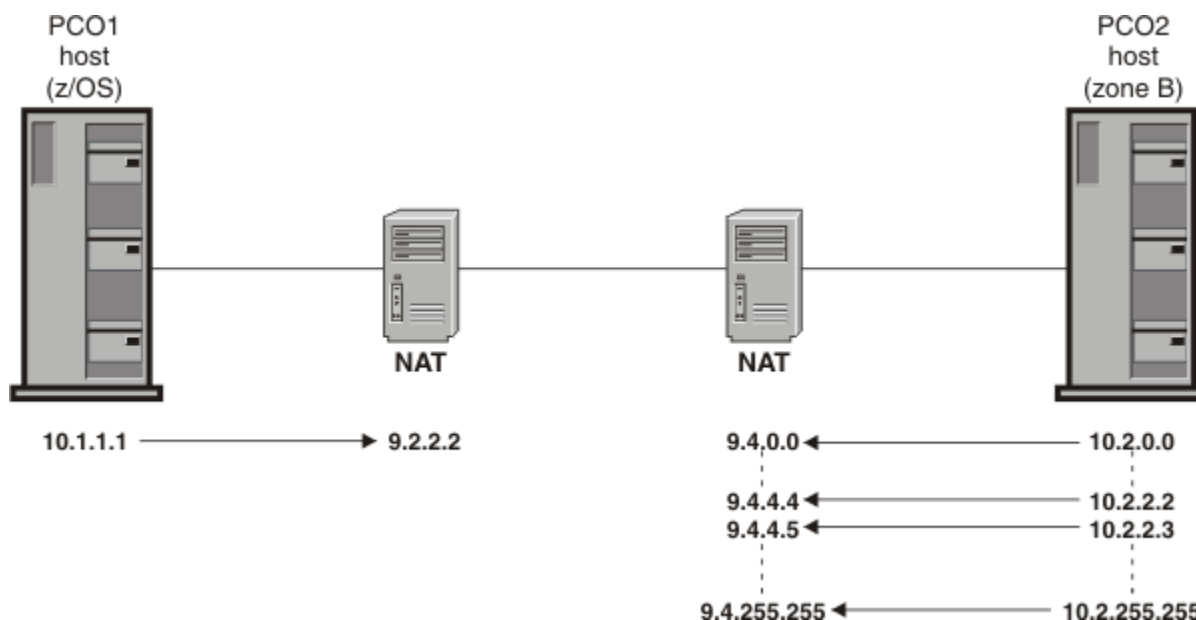

Figure 132. Partner company with NAT model

The steps in this topic will describe the configuration considerations and requirements when the NATT solution is implemented to traverse NAT devices in a host-to-host environment. The partner company with NAT model has the same basic security requirements as the partner company model. Configuration statements added or changed for the partner company with NAT model are shown in **bold**. The example describes the policy for partner company 1 (PCO1).

For this example, assume you must meet the following requirements to allow network communications from a partner company (PCO2) in an untrusted zone B behind a NAT over a connected network (9.4.0.0/16) to a server on this host that is behind a NAT:

- IKE traffic from untrusted zone B that is behind a NAT is allowed to this host that is behind a NAT.
- Secure FTP traffic (using TLS/SSL) from untrusted zone B is allowed to a secure FTP server running on this host.
- Enterprise Extender (EE) traffic from untrusted zone B is allowed to an EE service running on this host using a dynamic IPsec tunnel with strong encryption and authentication.
- FTP traffic from untrusted zone B is allowed to an FTP server running on this host using a dynamic IPsec tunnel with strong authentication.
- The dynamic IPsec tunnel for EE is activated when outbound EE traffic is detected (on-demand activation).
- A dynamic IPsec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPsec tunnel for normal FTP data activates for each remote host that initiates an FTP data connection (remote activation).
- Peers authenticate themselves using the RSA signature method.

Procedure

Perform the following steps to meet these requirements and configure the partner company with NAT model.

1. For each zone, determine what services are allowed:

- IKE traffic
- Normal FTP traffic
- Secure FTP traffic

- Enterprise Extender traffic
2. Define an IpService statement for each wanted service.

- IKE traffic

When NAT traversal is allowed, IKE uses UDP port 500 and port 4500 for message exchanges. NAT traversal is controlled by the AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements.

```

IpService                               IKE-local-500
{
  SourcePortRange                       500
  DestinationPortRange                 500
  Protocol                             UDP
  Direction                           bidirectional
  Routing                             local
  SecurityClass                        0
}

IpService                               IKE-local-4500
{
  SourcePortRange                       4500
  DestinationPortRange                 4500
  Protocol                             UDP
  Direction                           bidirectional
  Routing                             local
  SecurityClass                        0
}

```

- Normal FTP traffic

When a NAT is being traversed, FTP clients typically need to use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server, allowing inbound connections but not outbound connection requests. For more information on active and passive mode FTP, see [“Considerations for IPsec-encapsulated FTP traffic when traversing a NAT” on page 1067](#).

Two services are required, one for the control connection and one for the data connection. The range of server ports specified for the data connection reflects the port range specified for PASSIVEDATAPORTS in the server's FTP.DATA file. For more information on PASSIVEDATAPORTS (FTP server) statement, see [z/OS Communications Server: IP Configuration Reference](#).

The following definitions show the services required for the FTP server for EPSV mode:

```

IpService                               FTPServer-Control
{
  SourcePortRange                       21
  DestinationPortRange                 1024 65535
  Protocol                             tcp
  Direction                           bidirectional InboundConnect
  Routing                             local
  SecurityClass                        0
}

IpService                               FTPServer-Data-Passive
{
  SourcePortRange                       50000 50200
  DestinationPortRange                 1024 65535
  Protocol                             tcp
  Direction                           bidirectional InboundConnect
  Routing                             local
  SecurityClass                        0
}

```

- Secure FTP traffic

Again, when a NAT is being traversed, FTP clients typically need to use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server, allowing inbound connections but not

outbound connection requests. Two services are required, one for the control connection and one for the data connection.

```

IpService      SecureFTPServer-Control
{
  SourcePortRange      990
  DestinationPortRange 1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         0
}

IpService      SecureFTPServer-Data-Passive
{
  SourcePortRange      50201 50400
  DestinationPortRange 1024 65535
  Protocol              tcp
  Direction             bidirectional InboundConnect
  Routing               local
  SecurityClass         0
}

```

- Enterprise Extender traffic

Allow both inbound and outbound connections.

```

IpService      Enterprise-Extender
{
  SourcePortRange      12000 12004
  DestinationPortRange 12000 12004
  Protocol              UDP
  Direction             bidirectional
  Routing               local
  SecurityClass         0
}

```

3. Determine the data endpoints that are to be protected.

In this case, the local data endpoint is the private address of the server, local IP address 10.1.1.1.

The remote data endpoint is the partner company's internal network. The z/OS implementation does not require you to code private addresses for the remote endpoint; the network address translated public addresses should be configured as the remote data endpoint. In this example, the private addresses in the PCO2 internal network (10.2.0.0/16) are translated into the public address range 9.4.0.0/16. Thus, the remote subnetwork is 9.4.0.0/16.

4. Determine what level of security is needed between each set of data endpoints.

```

IKE traffic - permit
Secure FTP traffic - permit
EE traffic - IPSec encryption and authentication
FTP traffic - IPSec authentication

```

5. Configure an IpGenericFilterAction statement for the level of security that is required.

The requirements stated that IKE and secure FTP should be allowed, and that EE and normal FTP traffic required IPSec protection. Because no logging requirements were specified, two actions are needed, permit and ipsec.

```

IpGenericFilterAction  permit-nolog
{
  IpFilterAction        permit
  IpFilterLogging        no
}

IpGenericFilterAction  ipsec-nolog
{
  IpFilterAction        ipsec
}

```

```

    IpFilterLogging      no
}

```

6. If IPSec is required between any two endpoints, take the following actions:

a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

- i) Determine the required type and strength of protection for the phase 1 Security Association. Phase 1 Security Associations must use both authentication and encryption. Because strong encryption was specified for phase 2, use strong encryption for phase 1:

```

Authentication, SHA1 algorithm
Encryption, 3DES algorithm
DHGroup, Diffie-Hellman Group2

```

Tip: The greater the Diffie-Hellman group specified, the greater the protection provided.

ii) Decide what type of peer authentication is used:

```

RSA signature

```

Because the remote data endpoint represents multiple hosts in this example, RSA signature is used. RSA signature authentication provides greater flexibility, scalability, and security than pre-shared key authentication. Because there are potentially multiple remote peers in the partner company's subnet, RSA signature is a reasonable choice.

The use of RSA signature requires setup of RACF certificates and certificate authority information. Both IKE peers need access to a key ring with at least one X.509 digital certificate to identify itself. To set up the IKE daemon for certificates, see Appendix E, “Steps for preparing to run IP security,” on page 1391. The site should decide what certificate authorities are recognized. A certificate authority can be an outside commercial entity, or it can be defined locally in RACF. For information about installing certificate authorities in RACF, see [z/OS Security Server RACF Security Administrator's Guide](#).

In this example, the IKEv1 protocol is used and the IKE daemon is using the native certificate service. A certificate authority with label CA4PartnerCompany is used, which is presumed to have been defined as a certificate authority in the RACF database. The label CA4PartnerCompany should be added to the iked.conf file as a recognized certificate authority as follows:

```

SupportedCertAuth CA4PartnerCompany

```

Guideline: For more efficient processing of certificates when the IKED is using the native certificate service, you should code SupportedCertAuth for each acceptable certificate authority that will be used to sign certificates for remote IKE peers.

iii) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation, including type of peer authentication, strength of encryption, and how often the phase 1 keys are refreshed. Because KeyExchangeOffer statements are reusable, give it a descriptive name as follows:

```

KeyExchangeOffer RSA-SHA1-3DES-DH2
{
    HowToEncrypt      3DES
    HowToAuthMsgs     SHA1
    HowToAuthPeers    RSASignature
    DHGroup           Group2
    RefreshLifetimeProposed 480
    RefreshLifetimeAccepted 240 1440
    RefreshLifesizeProposed none
    RefreshLifesizeAccepted none
}

```

iv) Decide whether NAT traversal will be allowed.

The AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements allows IKE to advertise NAT traversal support. When a phase 1 Security Association is being negotiated, if both IKE peers support NAT traversal, several IKE payloads are exchanged that allow the peers to determine if one or more NAT devices are being traversed. If a NAT is being traversed, the IKE peers negotiate a UDP-encapsulated transport mode or UDP-encapsulated tunnel mode phase 2 Security Association to allow IPSec traffic to traverse the NATs successfully. If a NAT is not being traversed, a standard transport or tunnel mode phase 2 Security Association is negotiated.

The AllowNat parameter can be specified on the overall KeyExchangePolicy statement or for a specific KeyExchangeAction statement. If AllowNat is No, IKE does not advertise its support for NAT traversal. You might want to disable NAT traversal for interoperability purposes (certain remote resources might not be able to tolerate NAT traversal protocols) or security concerns (for example, NAT traversal exposes private internal addresses to the IKE peer). If NAT traversal is disabled and there is a NAT device in the path, ipsec processing might fail to negotiate the Security Association or fail to send data over the Security Association.

For this model, allow NAT traversal support to be advertised for all phase 1 Security Associations by coding the following parameter on the KeyExchangePolicy statement:

```
AllowNat Yes
```

A NatKeepAliveInterval parameter is also provided on the KeyExchangePolicy statement. A NAT keep-alive timer is maintained to ensure that NAT mappings do not expire. If z/OS is behind a NAT, a NAT keep-alive timer is started with the interval specified on the NatKeepAliveInterval parameter. If z/OS is behind a NAT that is using static mappings that will not expire, the NatKeepAliveInterval parameter should be set to 0. It is not necessary to run a NAT keep-alive timer in this case.

For this model, because static mapping is being used for the NAT in front of PC01, the NatKeepAliveInterval parameter is set to 0:

```
NatKeepAliveInterval 0
```

- v) Determine the negotiation mode. Main mode is used for phase 1 in this example, providing added security by encrypting the identities of the two IKE peers during the phase 1 negotiation.
- vi) Configure a KeyExchangeAction statement that defines the control information for the phase 1 negotiation. The key exchange action determines the mode of the phase 1 negotiation and the parameters that are included in the KeyExchangeOffer statement. Although multiple KeyExchangeOffer statements are acceptable, only one is required. Both peers must agree on the parameters. Use the KeyExchangeOffer statement that was configured previously:

```
KeyExchangeAction Main-RSA-SHA1-3DES-DH2
{
    HowToInitiate      main
    HowToRespondIKEv1  main
    KeyExchangeOfferRef RSA-SHA1-3DES-DH2
}
```

- vii) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement. In this example, the local security endpoint is the local host. An identity and IP address of the local IKE peer is required as follows:

```
LocalSecurityEndpoint Local_IKED
{
    Identity      Fqdn Server.PC01.example.com
    Location      10.1.1.1
}
```

The value specified for Identity on the LocalSecurityEndpoint statement is sent to the remote peer to identify this endpoint. The remote peer uses this value to determine if a Security

Association can be negotiated and which policy should be used. Identity can be specified in different formats, such as an IP address or fully qualified domain name.

The partner company model specified an IP address for Identity, and an IP address could be used in this model. However, PCO1's private IP address 10.1.1.1 is not meaningful in the PCO2 configuration, so one of the other Identity types was chosen. The fully qualified domain name (Fqdn) identifies the local security endpoint.

An identity and IP address are also needed for the remote hosts. Notice that in the following RemoteSecurityEndpoint statement, the Identity and Location attributes use a wildcard to include a group of remote hosts with similar identities. It is possible to use a wildcard for the values because the key exchange requirements are the same for the hosts included in the specified range.

The Identity attribute is specified as Fqdn (fully qualified domain name), and the Location attribute is the range of public IP addresses used by the PCO2 internal network. PCO2 internal private addresses are not coded because they have no meaning for PCO1.

```
RemoteSecurityEndpoint    ZoneB_IKED
{
  Identity               Fqdn    *.PCO2.example.com
  Location                9.4.0.0/16
  CaLabel                 CA4PartnerCompany
}
```

The use of a fully qualified domain name on the Identity parameter for the Local_IKED security endpoint requires that the X.509 digital certificate for the local IKE daemon include the fully-qualified domain name in the Subject Alternative Name field of the certificate. The use of a wild-carded domain name on the Identity parameter for the ZoneB_IKED security endpoint requires that a fully-qualified domain name ending with .PCO2.example.com appear in the Subject Alternative Name field of the X.509 digital certificate for the remote IKE daemon.

The inclusion of the CaLabel parameter in the ZoneB_IKED security endpoint emphasizes the fact that the local host requests that the remote host use only certificates that are signed by the certificate authority that is identified by the label CA4PartnerCompany.

Rule: For RSA signature mode authentication, the identity of a security endpoint must be contained in its X.509 digital certificate, either in the Subject Name field or the Subject Alternative Name field.

For detailed specifications on the use of wildcards in the [RemoteSecurityEndpoint statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

- viii) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action:

```
KeyExchangeRule           ZoneB_KeyExRule1
{
  LocalSecurityEndpointRef Local_IKED
  RemoteSecurityEndpointRef ZoneB_IKED
  KeyExchangeActionRef     Main-RSA-SHA1-3DES-DH2
}
```

- ix) Include the key exchange rule in the KeyExchangePolicy statement block. Also include the AllowNat parameter:

```
KeyExchangePolicy
{
  AllowNat               Yes
  KeyExchangeRuleRef      ZoneB_KeyExRule1
}
```

- b) Configure an IpDynVpnAction statement that defines the parameters of the phase 2 negotiation as follows:

- i) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, there is a unique requirement for each traffic type. Therefore, there are two types of IPSec protection for each type of traffic as follows:

```
EE traffic - strong encryption: ESP, 3DES
             strong ESP authentication: Hmac SHA1
Normal FTP traffic - strong ESP authentication, Hmac SHA1
```

The partner company model used AH authentication for normal FTP traffic, but the NATT solution defined by the IETF is based on the ESP protocol. The AH protocol is not supported for NATT, and ESP authentication is used in this model.

This information eventually translates into two `IpDataOffer` statements.

- ii) Determine whether tunnel or transport mode is required.

Tunnel mode is required only if either endpoint of the Security Association is a secure gateway. The choice is optional in a host-to-host configuration, but transport mode is typically used.

- iii) Configure `IpDataOffer` statements that define the parameters of the phase 2 negotiation.

- Authenticated offer for FTP:

```
IpDataOffer TRAN-ESPSHA-NOENCR
{
    HowToEncap Transport
    HowToEncrypt DoNot
    HowToAuth      ESP HMAC_SHA1
    RefreshLifetimeProposed 240
    RefreshLifetimeAccepted 120 480
    RefreshLifesizeProposed none
    RefreshLifesizeAccepted none
}
```

- Encrypted and authenticated offer for EE:

```
IpDataOffer TRAN-ESPSHA-3DES
{
    HowToEncap Transport
    HowToEncrypt 3DES
    HowToAuth      ESP HMAC_SHA1
    RefreshLifetimeProposed 240
    RefreshLifetimeAccepted 120 480
    RefreshLifesizeProposed none
    RefreshLifesizeAccepted none
}
```

- iv) Determine which peer is allowed to initiate the negotiation.

When an IKE peer is behind a NAT device, there are implications regarding which peer can initiate. In a host-to-host configuration, IKE should initiate only to a peer whose IP address is unambiguous. If the peer is not behind a NAT, or if the peer's NAT mapping is static, the address is unambiguous. In this model, assume that static mapping is being used for both PCO1 and PCO2.

Because the EE VPN activates when outbound EE traffic is detected, you need to be able to start the negotiation locally. For PASV mode or EPSV mode FTP, both the FTP control connection and the FTP data connection initiate the negotiation of the Security Association remotely, so local initiation is not required.

- v) Configure an `IpDynVpnAction` statement that defines the control information for the phase 2 negotiation.

The `IpDynVpnAction` statement can control which host is allowed to initiate the negotiation. Both the FTP control connection and data connection will be initiated remotely. EE should be allowed to initiate an IKE negotiation locally.

- Authenticated VPN action for FTP:

```
IpDynVpnAction FTP-vpnaction
{
    Initiation                remoteonly
    InitiateWithPfs            group2
    AcceptablePfs              group2
    VpnLife                    1440
    IpDataOfferRef           TRAN-ESPSHA-NOENCR
}
```

- Encrypted and authenticated VPN action for EE traffic:

```
IpDynVpnAction EE-vpnaction
{
    Initiation                localonly
    InitiateWithPfs            group2
    AcceptablePfs              group2
    VpnLife                    1440
    IpDataOfferRef           TRAN-ESPSHA-3DES
}
```

c) Decide how the Security Association is to be activated as follows:

- Configure an optional LocalDynVpnPolicy statement, if command-line activated or autoactivated.

Neither the EE nor FTP VPNs require a LocalDynVpnPolicy statement, because neither is command-line activated or autoactivated.

- Configure an optional IpLocalStartAction statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivated) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the IpLocalStartAction statement in the IP filter rule.

Before a phase 2 negotiation can initiate, the IKE daemon needs to know the IP addresses, ports, and protocols that the Security Association covers. In most cases, these can be inferred from the filter rule, or from the packet that started the on-demand activation. An IpLocalStartAction statement explicitly defines where these parameters are obtained. The granularity setting determines whether the information comes from the matching filter rule, or from the packet. By explicitly specifying packet, you can guarantee that a new Security Association is created for each connection request.

```
IpLocalStartAction          ZoneB-Start-Action
{
    AllowOnDemand            yes
    LocalPortGranularity      packet
    RemotePortGranularity    packet
    ProtocolGranularity       packet
    LocalIpGranularity         packet
    RemoteIpGranularity       packet
    LocalSecurityEndpointRef Local_IKED
    RemoteSecurityEndpointRef ZoneB_IKED
}
```

In this example, specifying packet for LocalPortGranularity and RemotePortGranularity is not required. IKE detects that the filter rule has a range of ports specified and resorts to packet granularity instead of the default of rule. Specifying packet is required, however, if the EE rules had all ports specified. In that case, one Security Association is negotiated for all ports, not a single port. To avoid confusion, it is better to specify your intention.

- Set the global PreDecap parameter of the IpFilterPolicy statement to off, or create an IpFilterRule statement that allows IPsec traffic (AH and ESP).

In this example, set PreDecap off in the IpFilterPolicy statement

7. Define an IpFilterRule statement for each set of data endpoints.

The secure host and zone B represent the data endpoints. The IpService statements were defined previously. Place the IpDynVpnAction statements that were created previously with the appropriate rule. Notice that the parameters of the IpGenericFilterAction statement include ipsec as well as permit and deny. Because no logging requirements were specified, two actions are needed, permit and ipsec.

```

IpFilterRule      ZoneB-Permitted-traffic
{
    IpSourceAddrRef      PrivateServerAddress
    IpDestAddrSetRef      ZoneB-subnet
    IpServiceRef         IKE-local-500
    IpServiceRef         IKE-local-4500
    IpServiceGroupRef      SecureFTPServer
    IpGenericFilterActionRef permit-nolog
}

IpFilterRule      FTPServer-ZoneB
{
    IpSourceAddr         10.1.1.1
    IPDestAddrSet        9.4.0.0/16
    IpServiceRef          FTPServer-Control
    IpServiceRef         FTPServer-Data-Passive
    IpGenericFilterActionRef ipsec-nolog
    IpDynVpnAction        FTP-vpnaction
}

IpFilterRule      EE-ZoneB
{
    IpSourceAddr         10.1.1.1
    IPDestAddrSet        9.4.0.0/16
    IpServiceRef          Enterprise-Extender
    IpGenericFilterActionRef ipsec-nolog
    IpDynVpnAction        EE-vpnaction
    IpLocalStartActionRef ZoneB-Start-Action
}

```

Because IKE port 500, IKE port 4500, and secure FTP without IPSec protection are permitted, a separate IpFilterRule statement for each is not needed. The services can be combined into one IpFilterRule statement.

Tip: Any services that share the same data endpoints and the same security requirements can be placed together in one IpFilterRule statement.

8. Include the IpFilterRule statements in the IpFilterPolicy block.
9. Define an IP filter group for each zone and include the IpFilterRule statements that belong to that zone. Although the creation of reference objects and groups is not mandatory, they provide for ease of maintenance as the IP security policy grows more complex.
10. Include all configured statements in the stack-specific IP security configuration file.

Results

A completely configured policy, including all objects and their references, is as follows:

```

# IpFilterPolicy for secure public server

IpFilterPolicy
{
    PreDecap      off
    IpFilterGroupRef  ZoneB
}

KeyExchangePolicy
{
    AllowNat      Yes
    NatKeepAliveInterval 0
    KeyExchangeRuleRef  ZoneB_KeyExRule1
}

```

```

}

Steps for configuring the partner company with NAPT model (host-to-host with IPSec)

The partner company with NAPT model modifies the partner company with NAT model, replacing the NAT device in front of the internal network of each partner company with a NAPT device.

Before you begin

The following statements and concepts are covered in the discussion of this model:

- Using wildcard values for the remote port for IKE traffic
- NAPT implications for host-to-host dynamic IKE negotiations:
 - Local and remote data endpoints
 - Local and remote security endpoints
 - IKE initiator and responder roles

The partner company model assumed a network topology with both partner companies using public IP addresses in their internal networks. The partner company with NAT model modified the partner company model to include private addressing in the private network of each partner company, with a NAT device in front of each private network. Both NAT devices used static one-to-one address mappings.

The partner company with NAPT model modifies the partner company with NAT model, replacing the NAT device in front of the partner company's internal network with a NAPT device. The NAPT device uses many-to-one address and port mappings. The NAT in front of the z/OS host continues to use static one-to-one address mappings.

Figure 133 on page 1040 shows the partner company with NAPT topology.

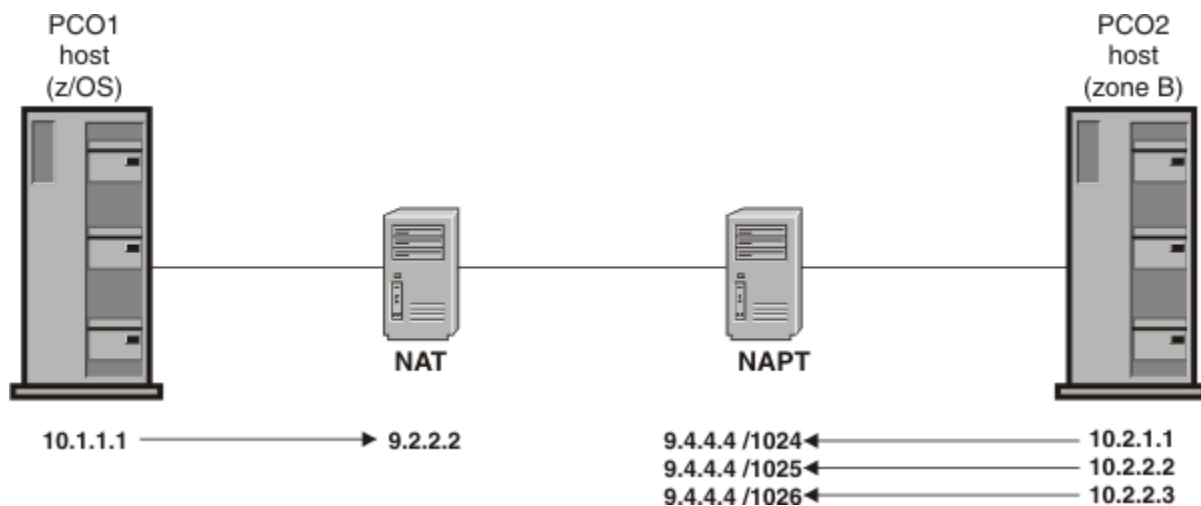

Figure 133. Partner company with NAPT model

The partner company with NAPT model has the same basic security requirements as the partner company with NAT model. One difference is that IPSec protection for Enterprise Extender (EE) traffic has been eliminated from the example. EE traffic is not compatible with the use of NAPT, with or without IPSec protection. For more information, see [“Enterprise Extender considerations when traversing a NAT”](#) on page 1068.

This example includes only the configuration steps that are impacted by a change from static one-to-one address mappings to NAPT mappings. Configuration statements added or changed for the partner company with NAPT model are shown in **bold**. The example describes the policy for partner company 1 (PCO1).

For this example, assume you must meet the following requirements to enable network communications from a partner company (PCO2) in an untrusted zone B behind a NAPT (9.4.4.4), over a connected network, to a server on this host that is behind a NAT, using static one-to-one address mapping:

- IKE traffic from untrusted zone B is allowed to this host.
- Secure FTP traffic (using TLS/SSL) from untrusted zone B is allowed to a secure FTP server running on this host.
- FTP traffic from untrusted zone B is allowed to an FTP server running on this host using a dynamic IPsec tunnel with strong authentication.
- A dynamic IPsec tunnel for normal FTP control activates for each remote host that initiates an FTP connection (remote activation).
- A dynamic IPsec tunnel for normal FTP data activates for each remote host that initiates an FTP data connection (remote activation).
- Peers authenticate themselves using the RSA signature method.

Procedure

Starting with the partner company with NAT policy, the following changes need to be made to meet these requirements when there is a NAPT in front of the partner company's internal network (Zone B):

- Modify the IpService statements for the IKE traffic to specify a wildcard value for the remote port.

The NAPT will update both the IP address and port values of an IKE packet, so that the traffic can no longer be described with a constant value of 500 or 4500.

```

IpService      IKE-local-500
{
  SourcePortRange      500
  DestinationPortRange 0
  Protocol              UDP
  Direction             bidirectional
  Routing               local
  SecurityClass         0
}

IpService      IKE-local-4500
{
  SourcePortRange      4500
  DestinationPortRange 0
  Protocol              UDP
  Direction             bidirectional
  Routing               local
  SecurityClass         0
}

```

- Modify the remote data endpoint to reflect the NAPT's single IP address, 9.4.4.4.

The remote data endpoint is the partner company's internal network. The z/OS implementation does not require you to code private addresses for the remote endpoint; the network address translated public address should be configured as the remote data endpoint. In this example, the private addresses in the PCO2 internal network (10.2.0.0/16) are translated into the public address 9.4.4.4. Thus, the remote data endpoint is 9.4.4.4.

```

IpAddr      ZoneB
{
  Addr      9.4.4.4
}

```

- Modify the remote security endpoint.

```

RemoteSecurityEndpoint  ZoneB_IKED
{

```

```

    Identity      Fqdn *.PC02.example.com
    Location      9.4.4.4
    CaLabel       CA4PartnerCompany
}

```

Results

A completely configured policy, including all objects and their references, is as follows:

```

# IpFilterPolicy for secure public server
IpFilterPolicy
{
    PreDecap                off
    IpFilterGroupRef        ZoneB
}

KeyExchangePolicy
{
    AllowNat                Yes
    NatKeepAliveInterval    0
    KeyExchangeRuleRef      ZoneB_KeyExRule1
}

Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)

The branch office model part 1 consists of two networks whose IP connectivity relies on the Internet. The server is protecting traffic that originates from hosts outside the internal network, which at some point is routed over the Internet.

Before you begin

The following topics are covered in the discussion of this model:

- Host-to-gateway
- Gateway-to-gateway
- Autoactivation
- Command-line activation
- Using wildcards for location and identity
- Pre-shared key peer authentication

Figure 134 on page 1045 shows the branch office portion of the security model network.

Figure 134. Branch office model

Transport-mode IPSec is used exclusively for transporting encrypted data directly between two hosts. Tunnel-mode IPSec encapsulation must be used if one of the security endpoints is a security gateway routing traffic for any number of hosts. In the branch office model, there can be multiple hosts behind a security gateway that is providing the security mechanism for all hosts that are behind the security gateway. The base assumption is that the local secure server represents a single data endpoint and a single security endpoint, whereas the remote subnetwork represents multiple data endpoints which share a common security endpoint, namely the security gateway host. Traffic from the local server to the branch office gateway is IPSec protected, while traffic from the branch office gateway to the hosts behind the security gateway need not be encrypted or even filtered.

As in the previous models, a complete IP security policy defines the traffic that is allowed between the local server and the zone representing the branch office. However, the difference lies primarily in where the remote security endpoint is situated. In the previous examples, all of the IPSec protection was provided on a host-to-host basis. Each set of communicating endpoints had a single dynamic VPN that represented a secure channel of communication between two hosts, local and remote. In contrast, any scenario that involves an IPSec security gateway can require that one VPN carry traffic for multiple hosts. This difference is highlighted in this branch office example.

For this example, assume the following requirements to allow network communications from zone C, a branch office network (9.6.0.0/16), to a public IP address (9.3.3.3) on this host. The hosts on the branch office network connect to the Internet through the public branch office gateway server (9.5.5.5).

- Allow IKE traffic from branch office zone C to this host.
- Allow EE traffic from branch office zone C to an EE service running on this host, using a dynamic VPN with strong authentication and encryption. The VPN should be up when the stack initializes.
- Allow normal FTP traffic from branch office zone C to an FTP server running on this host, using a dynamic VPN with strong authentication and encryption. The VPN is command-line activated. Only one VPN should be established to carry all FTP traffic. There will not be one VPN per connection, but rather one Security Association will be negotiated for all of the remote FTP clients.

Restriction: Negotiating a single Security Association for multiple remote clients is possible only when the remote security endpoint is acting as a secure gateway.

- Peers authenticate themselves using the pre-shared key method.

Procedure

Perform the following steps to meet these requirements and configure part 1 of the branch office model.

1. Determine the number of zones to be protected.

The branch office represents one zone, zone C.

2. For each zone, determine what services are allowed and define an IpService block for each wanted service.

Services are defined by their protocols and the well-known ports they use.

The definitions that describe FTP traffic can be combined in an IP service group as follows:

```

IpServiceGroup
{
  IpService
  {
    SourcePortRange    21
    Protocol            tcp
    Direction          bidirectional InboundConnect
    Routing            local
    SecurityClass      0
  }
  IpService
  {
    SourcePortRange    20
    Protocol            tcp
    Direction          bidirectional OutboundConnect
    Routing            local
    SecurityClass      0
  }
  IpService
  {
    SourcePortRange    50000 50200
    Protocol            tcp
    Direction          bidirectional InboundConnect
    Routing            local
    SecurityClass      0
  }
}

```

The traffic pattern for Enterprise Extender can be defined in one IpService block as follows:

```
IpService      Enterprise-Extender
{
  SourcePortRange 12000 12004
  DestinationPortRange 12000 12004
  Protocol        udp
  Direction       bidirectional
  Routing          local
  SecurityClass    0
}
```

3. Determine the data endpoints to be protected.

Typically, this is both a local and remote IP address or subnetwork.

In this example, for the local host public IP address, 9.3.3.3, define the following statement:

```
IpAddr      PublicServerAddressA1
{
  Addr       9.3.3.3
}
```

For the remote subnet, 9.6.0.0/16, the following statement is defined:

```
IpAddrSet    SubnetC
{
  Prefix      9.6.0.0/16
}
```

Because it is necessary to permit IKE traffic between the local public server and the remote branch office gateway, the IP address of the remote gateway must also be defined as follows:

```
IpAddr      BranchOfficeGateway
{
  Addr       9.5.5.5
}
```

4. Determine what level of security is needed between each set of data endpoints.

In this example, strong authentication and encryption is needed for both EE and FTP traffic, so ESP authentication and ESP encryption are used.

5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged, as follows:

```
IpGenericFilterAction    ipsec
{
  IpFilterAction          ipsec
}
```

6. If IPSec is required between any two endpoints, take the following actions:

a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:

i) Determine the required type and strength of protection for the phase 1 Security Association.

In this example, SHA1 authentication is used because it is more secure than MD5, and AES encryption is used because it is stronger than DES. Diffie-Hellman Group5 and Group14 are considered strong enough to generate keying material for AES using a 128 bit key. Group14 is used in this example.

ii) Decide what type of peer authentication to use.

In this example, pre-shared key authentication is specified in the requirements. Typically, the RSA signature method is preferable, given its numerous advantages, but for the purposes of example the pre-shared key method is used here. Because there is only one remote IKE peer in the branch office scenario (the remote security gateway), and because it is relatively simple to configure, pre-shared key authentication is a reasonable choice.

- iii) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation as follows:

```
KeyExchangeOffer      SHA1-AES-PSK
{
  HowToEncrypt        AES_CBC KeyLength 128
  HowToAuthMsgs       SHA1
  HowToAuthPeers      PresharedKey
  DHGroup             Group14
}
```

- iv) Decide whether NAT traversal will be allowed.

In this example, the following parameter is used:

```
AllowNat No
```

- v) Determine the negotiation mode, Main or Aggressive.

Because security is a priority in the branch office model, the more secure Main mode is used for the phase 1 negotiation.

- vi) Configure a KeyExchangeAction statement as follows:

```
KeyExchangeAction      Gold-PSK
{
  HowToInitiate        main
  HowToRespondIKEv1    main
  KeyExchangeOfferRef  SHA1-AES-PSK
}
```

- vii) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement as follows:

```
LocalSecurityEndpoint  Public_IKED
{
  Identity             IpAddr 9.3.3.3
  LocationRef          PublicServerAddressA1
}

RemoteSecurityEndpoint ZoneC_IKED
{
  Identity             Fqdn gateway.B0.example.com
  LocationRef          BranchOfficeGateway
}
```

- viii) Configure a KeyExchangeRule statement that includes the two endpoints, the key exchange action, and the pre-shared key as follows:

```
KeyExchangeRule        ZoneC_KeyExRule1
{
  LocalSecurityEndpointRef Public_IKED
  RemoteSecurityEndpointRef ZoneC_IKED
  KeyExchangeActionRef   Gold-PSK
  PresharedKey           abracadabra
}
```

- ix) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block, as follows:

```
KeyExchangePolicy
{
  KeyExchangeRuleRef    ZoneC_KeyExRule1
}
```

- b) Configure an IpDynVpnAction statement defining the control of the phase 2 negotiation, as follows:

- i) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, authentication is ESP HMAC_SHA1 and encryption is AES.

- ii) Determine whether tunnel or transport mode is required.

Tunnel mode is required when one of the security endpoints is a security gateway.

- iii) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation, as follows:

```
IpDataOffer          SHA-AES-Tunnel
{
  HowToEncap          tunnel
  HowToEncrypt         AES_CBC KeyLength 128
  HowToAuth            ESP HMAC_SHA1
}
```

- iv) Determine which peer is allowed to initiate the negotiation.

Because the EE VPN is up when the stack starts, you need to be able to start the negotiation locally (that is, autoactivate it). The FTP VPN is command-line activated, so you need to be able to start the negotiation locally.

- v) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation, as follows:

```
IpDynVpnAction       Gold-TunnelMode
{
  Initiation           either
  InitiateWithPfs       group2
  AcceptablePfs         group2
  IpDataOfferRef        SHA-AES-Tunnel
}
```

- c) Decide how the Security Association is activated.

- i) Optionally, configure a local dynamic VPN policy, if command-line activated or autoactivated.

A LocalDynVpnRule statement is required for each Security Association because none are on-demand activated, five for the EE traffic and two for the FTP traffic, as follows:

```
LocalDynVpnRule      ZoneC_VPN-EE1
{
  LocalIpRef           PublicServerAddressA1
  RemoteIpSetRef        SubnetC
  LocalDataPort         12000
  RemoteDataPort        12000
  Protocol              UDP
  AutoActivate          Yes
}

LocalDynVpnRule      ZoneC_VPN-EE2
{
  LocalIpRef           PublicServerAddressA1
  RemoteIpSetRef        SubnetC
  LocalDataPort         12001
  RemoteDataPort        12001
  Protocol              UDP
  AutoActivate          Yes
}

LocalDynVpnRule      ZoneC_VPN-EE3
{
  LocalIpRef           PublicServerAddressA1
  RemoteIpSetRef        SubnetC
  LocalDataPort         12002
  RemoteDataPort        12002
  Protocol              UDP
  AutoActivate          Yes
}
```

```

}

LocalDynVpnRule          ZoneC_VPN-EE4
{
    LocalIpRef            PublicServerAddressA1
    RemoteIpSetRef         SubnetC
    LocalDataPort          12003
    RemoteDataPort         12003
    Protocol               UDP
    AutoActivate           Yes
}

LocalDynVpnRule          ZoneC_VPN-EE5
{
    LocalIpRef            PublicServerAddressA1
    RemoteIpSetRef         SubnetC
    LocalDataPort          12004
    RemoteDataPort         12004
    Protocol               UDP
    AutoActivate           Yes
}

LocalDynVpnRule          ZoneC_VPN-FTP-Data
{
    LocalIpRef            PublicServerAddressA1
    RemoteIpSetRef         SubnetC
    LocalDataPort          20
    RemoteDataPort         0
    Protocol               TCP
    AutoActivate           Yes
}

LocalDynVpnRule          ZoneC_VPN-FTP-Control
{
    LocalIpRef            PublicServerAddressA1
    RemoteIpSetRef         SubnetC
    LocalDataPort          21
    RemoteDataPort         0
    Protocol               TCP
    AutoActivate           Yes
}

```

- ii) Configure an optional `IpLocalStartAction` statement, if the Security Association is to be activated locally (that is, on-demand, command-line, or autoactivation) and one of the security endpoints is acting as a security gateway (that is, not a host-to-host Security Association). Include a reference to the `IpLocalStartAction` statement in the IP filter rule.

If the local secure server initiates an IKE negotiation, it must be able to identify a remote IKE peer. However, in this case, the remote data endpoint is not a single host, but multiple endpoints in a subnetwork, ZoneC. The `IpLocalStartAction` statement is used to identify the remote IKE peer, and is required if the local IKE daemon initiates an ipsec connection with a remote security gateway.

```

IpLocalStartAction        StartZoneC
{
    RemoteSecurityEndpointRef  ZoneC_IKED
}

```

- iii) Create an `IpFilterRule` statement that allows IPSec traffic (AH and ESP), or set the global `IpFilterPolicy` statement parameter `PreDecap` to `off`.

In this example, `PreDecap off` is used in the `IpFilterPolicy` statement.

7. Define an `IpFilterRule` statement for each set of data endpoints.

The rule should include the services that are allowed (one `IpService` statement for each allowed service), and the level of security that is required (a reference to the `IpGenericFilterAction` statement). If IPSec is required, create an `IpFilterRule` statement that allows IKE traffic (UDP, port

500). If NAT traversal is allowed, create an IpFilterRule statement that allows IKE UDP traffic on port 4500. See the IpAddr and IpAddrSet statements configured in step “3” on page 1047.

```

IpFilterRule          Rule1C
{
    IpSourceAddrRef    PublicServerAddressA1
    IpDestAddrRef      BranchOfficeGateway
    IpServiceRef        IKE
    IpGenericFilterActionRef  permit
}

IpFilterRule          Rule2C
{
    IpSourceAddrRef    PublicServerAddressA1
    IpDestAddrSetRef    SubnetC
    IpServiceRef        Enterprise-Extender
    IpServiceGroupRef    FTPServer
    IpGenericFilterActionRef  ipsec
    IpDynVpnActionRef    Gold-TunnelMode
    IpLocalStartActionRef  StartZoneC
}

```

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.
9. Include all IpFilterGroup references and, optionally, any additional IpFilterRule statements as needed, in the IpFilterPolicy block.
10. Include all configured statements in the stack-specific IP security configuration file.

Results

The following policy is a complete IP security policy for traffic from the local secure server to zone C, assuming that the reusable statements are included in the common IP security configuration file:

```

#-----
# Filter Policy for Secure Server
#-----
IpFilterPolicy
{
    PreDecap                off
    FilterLogging            on
    AllowOnDemand            no
    IpFilterGroupRef        ZoneC
}

#-----
# KeyExchange Policy for Secure Server
#-----
KeyExchangePolicy
{
    KeyExchangeRuleRef      ZoneC_KeyExRule1
}

#-----
# LocalDynVpn Policy for Secure Server
#-----
LocalDynVpnPolicy
{
    LocalDynVpnGroupRef      ZoneC_BranchOfficeVPNs
}

}

```

Steps for configuring the branch office with NAT model (host-to-gateway with IPSec)

The branch office with NAT model modifies the branch office model topology to include a NAT in front of the security gateway.

Before you begin

The following NAT implications for host-to-gateway dynamic IKE negotiations are covered in the discussion of this model:

- Local and remote data endpoints
- Local and remote security endpoints
- IKE initiator and responder roles
- Restriction on HowToAuth protocol (AH not supported)

“Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)” on page 1045 assumed a network topology with both the host and the security gateway, as well as the hosts behind the security gateway, using public IP addresses. Often one or both security endpoints are behind a NAT using a private IP address.

Modifying the branch office model topology to include a NAT in front of the security gateway, the branch office with NAT topology becomes as shown in [Figure 135 on page 1054](#):

Figure 135. Branch office with NAT model

This example will describe the configuration considerations and requirements when the NAT solution is implemented to traverse NAT devices in a host-to-security gateway environment. The branch office with NAT model has the same basic security requirements as the branch office model. Configuration statements added or changed for the branch office with NAT model are shown in **bold**. The example describes the policy for host 9.3.3.3.

For this example, assume the following requirements to enable network communications from zone C, a branch office network using private IP addresses (10.3.0.0/16), to a public IP address (9.3.3.3) on this host. The hosts on the branch office network connect to the Internet through the branch office gateway

server, which is behind a NAT. In this model, the NAT has a static mapping of the security gateway's private address 10.3.3.3 to the public address 9.5.5.5.

- Allow IKE traffic from the branch office zone C security gateway to this host.
- Allow EE traffic from branch office zone C to an EE service running on this host, using a dynamic VPN with strong authentication and encryption. Only one host behind the security gateway (branch office zone C) will be able to send EE traffic.

Guideline: In most cases, EE hosts should not be located behind a security gateway that is behind a NAT. Instead, a host-to-host Security Association should be negotiated for each EE host.

In “Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)” on page 1045, the VPN was brought up when the z/OS stack initialized by setting the AutoActivate parameter to Yes on the LocalDynVpnRule statement. In this scenario, the hosts behind the gateway do not have public addresses that can be configured in the policy. Therefore, initiation from host 9.3.3.3 to the security gateway 9.5.5.5 becomes ambiguous because the IP address of the remote data endpoint is unknown. z/OS does not allow initiation of a UDP-encapsulated tunnel mode Security Association to a security gateway. The Security Associations between the security gateway 9.5.5.5 and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as responder.

- Allow normal FTP traffic from branch office zone C to an FTP server running on this host, using a dynamic VPN with strong authentication and encryption. In “Steps for configuring the branch office model: Part 1 (host-to-gateway with IPSec)” on page 1045, the VPN was activated by an administrator from the z/OS UNIX command line. Again, z/OS does not allow initiation of a UDP-encapsulated tunnel mode Security Association to a security gateway. The Security Associations between the security gateway and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as the responder.
- Peers authenticate themselves using the pre-shared key method.

Procedure

Perform the following steps to meet these requirements and configure the branch office with NAT model.

1. Determine the number of zones to be protected.

The branch office represents one zone, zone C.

2. For each zone, determine what services are allowed and define an IpService block for each wanted service.

Services are defined by their protocols and the well-known ports that they use.

The definitions that describe FTP traffic can be combined in an IP service group. Typically, FTP clients use passive mode (PASV) or extended passive mode (EPSV) to connect to the FTP server when the client is behind a NAT. For more information on active and passive mode FTP, see “Considerations for IPSec-encapsulated FTP traffic when traversing a NAT” on page 1067.

The range of server ports specified for the data connection reflects the port range specified for PASSIVEDATAPORTS in the server's FTP.DATA file. For more information on PASSIVEDATAPORTS (FTP server) statement, see z/OS Communications Server: IP Configuration Reference.

The following definitions show the services required for the server for PASV or EPSV:

```

IpServiceGroup      FTPServer
{
  IpService          FTPServer-Control
  {
    SourcePortRange  21
    Protocol          tcp
    Direction        bidirectional InboundConnect
    Routing           local
    SecurityClass     0
  }
  IpService          FTPServer-Data-Passive
  {
    SourcePortRange    50000 50200
  }
}

```

```

    Protocol
    Direction
    Routing
    SecurityClass
  }
}
tcp
bidirectional
local
0

```

The traffic pattern for Enterprise Extender can be defined in one IpService block as follows:

```

IpService
{
  SourcePortRange      12000 12004
  DestinationPortRange 12000 12004
  Protocol              udp
  Direction             bidirectional
  Routing               local
  SecurityClass         0
}
Enterprise-Extender

```

3. Determine the data endpoints to be protected.

In this example, for the local host public IP address, 9.3.3.3, define the following statement:

```

IpAddr
{
  Addr      9.3.3.3
}
PublicServerAddressA1

```

In this case, the remote data endpoints are in the branch office's internal network. The z/OS NATT implementation does not require the coding of private addresses for the remote endpoints. Instead, the security gateway's public address is treated as the remote data endpoint. The NAT is using a static mapping for the security gateway, so the public address of the gateway is specified. If the NAT was using dynamic mappings, the range of public IP addresses to which the security gateway could be mapped would need to be included in this definition.

```

IpAddr
{
  Addr      9.5.5.5
}
BranchOfficeGateway

```

This IP address is also needed to permit IKE traffic between the local public server and the remote branch office gateway.

4. Determine what level of security is needed between each set of data endpoints.

In this example, strong authentication and encryption is needed for both EE and FTP traffic, so ESP authentication and ESP encryption are used. ESP must be used when NAT traversal support is being used.

5. Configure an IpGenericFilterAction statement for the level of security that is required (permit, deny, ipsec), including whether the connection should be logged, as follows:

```

IpGenericFilterAction
{
  IpFilterAction      ipsec
}
ipsec

```

6. If IPSec is required between any two endpoints, take the following actions:

- a) Configure a key exchange policy that defines the parameters of the phase 1 negotiation as follows:
 - i) Determine the required type and strength of protection for the phase 1 Security Association.
In this example, SHA1 authentication is used because it is more secure than MD5, and AES encryption is used.
 - ii) Decide what type of peer authentication to use.

In this example, pre-shared key authentication is specified in the requirements. Typically, the RSA signature method is preferable, given its numerous advantages, but for the purposes of example the pre-shared key method is used here. Because there is only one remote IKE peer in the branch office scenario (the remote security gateway), and because it is relatively simple to configure, pre-shared key authentication is a reasonable choice.

- iii) Configure a KeyExchangeOffer statement that defines the parameters for the phase 1 negotiation as follows:

```
KeyExchangeOffer          SHA1-AES-PSK
{
  HowToEncrypt            AES_CBC KeyLength 128
  HowToAuthMsgs           SHA1
  HowToAuthPeers          PresharedKey
  DHGroup                 Group14
}
```

- iv) Decide whether NAT traversal will be allowed.

The AllowNat parameter on the KeyExchangePolicy and KeyExchangeAction statements enables the IKED to advertise NAT traversal support. For this model, allow NAT traversal support to be advertised for all phase 1 Security Associations by specifying Yes on the AllowNat parameter on the KeyExchangePolicy statement:

AllowNat Yes

For this model, use the NatKeepAliveInterval parameter default value, 20 seconds. When z/OS is behind a NAT, a NAT keep-alive timer is started, with the interval specified in NatKeepAliveInterval parameter on the KeyExchangePolicy statement. Because z/OS is not behind a NAT in this model, a NAT keep-alive is not kept regardless of the value specified or the default for NatKeepAliveInterval.

- v) Determine the negotiation mode, Main or Aggressive.

Because security is a priority in the branch office with NAT model, the more secure Main mode is used for the phase 1 negotiation.

- vi) Configure a KeyExchangeAction statement as follows:

```
KeyExchangeAction         Gold-PSK
{
  HowToInitiate            main
  HowToRespondIKEv1        main
  KeyExchangeOfferRef      SHA1-AES-PSK
}
```

- vii) Configure a LocalSecurityEndpoint statement and RemoteSecurityEndpoint statement as follows:

```
LocalSecurityEndpoint      Public_IKED
{
  Identity                 IpAddr 9.3.3.3
  LocationRef              PublicServerAddressA1
}

RemoteSecurityEndpoint      ZoneC_IKED
{
  Identity                 Fqdn gateway.B0.example.com
  LocationRef              BranchOfficeGateway
}
```

- viii) Configure a KeyExchangeRule statement that includes the two endpoints and the key exchange action, as follows:

```
KeyExchangeRule           ZoneC_KeyExRule1
{
  LocalSecurityEndpointRef Public_IKED
}
```

```

RemoteSecurityEndpointRef  ZoneC_IKED
KeyExchangeActionRef      Gold-PSK
PresharedKey              abracadabra
}

```

- ix) Include the KeyExchangeRule statement in the KeyExchangePolicy statement block, as follows:

```

KeyExchangePolicy
{
    AllowNat                Yes
    KeyExchangeRuleRef      ZoneC_KeyExRule1
}

```

- b) Configure an IpDynVpnAction statement defining the control of the phase 2 negotiation, as follows:

- i) Determine the required type and strength of IPSec protection for the phase 2 Security Association.

In this example, authentication is ESP HMAC_SHA1 and encryption is AES.

- ii) Determine whether tunnel or transport mode is required.

Tunnel mode is required when one of the security endpoints is a security gateway.

- iii) Configure an IpDataOffer statement that defines the parameters of the phase 2 negotiation, as follows:

```

IpDataOffer              SHA-AES-Tunnel
{
    HowToEncap            tunnel
    HowToEncrypt          AES_CBC KeyLength 128
    HowToAuth             ESP HMAC_SHA1
}

```

- iv) Determine which peer is allowed to initiate the negotiation.

In this scenario, the hosts behind the gateway do not have public addresses that can be configured in the policy. Therefore, initiation from host 9.3.3.3 to the security gateway 9.5.5.5 becomes ambiguous because the IP address of the remote data endpoint is unknown. z/OS does not allow initiation of a UDP-encapsulated tunnel mode Security Association to a security gateway. The Security Associations between the security gateway 9.5.5.5 and host 9.3.3.3 must be initiated by the security gateway, with host 9.3.3.3 acting as responder.

- v) Configure an IpDynVpnAction statement that defines the control information for the phase 2 negotiation, as follows:

```

IpDynVpnAction           Gold-TunnelMode
{
    Initiation              remoteonly
    InitiateWithPfs        group2
    AcceptablePfs          group2
    IpDataOfferRef         SHA-AES-Tunnel
}

```

- c) Decide how the Security Association is activated.

- i) Only remote initiation of the Security Association is allowed, as specified for the Initiation parameter on the Gold-TunnelMode IpDynVpnAction statement. No LocalDynVpnRule or IpLocalStartAction statements are needed.

- ii) Create an IpFilterRule statement that allows IPSec traffic (ESP), or set the global IpFilterPolicy statement parameter PreDecap to off.

In this example, PreDecap off is used in the IpFilterPolicy statement.

7. Define an IpFilterRule statement for each set of data endpoints.

The rule should include the services that are allowed (one IpService statement for each allowed service), and the level of security that is required (a reference to the IpGenericFilterAction statement). If IPSec is required, create an IpFilterRule statement that allows IKE traffic (UDP, port 500 and 4500). See the IpAddr and IpAddrSet statements configured previously.

```

IpFilterRule                                Rule1C
{
    IpSourceAddrRef                        PublicServerAddressA1
    IpDestAddrRef                         BranchOfficeGateway
    IpServiceRef                           IKE-local-500
    IpServiceRef                           IKE-local-4500
    IpGenericFilterActionRef               permit
}

IpFilterRule                                Rule2C
{
    IpSourceAddrRef                        PublicServerAddressA1
    IpDestAddrRef                           BranchOfficeGateway
    IpServiceRef                           Enterprise-Extender
    IpServiceGroupRef                       FTPServer
    IpGenericFilterActionRef                 ipsec
    IpDynVpnActionRef                       Gold-TunnelMode
}

```

8. Define an IpFilterGroup statement for each zone and include the IpFilterRule statements that belong to that zone.
9. Include all IpFilterGroup references and, optionally, any additional IpFilterRule statements as needed, in the IpFilterPolicy block.
10. Include all configured statements in the stack-specific IP security configuration file.

Results

The following policy is the complete IP security policy for traffic from the local secure server to zone C, assuming that the reusable statements are included in the common IP security configuration file:

```

#-----
# Filter Policy for Secure Server
#-----
IpFilterPolicy
{
    PreDecap                        off
    FilterLogging                    on
    AllowOnDemand                    no
    IpFilterGroupRef                 ZoneC
}

#-----
# KeyExchange Policy for Secure Server
#-----
KeyExchangePolicy
{
    AllowNat                                Yes
    KeyExchangeRuleRef                 ZoneC_KeyExRule1
}

Steps for configuring the branch office model: Part 2 (gateway-to-gateway with IPsec)

The branch office model part 2 is similar to the branch office model part 1. Here, there are multiple data endpoints on both the local side and the remote side, but only one pair of security endpoints, one local and one remote.

Before you begin

It is not likely that the z/OS system will function strictly as a router or a firewall at the network perimeter, but it is possible to configure the z/OS system to provide the IPsec functionality that many secure gateway devices provide. This topic includes instructions on how to configure a scenario in which the z/OS system is routing network traffic from inside the internal network. This functionality is similar to the functionality that is provided by the branch office gateway in [“Steps for configuring the branch office model: Part 1 \(host-to-gateway with IPsec\)”](#) on page 1045. Here, there are multiple data endpoints on both the local side and the remote side, but only one pair of security endpoints, one local and one remote.

In this example, assume that the local z/OS system is acting as a secure gateway for hosts on an internal network A, and tunneling the IPsec-protected traffic to a remote secure gateway for subnetwork C. The following list summarizes the requirements for this example:

- Permit IKE negotiations between the two security gateways, the secure local host and the secure remote gateway for subnetwork C.
- Permit traffic from the internal network to the internal interface on the secure local host.
- Add IPsec protection to any traffic that flows between the two secure gateways.

In this scenario, the z/OS system is a secure forwarding agent for the internal hosts, rather than a data endpoint. Traffic from the internal hosts that is destined for the remote network first comes to the secure local gateway in the clear. Before it is sent out to the remote network, it is IPSec encapsulated. The process is reversed for traffic that comes from the remote network. Traffic that comes from the remote network to the local secure gateway is IPSec decapsulated on the local secure host and forwarded to the internal host in the clear.

Procedure

Perform the following steps to meet the above requirements and configure part 2 of the branch office model.

1. Permit IKE negotiations between the two secure gateways.

UDP port 500 traffic must be allowed for IKE negotiations.

```

IpFilterRule          Rule1AtoC
{
    IpSourceAddrRef    PublicServerAddressA1
    IpDestAddrRef      BranchOfficeGateway
    IpServiceRef        IKE
    IpGenericFilterActionRef  permit
}

```

2. Permit traffic from the internal network to the internal interface on the secure host.

```

IpFilterRule          Rule2AtoC
{
    IpSourceAddrSetRef SubnetC
    IpDestAddrSetRef   InternalNetworkA
    IpServiceGroupRef   All-traffic-routed
    IpGenericFilterActionRef  permit
}

```

The bidirectional keyword on the IpService statement creates two filter rules, one inbound and one outbound. Expansion of this IpFilterRule statement is shown in [Table 52 on page 1061](#).

Table 52. Expanded filter rule for internal traffic

Source	Destination	Routing	Direction	Action
SubnetC	InternalNetworkA	Routed	Outbound	permit
InternalNetworkA	SubnetC	Routed	Inbound	permit

As required, traffic that enters the secure server from InternalNetworkA that is destined for SubnetC is permitted by the secure host as an inbound routed packet. Traffic that leaves the secure server from SubnetC destined for InternalNetworkA is permitted by the secure host as an outbound routed packet.

3. Add IPSec protection to any traffic that flows between the two secure gateways.

```

IpFilterRule          Rule3AtoC
{
    IpSourceAddrSetRef InternalNetworkA
    IpDestAddrSetRef   SubnetC
    IpServiceGroupRef   All-traffic-routed
    IpGenericFilterActionRef  ipsec-log
}

```

Expansion of this rule is shown in [Table 53 on page 1061](#).

Table 53. Expanded filter rule for remote traffic

Source	Destination	Routing	Direction	Action
InternalNetworkA	SubnetC	Routed	Outbound	ipsec
SubnetC	InternalNetworkA	Routed	Inbound	ipsec

Traffic that leaves the secure server from InternalNetworkA that is destined for SubnetC is permitted with ipsec. Traffic that enters the secure server from SubnetC that is destined for InternalNetworkA is permitted with ipsec.

Additional topologies

There are alternative security models that might be suitable for particular networks. Each of these configurations is supported by z/OS IP security.

Cascaded tunnels

If there are multiple hops from data endpoint to data endpoint, there might be Security Associations between any two hosts along the path. For example, the data might be authenticated from a host to the secure gateway, then encrypted for transportation over the Internet, then possibly authenticated and encrypted from the second secure gateway to the host on the other side, as shown in [Figure 136 on page 1062](#):

Figure 136. Cascaded tunnels

Nested tunnels

In a nested environment, data is encapsulated multiple times over multiple hops. If the local and remote hosts are both behind a secure gateway, there could be a tunnel-mode Security Association that carries the traffic from one secure gateway to the other. Meanwhile, a transport-mode Security Association could carry the traffic from one host to the other, end-to-end. In this case, the transport-mode Security Association is nested in the tunnel-mode Security Association. Data from the local host is encapsulated once when leaving the local machine, encapsulated again at the secure gateway, decapsulated at the other secure gateway, and decapsulated one final time at the remote host, leaving only the original packet.

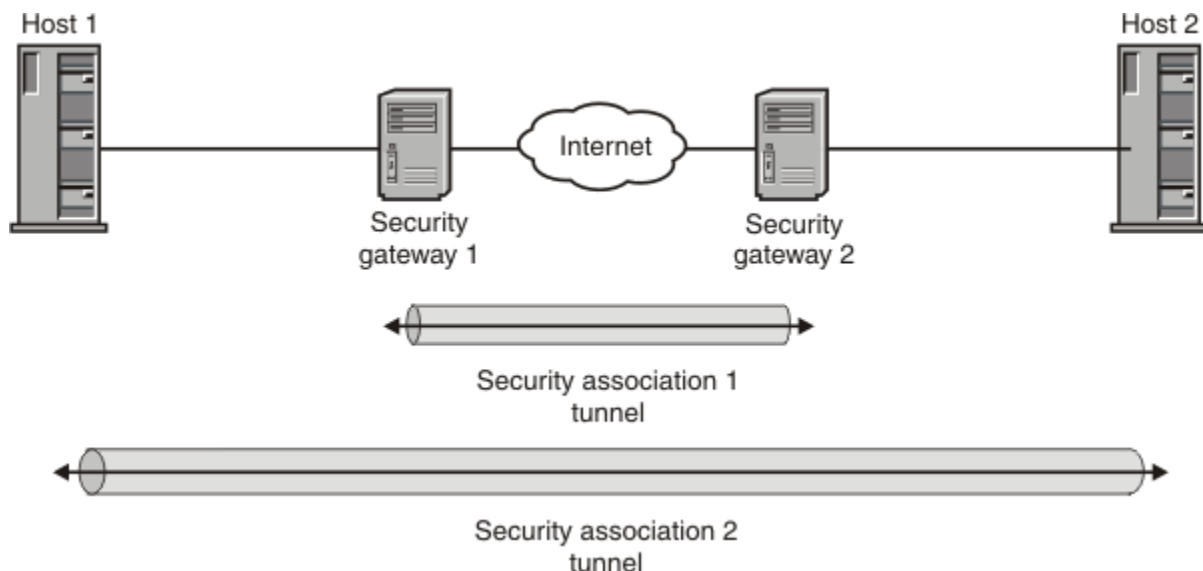

Figure 137. Nested tunnels

Mobile users

Mobile users represent a unique security model, because their IP address is not fixed and can be unpredictable. Instead of selecting traffic based on remote IP address, the mobile user's IKE identity can be used to select traffic. IPsec protection is required so that the IKE identity is known. You configure this security model similarly to other security models that require IPsec protection, except that the peer's remote identity is indicated on the RemoteIdentity parameter of the IpFilterRule statement, and the IpDestAddr parameter typically uses a wildcard value to indicate all addresses.

Multicast traffic

Multicast traffic can be protected by IPsec, but only manual tunnels are supported because the IKED supports negotiating dynamic tunnels with only a single peer rather than with a group of peers.

Multicast traffic is one-to-many (sent by individual nodes but received by multiple nodes) and is normally both sent and received; therefore, to use manual tunnels for multicast, you must use the same Security Parameter Index (SPI) and keys for inbound and outbound traffic. You must coordinate the SPI values and keys that are used with all multicast peers on the LAN segment. Also, because this manual tunnel is to be used to protect traffic with various source and destination addresses, you must specify any or any6 for the local and remote security endpoint locations. The following example shows AH authentication using the SHA algorithm, and ESP encryption using the DES algorithm.

```
IpManVpnAction tunnel-multicast
{
  LocalSecurityEndpointAddr any
  RemoteSecurityEndpointAddr any
  HowToAuth AH HMAC_SHA1
    AuthOutboundSa 2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
    AuthInboundSa 2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
  HowToEncrypt DES
    EncryptOutboundSa 2701 0x3e6dcf72459ef551
    EncryptInboundSa 2701 0x3e6dcf72459ef551
  HowToEncap transport
}
```

Requirement: You must define two filter rules for the multicast traffic. The first rule matches outbound multicast traffic, which has a unicast source address and a multicast destination address. The second rule matches inbound multicast traffic, which has a remote (destination) address that is unicast, and a local (source) address that is multicast. The addresses of the inbound rule are reversed from those that you might expect, because bidirectional rules are written from an outbound perspective. These rules are as follows:

```

IpFilterRule outbound-multicast
{
  IpSourceAddrSetRef      lan-home-address
  IpDestAddr              224.0.0.1
  IpServiceRef             service-udp
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-multicast
}
IpFilterRule inbound-multicast
{
  IpSourceAddr            224.0.0.1
  IpDestAddr              lan-subnet
  IpServiceRef             service-udp
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-multicast
}

```

It is possible to restrict the tunnel to the multicast address that is being used. Define separate tunnels for different multicast addresses and use the same SPI value (the combination of address and SPI makes the tunnel unique). Because the local system is expected to participate in both sending and receiving multicast messages, you must create two manual tunnels. The following example shows this approach. In this example, one endpoint address is known for each tunnel, so you specify that address for the particular security endpoint address.

```

IpManVpnAction tunnel-multicast-outbound
{
  LocalSecurityEndpointAddr any
  RemoteSecurityEndpointAddr 224.0.0.1
  HowToAuth                 AH HMAC_SHA1
  AuthOutboundSa             2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
  AuthInboundSa              2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
  HowToEncrypt               DES
  EncryptOutboundSa          2701 0x3e6dcf72459ef551
  EncryptInboundSa           2701 0x3e6dcf72459ef551
  HowToEncap                 transport
}
IpManVpnAction tunnel-multicast-inbound
{
  LocalSecurityEndpointAddr 224.0.0.1
  RemoteSecurityEndpointAddr any
  HowToAuth                 AH HMAC_SHA1
  AuthOutboundSa             2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
  AuthInboundSa              2700 0xa66e1b72e58a367ebd39d62daef84d5d9222cfe1
  HowToEncrypt               DES
  EncryptOutboundSa          2701 0x3e6dcf72459ef551
  EncryptInboundSa           2701 0x3e6dcf72459ef551
  HowToEncap                 transport
}
IpFilterRule outbound-multicast
{
  IpSourceAddrSetRef      lan-home-address
  IpDestAddr              224.0.0.1
  IpServiceRef             service-udp
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-multicast-outbound
}
IpFilterRule inbound-multicast
{
  IpSourceAddr            224.0.0.1
  IpDestAddr              lan-subnet
  IpServiceRef             service-udp
  IpGenericFilterActionRef ipsec-nolog
  IpManVpnActionRef        tunnel-multicast-inbound
}

```

Tip: Configuration of manual tunnels for IPv6 multicast is similar. For specific examples of configuring this for OSPFv3 security, see [“Considerations for IPv6 OSPF security”](#) on page 927.

Configuration scenarios supported for NAT traversal

Communications Server can act as a host Security Association endpoint for UDP-encapsulated mode Security Associations that are negotiated to enable IPsec traffic to traverse a NAT. The partner company with NAT model and the partner company with NAPT model describe Communications Server's host-to-

host support. The branch office with NAT model describes Communications Server's host-to-security gateway support.

Rule: Communications Server does not support acting as a security gateway endpoint for UDP-encapsulated tunnel mode Security Associations. This is different than the Communications Server support provided for tunnel mode Security Associations, where Communications Server can act as a security gateway, although Communications Server is not typically deployed in this manner.

The figures in the subtopics show z/OS configuration support for UDP-encapsulated Security Associations. A Security Association is negotiated by two IKE peers, with one initiating the negotiation and the other acting in responder mode. The location of the NAT, and the NAT's functionality, affect which IKE peer can initiate the Security Association. A traditional dynamic NAT implementation requires outbound traffic to be sent first to create an address mapping, before inbound traffic can be accepted. The dynamic NAT can be creating one-to-one address mappings from a dynamic pool of public IP addresses, or creating many-to-one address port mappings using a single public IP address and a pool of port values. When an IKE responder is behind a NAT, the NAT's address mapping must be static, allowing inbound traffic for the address to be received prior to outbound traffic being sent.

Host-to-host scenario 1 - z/OS-to-z/OS

Figure 138 on page 1065 shows a NAT in front of both z/OS hosts. A configuration with a NAT in front of only one of the z/OS hosts is supported as well. If there is a NAT device in front of the responder, the NAT's address mapping must be static. If there is a NAT device in front of the initiator, the NAT's address mapping can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

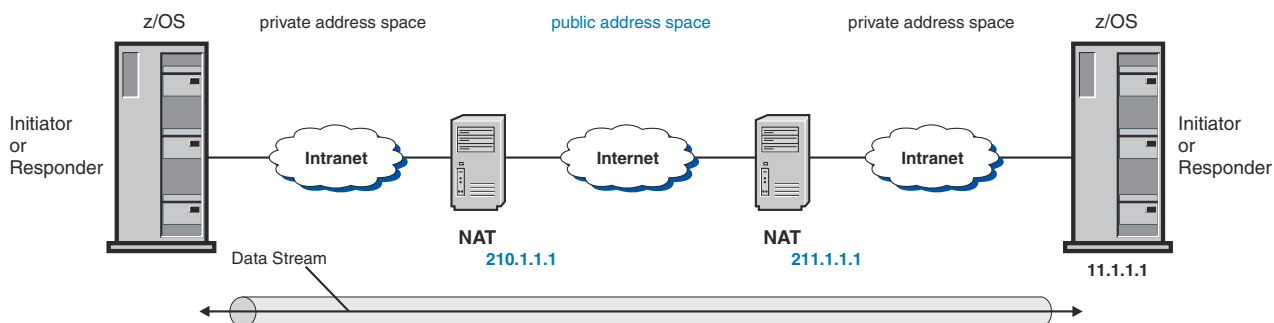

Figure 138. z/OS host to z/OS host, double NAT

Either UDP-encapsulated transport mode or UDP-encapsulated tunnel mode can be negotiated in a z/OS host-to-z/OS host configuration.

Rule: The z/OS host is limited to acting in responder mode when the remote endpoint is behind a NAPT. The negotiation of the phase 1 and phase 2 Security Associations must be initiated by the client behind the NAPT. Data must be initiated by the client behind the NAPT.

Host-to-host scenario 2 - z/OS-to-non-z/OS

Figure 139 on page 1066 shows a NAT in front of the z/OS host and the non-z/OS host. A configuration with a NAT in front of only one of the hosts is supported as well. If there is a NAT device in front of the responder, the NAT's address mapping must be static. If there is a NAT device in front of the initiator, the NAT's address mapping can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

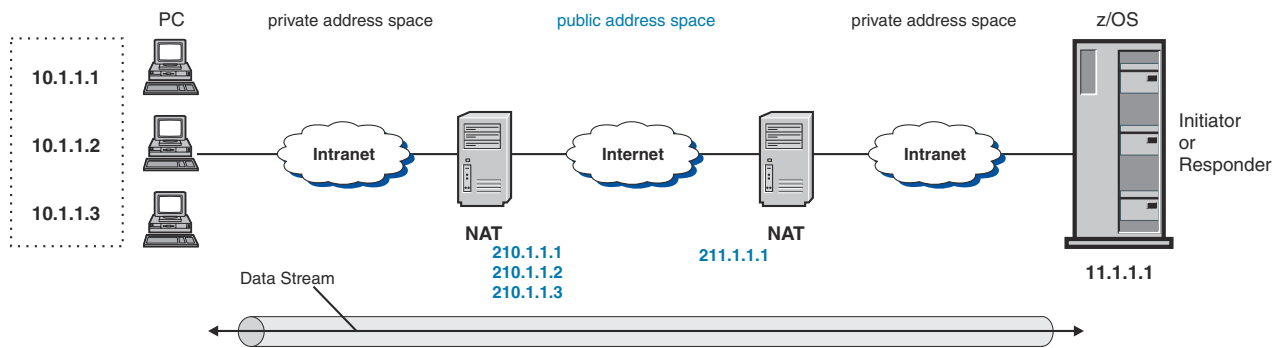

Figure 139. z/OS host to non-z/OS host, double NAT

Either UDP-encapsulated transport mode or UDP-encapsulated tunnel mode can be negotiated in a z/OS host-to-non-z/OS host configuration.

Rule: The z/OS host is limited to acting in responder mode when the remote endpoint is behind a NAT. The negotiation of the phase 1 and phase 2 Security Associations must be initiated by the client behind the NAT. Data must be initiated by the client behind the NAT.

Interoperability Considerations

z/OS is typically used to provide a server function. The client initiates the phase 2 Security Association (SA) and data, with z/OS acting in the role of IKE responder and data responder. z/OS provides robust NAT traversal responder support, allowing it to interoperate with a variety of clients.

z/OS can also act as the initiator of the phase 2 SA and data. Potential incompatibilities exist in the following cases, depending on the support that the non-z/OS peer provides:

- Any IKEv2 tunnel mode phase 2 SA

When z/OS initiates an IKEv2 tunnel mode phase 2 SA, it represents the data that is being protected by the SA with the following addresses:

- The local IP address as it appears in the home list. This address might be a private IP address if z/OS is behind a NAT.
- The public IP address of the client.

The phase 2 SA negotiation should succeed if the non-z/OS peer supports receiving a tunnel mode traffic specification that is using these IP addresses.

- IKEv1 phase 2 SAs that protect specific ports, protocols, or both

When initiating this type of phase 2 SA, z/OS represents the data being protected by the SA with the following addresses and values:

- The local IP address as it appears in the home list. This could be a private IP address if z/OS is behind a NAT.
- The client's public IP address.
- The specific port and protocol values.

The Phase 2 SA negotiation should succeed if the non-z/OS peer supports receiving this specification.

- IKEv1 tunnel mode phase 2 SAs that protect all ports and protocols

When z/OS initiates this type of phase 2 SA, it does not explicitly include the IP addresses of the data being protected in the negotiation of the SA. This allows the non-z/OS peer to view the protected data in terms of the IP addresses that it understands, the public address of the remote endpoint and the private address of the local endpoint. The phase 2 SA negotiation should be successful.

If data is initiated from z/OS over the SA, the data packet contains the following addresses:

- The local IP address as it appears in the home list. This address might be a private IP address if z/OS is behind a NAT.

- The client's public IP address.

If the non-z/OS peer supports receiving a packet with these IP addresses, the data flow should be successful. When z/OS receives data packets from the non-z/OS peer, z/OS sends packets that contain the IP addresses used by the peer.

Host-to-security gateway scenario

Figure 140 on page 1067 shows both the security gateway and the host behind a NAT. z/OS also supports acting in responder mode when only one endpoint (either the security gateway or the z/OS host) is behind a NAT. When there is a NAT device in front of the z/OS host (acting as responder), the address mapping of the NAT must be static. If there is a NAT device in front of the security gateway, the address mapping of the NAT can be static or dynamic. A dynamic mapping can use either one-to-one address translation or many-to-one address port translation (NAPT).

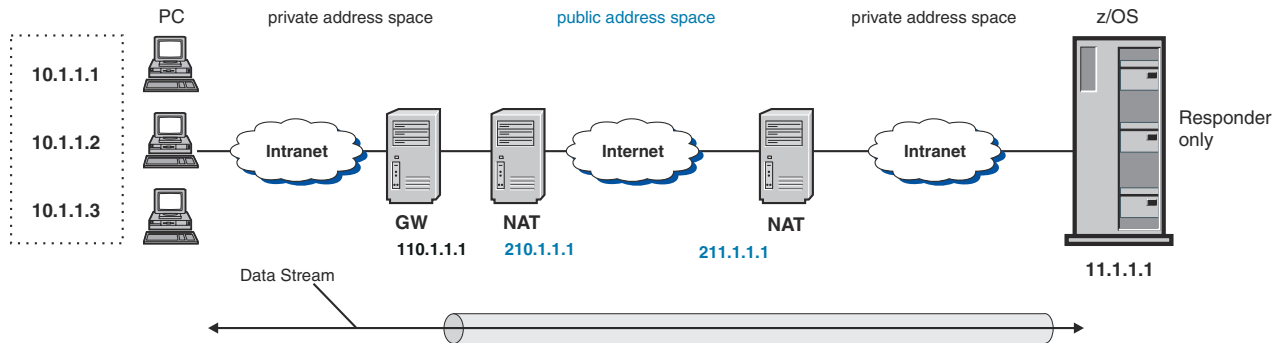

Figure 140. z/OS in a host-to-security gateway configuration

Rule: The z/OS host is limited to acting in responder mode in a host-to-security gateway configuration when a NAT is traversed. The phase 2 Security Association negotiation must be initiated by the security gateway. Data must be initiated by the client behind the security gateway.

Figure 140 on page 1067 shows the clients and the security gateway as separate devices. However, whenever a Security Association is negotiated to protect something other than a single IP address (for example, a range of IP addresses), that IKE daemon negotiating the Security Association is acting as a security gateway.

When the security gateway is behind a NAT, the individual hosts behind the NAT cannot be distinguished. If only one NAT address is available, all Security Associations negotiated between the security gateway (GW) and z/OS are negotiated using the NAT address, and have the same security characteristics. If multiple security characteristics are required to protect the traffic behind the security gateway, more NAT addresses are needed so that z/OS can locate different policies based on the NAT address.

Considerations for IPSec-encapsulated FTP traffic when traversing a NAT

FTP requires both a control connection and a data connection. For active-mode FTP, the client initiates the control connection and provides IP address and port information for the server to initiate the data connection. If the client is behind a NAT, the client provides its private IP address. The NAT updates the IP address in the FTP data for a packet that is not encapsulated; however, when you use IPSec encapsulation to secure your FTP connection, the NAT is unable to update the IP address in the FTP data.

Rule: When the FTP client is behind a NAT, you must use passive-mode FTP.

For passive-mode FTP, the client initiates the control connection. When a file transfer is to be started, the client sends a passive (PASV) command to the server. In response to the PASV command, the server provides the IP address and port information for establishing the data connection. The client is then able to initiate the data connection to the IP address and port.

When the FTP server is behind a NAT, the IP address provided in the PASV response is its private address. The NAT updates the IP address in the FTP data for a packet that is not encapsulated; however, when you use IPSec encapsulation to secure your FTP connection, the NAT is unable to update the IP address in the FTP data.

Rule: When the FTP server is behind a NAT, you must use extended passive-mode FTP.

Extended passive-mode FTP eliminates the IP address from the FTP data. The server provides the port for the data connection, and the client connects to the same IP address that was used for the control connection.

The z/OS FTP client and server support extended passive-mode FTP using the EPSV command. If you are using the z/OS FTP client and the FTP server that you are accessing does not support the EPSV command, you can configure the PASSIVEIGNOREADDR statement for the z/OS FTP client and use passive-mode FTP, which is widely supported. The PASSIVEIGNOREADDR statement directs the z/OS FTP client to ignore the IP address in the PASV reply, and to connect to the same IP address used for the control connection.

For more information about FTP, see [Chapter 12, “Transferring files using FTP,” on page 687](#). For a sample FTP.DATA data set, or for information about the [LOCSite subcommand--Specify site information to the local host](#), see [z/OS Communications Server: IP User's Guide and Commands](#).

Enterprise Extender considerations when traversing a NAT

The implementation of Enterprise Extender (EE) requires that the EE connection endpoints be defined by unique static VIPA addresses. NAT functions are limited in the EE environment as follows:

- The NAT mapping must be a one-to-one address mapping. NAPT is not supported.
- Dynamic mappings are generally unreliable for an EE connection. A static mapping of internal IP address to external IP address should be defined when an EE endpoint is behind a NAT.
- When IPSec protection is added for EE traffic that traverses a NAT, only one host that is behind a security gateway that is behind a NAT will be able to send EE traffic. In most cases, EE hosts should not be located behind a security gateway that is behind a NAT. Instead, a host-to-host Security Association should be negotiated for each EE host.

Additional configuration concerns for NAT traversal

The following list contains some additional configuration concerns for NAT traversal:

- When using NAT traversal, z/OS views its own address as the one configured in the z/OS home list. If the z/OS host is behind a NAT, this address is a private address. Otherwise, it is the public address of the z/OS host.

The z/OS implementation does not use private addresses in its configuration to describe the remote IKE peer or remote IP connection endpoint. z/OS views its IPSec peer and the remote IP connection endpoint as a public IP address. If a NAT is in front of the IPSec peer, the z/OS host perceives the IPSec peer and connection endpoint addresses to be that of the NAT.

- For IKEv1 Security Associations, you should not configure pre-shared keys in Main mode when multiple remote peers are behind a NAT and the peers do not map to unique RemoteSecurityEndpoint specifications. RFC 3947 states that pre-shared keys cannot be used with Main mode, unless group shared keys for all those behind the NAT are deployed. The use of group pre-shared keys is considered a security risk.
- If a NAT address is coming out of a dynamic NAT pool, addresses assigned to a host from the pool can be assigned any of the pooled addresses. In this case, there are additional considerations. When z/OS is the responder, the IPSec policy intended for a host must be broad enough to cover the entire range of IP addresses in the dynamic NAT pool. When z/OS is the initiator and the responder is behind a NAT, the identity of the target host can be ambiguous. Do not configure a z/OS host to initiate to an ambiguous target host.
- When a remote security endpoint is behind a NAT, its identity must be unique. During a phase 1 negotiation, the remote security endpoint sends its identity in an ID payload. The IKE daemon can manage multiple remote security endpoints using the same ID when those endpoints are not behind a NAT. However, when a remote security endpoint is behind a NAT, it must use a unique IKE identity.
- When the remote security endpoint is a security gateway behind a NAT or a host behind a NAPT, only TCP, UDP, and ICMP traffic is supported. ICMP traffic has limited support.

- z/OS allows traffic for a TCP connection to continue as long as the integrity of the connection can be verified. Two cases where z/OS can no longer verify the integrity of the connection are:

- Adding or removing IPsec protection for a TCP connection

When a TCP connection traverses a NAT, the TCP connection must be restarted after a filter policy change that causes the connection's traffic to change from IPsec-protected traffic to clear text, or from clear text to IPsec-protected traffic.

- NAT IP address remapping

If the peer's IP address is remapped by a NAT due to a timeout or reboot of the NAT device, the TCP connection must be restarted.

Configuring the IKE daemon

This topic describes considerations and steps for configuring the IKE daemon.

The IKE daemon's purpose is to manage dynamic IPsec tunnels and to provide a network management interface (NMI) for monitoring and controlling IP filtering and IPsec. The IKE daemon is not involved in the actual filtering, encapsulation, or decapsulation of packets. The IKE daemon is not required for the configuration or use of IP filters when no `IpDynVpnAction` statements are used. However, because the IKE daemon processes NMI monitoring requests, it must be running to gather monitoring data for IP filters, manual Security Associations, or dynamic Security Associations. To start the IKE daemon, it must be able to connect to the Policy Agent. For information about this requirement, see [“Policy Agent considerations” on page 1070](#). For more information about the [IPsec NMI](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Multiple TCP/IP stacks

A one-to-many relationship can exist between an instance of the IKE daemon and stacks configured with `IPCONFIG IPSECURITY`. A single instance of the IKE daemon can service all stacks configured with `IPCONFIG IPSECURITY` on a single z/OS image. Only one instance of the IKE daemon can run on a single z/OS image.

Each stack can be configured as a network security services (NSS) client. An NSS client makes use of network security services offered by the NSS server. For details about configuring an NSS server, see [Chapter 18, “Network security services,” on page 1111](#).

[“TCP/IP stack initialization access control” on page 168](#) describes a time interval during which limited stack access is available for stacks that have been configured for AT-TLS using the `TCPCONFIG` statement with the `TTLS` parameter. To enable the IKE daemon for a stack during this interval, the IKE daemon user ID must be permitted to the `EZB.INITSTACK.sysname.tcpname` resource profile. For examples of the security product commands needed to grant access to this profile, see member `EZARACF` in sample data set `SEZAINST`.

Run-time environment

The IKE daemon is a z/OS UNIX application, and it requires a z/OS UNIX file system such as z/OS File System. The IKE daemon can be started from an MVS started procedure, from the z/OS shell, with the `AUTOLOG` statement in the TCP/IP profile, or by using the `COMMNDxx` member of `PARMLIB`. The IKE daemon must be started by a RACF-authorized user ID, and it must be in an APF-authorized library. For more information about how to start the IKE daemon, see [“Starting the IKE daemon” on page 1076](#).

The IKE daemon uses the MVS operator's console, `syslogd`, `CTTRACE`, and `STDOUT` for its logging and tracing. The MVS operator's console and `STDOUT` are used for major events such as initialization, termination, and error conditions. `syslogd` is used for logging events related to dynamic IPsec tunnel management. `CTTRACE` is used for detailed tracing and debugging.

The IKE daemon uses a standard message catalog. The message catalog must be in the z/OS UNIX file system. The directory location for the message catalog path is set by the environment variables `NLSPATH` and `LANG`.

Language Environment run-time considerations

When starting the IKE daemon from a started or cataloged procedure, you should usually start the IKE daemon directly from the SEZALOAD data set using PGM=IKED. However, there is a situation where you might want to start the IKE daemon using BPXBATCH.

When the IKE daemon is started using PGM=IKED, the STDENV DD card, if used, is passed directly to the IKE daemon program. Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS= environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM= parameter and the options must be specified before any IKE daemon options. However, the PARM= statement allows a maximum of 100 characters. If the wanted Language Environment run-time options plus IKE daemon parameters exceeds 100 characters, consider using BPXBATCH to start the IKE daemon. When PGM=BPXBATCH is used, the Language Environment variable _CEE_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

IKE daemon configuration source information

The IKE daemon obtains configuration information from two sources.

- IKE daemon configuration file

The IKE daemon configuration file contains the IkeConfig statement. Parameters on the IkeConfig statement are global IKE daemon operational parameters. For details on the [IKE daemon configuration file statements](#) and the IkeConfig statement, see [z/OS Communications Server: IP Configuration Reference](#).

The IKE daemon configuration file is read when the IKE daemon initializes and can be reread dynamically. For more information, see [“Controlling the IKE daemon” on page 1078](#).

- Policy Agent

IP security policy includes dynamic IPsec tunnel configuration information required by the IKE daemon. The IKE daemon obtains IP security policy from the Policy Agent. The IKE daemon obtains IP security policy when connecting to the Policy Agent and whenever the Policy Agent informs the IKE daemon of a change in IP security policy. The IKE daemon connects only to stacks configured with IPCONFIG IPSECURITY, if there is an IP security policy defined for a stack. For details on configuring IP security policy, see [“Configuring specific security models” on page 1002](#).

Policy Agent considerations

The IKE daemon cannot perform management of dynamic IPsec tunnels until it has obtained IP security policy from the Policy Agent. While the Policy Agent is running, it can inform the IKE daemon of dynamic changes to IP security policy. After the IKE daemon has obtained an IP security policy, the Policy Agent can be stopped without impacting the IKE daemon. However, any changes to the IP security policy will not be detected until the Policy Agent is restarted, nor will IKE detect newly activated or reactivated stacks. The IKE daemon reconnects to the Policy Agent when the Policy Agent is restarted. For information about starting and monitoring policy related applications using the Policy Agent, see [“Step 7: Configuring Policy Agent to automatically monitor applications” on page 846](#).

Using network security services

The IKE daemon allows a stack to be defined as a network security services (NSS) client. When a stack is defined as an NSS client, the IKE daemon uses at least one network security service on behalf of that stack. Network security services are provided by an NSS server. An NSS server provides a certificate service and a remote management service. For details about the configuration of an NSS server, see [Chapter 18, “Network security services,” on page 1111](#).

The certificate service of the NSS server is used to create and verify digital signatures on behalf of an NSS client. Certificates for stacks that are configured to use the NSS certificate service must be on the key ring

of the NSS server. For details about configuring the IKE daemon to use the NSS certificate service, see [“Step 6: Setting up the IKE daemon for digital signature authentication \(optional\)” on page 1397](#).

Restriction: If you want the IKED to use a digital signature authentication method to negotiate an IKEv2 Security Association for a stack, the stack must be configured to use the NSS certificate service.

The remote management service of the NSS server enables the IP filter rules and Security Associations of an NSS client to be monitored and managed from the system on which the NSS server is executing. For details about using the `ipsec` command to monitor and manage NSS clients, see [z/OS Communications Server: IP System Administrator's Commands](#). For details about using the IPsec NMI to monitor and manage NSS clients, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

The NSS server does not need to be on the same system as the IKE daemon. The location of the NSS server is specified by the `NetworkSecurityServer` parameter and optionally by the `NetworkSecurityServerBackup` parameter of the `IkeConfig` statement. For additional details about the `IkeConfig` statement, see [z/OS Communications Server: IP Configuration Reference](#).

The `NssStackConfig` statement in the IKE daemon configuration file is used to define a stack as an NSS client. The `ServiceType` parameter of the `NssStackConfig` statement identifies what network security services are to be used by a stack. When a `ServiceType` value `Cert` is specified, the NSS certificate service is used. When a `ServiceType` value `RemoteMgmt` is specified, the NSS remote management service is used. The `ServiceType` parameter can be specified multiple times. For complete details about the `NssStackConfig` statement, see [z/OS Communications Server: IP Configuration Reference](#).

When a stack is configured to use the NSS remote management service, the NSS server can send the IKE daemon a request to switch between default IP filter policy and IP security filter policy. To change filter sets, the IKE daemon creates or deletes a specific marker file that the stack accesses. This marker file is the same marker file that is created or deleted by the `ipsec` command when the `ipsec -f reload` or `ipsec -f default` IP filter options are specified locally without the `-z` option. For details about the `ipsec` command, see [z/OS Communications Server: IP System Administrator's Commands](#).

The `ClientName` parameter of the `NssStackConfig` statement associates an NSS client name with a stack. This is the name by which the NSS server knows the stack. The `UserId` parameter of the `NssStackConfig` statement associates the NSS client name with a user ID defined on the NSS server's system. The NSS server uses both the client name and user ID when checking SERVAUTH profiles to verify that an NSS client is authorized to request a specific action. For details about SERVAUTH profiles checked by the NSS server, see [Chapter 18, “Network security services,” on page 1111](#).

The `AuthBy` parameter of the `NssStackConfig` statement defines how the user ID associated with a stack that is acting as an NSS client is to be authenticated. This user ID can be authenticated using a password or a `PassTicket`. When a `PassTicket` is used, the application key is stored in the local external security manager database.

Tip: Using a `PassTicket` is more secure than specifying a password.

To store the application key in the local external security manager database, the secure signon function must be enabled and a `PTKTDATA` profile must be created. This key must be associated with an application ID of the NSSD. For specific information about enabling the secure signon function and defining profiles to be used by the single signon function, see [z/OS Security Server RACF Security Administrator's Guide](#).

The following command is an example of a RACF command that you can issue to store the application key for the NSS server and NSS clients:

```
RDEFINE PTKTDATA NSSD SSIGNON(KEYMASKED(E001193519561977)) UACC(NONE)
```

[Figure 141 on page 1072](#) shows a partial configuration for the IKE daemon on system SYSTEMA. The `NetworkSecurityServer` parameter on the `IkeConfig` statement specifies that the IKE daemon is configured to use network security services from an NSS server that is listening on IP address 9.1.1.1. One `NssStackConfig` statement is shown. The `ClientName` parameter associates stack `STACK1` with an NSS client name `SYSTEMA_STACK1`. This is the name by which the NSS server knows this stack. The `UserId` parameter associates the client name with the user ID `A1S1`. The `A1S1` user ID must be defined on the NSS server's system. Both the client name and user ID are used by the NSS server when verifying

the authorization of an NSS client. The multiple ServiceType parameters indicate that the IKE daemon uses both the NSS certificate service and the NSS remote management service.

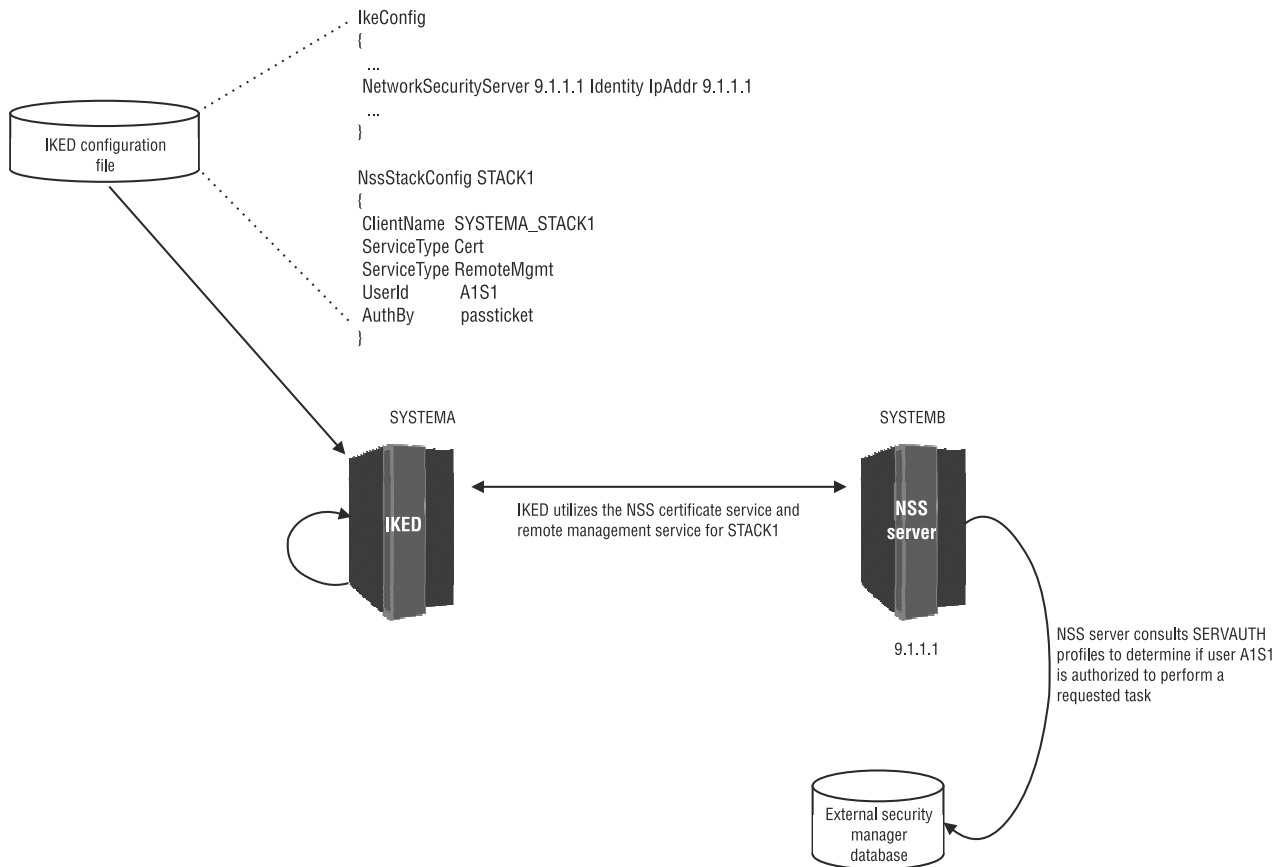

Figure 141. Enabling network security services

The IKE daemon requires that communication with the NSS server be protected using AT-TLS. During the AT-TLS handshake, the NSS server provides a certificate that can be used to authenticate its identity. The IKE daemon examines this certificate and verifies that the identity in the certificate matches the identity specified on the NetworkSecurityServer parameter of the IkeConfig statement.

The IKE daemon does not perform any SERVAUTH checks when processing an IPSec monitoring request or an IPSec management request from the NSS server. The NSS server performs SERVAUTH checks to make sure that the requester of an IPSec monitoring or management request is authorized. For details about the IPSec NMI imposed by the NSS server, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

The IKE daemon does perform a SERVAUTH check for the EZB.NETMGMT.sysname.sysname.IKED.DISPLAY profile when processing a local NMI request to display information about current NSS client state. For [IPSec NMI](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Certificate revocation checking

Certificate revocation checking is applicable only to digital signature authentication methods. The RevocationChecking parameter in the IPSec policy file controls the level of certificate revocation checking that is performed during an IKE negotiation. The following three levels of revocation checking are supported:

- Strict
- Loose
- None

You can specify the RevocationChecking parameter on the KeyExchangePolicy statement and the KeyExchangeAction statement. For more information about the KeyExchangePolicy statement and the KeyExchangeAction statement, see [z/OS Communications Server: IP Configuration Reference](#).

The native IKED certificate service does not support the retrieval and checking of certificate revocation information. When the IKED is configured to use the native IKE daemon certificate service, the RevocationChecking parameter is ignored.

The NSS certificate service does support the retrieval and checking of certificate revocation information in the form of certificate revocation lists (CRLs). For information about the NSS server requirements for retrieving CRLs, see “NSS server certificate revocation support” on page 1132. Ensure that these requirements can be met before you enable strict revocation checking in the IPsec policy file.

Steps for configuring the IKE daemon

The IKE daemon manages dynamic IPsec tunnels and provides a network management interface (NMI) for monitoring and controlling IP filtering and IPsec. Because the IKE daemon processes NMI monitoring requests, it must be running to gather monitoring data for IP filters, manual Security Associations, or dynamic Security Associations.

Procedure

Perform the following steps to configure the IKE daemon:

1. Create the IKE daemon configuration file.

A sample configuration file is provided in `/usr/lpp/tcpip/samples/iked.conf`.

The following search order is used by the IKE daemon to locate the configuration data set or file:

- a. If the environment variable `IKED_FILE` has been defined, the IKE daemon uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.
- b. `/etc/security/iked.conf`

You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the `IKED_CODEPAGE` environment variable to specify the code page that you want to use. The default code page is IBM-1047.

2. Set the `_BPX_JOBNAME` environment variable (optional).

When starting the IKE daemon from the z/OS shell, the environment variable `_BPX_JOBNAME` should be set. This enables a specific job name to be used when reserving ports for the IKE daemon. This name can also be used with the STOP or MODIFY console commands.

For more information on [Commonly used environment variables](#), see [z/OS UNIX System Services Planning](#)

3. Reserve the ports.

Update the PORT statement in PROFILE.TCPIP to reserve ports 500 and 4500 for the IKE daemon. Add the name of the member containing the IKE daemon cataloged procedure or the name as set using `_BPX_JOBNAME`:

```
PORT
      500 UDP IKED
      4500 UDP IKED
```

4. Update the IKE daemon cataloged procedure.

If the IKE daemon is to be started by a procedure, create the cataloged procedure by copying the following sample in SEZAINST(IKED) to your system or recognized PROCLIB. Specify IKE daemon parameters and change the data set names to suit your local configuration.

```
//IKED      PROC
//*
//* IBM Communications Server for z/OS
//* SMP/E distribution name: EZBIKPRC
```

```

/**
/** 5650-ZOS Copyright IBM Corp. 2005, 2013

/**
/**STDENV    DD DUMMY
/** Sample MVS data set containing environment variables:
/**STDENV    DD DSN=TCPIP.IKED.ENV(IKED),DISP=SHR
/** Sample HFS file containing environment variables:
/**STDENV    DD PATH='/etc/security/iked.env',PATHOPTS=(ORDONLY)
/**
/** Output written to stdout and stderr goes to the data set or
/** file specified with SYSPRINT or SYSOUT, respectively.
/**SYSPRINT DD SYSOUT=*
/**SYSOUT   DD SYSOUT=*

```

5. Authorize the IKE daemon to the external security manager.

See [“Step 3: Authorizing the IKE daemon to the external security manager”](#) on page 1392.

6. Configure and start syslogd.

The IKE daemon uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use z/OS File System as its underlying file system. For more information on syslogd, see [“Configuring the syslog daemon”](#) on page 235.

Tip: The system logging daemon (syslogd) can be configured to forward messages from the IKE daemon to a syslogd on another host. For information about [Syslog daemon](#), see [z/OS Communications Server: IP Configuration Reference](#). When a stack is configured as an NSS client, it can be advantageous to forward syslog messages from the IKE daemon to the syslogd running on the NSS server's system. Configuring syslogd in this manner allows all IKE messages relating to an NSS client to be in the same log file as the NSS server's messages.

7. Update the IKE daemon environment variables (optional).

The following environment variables are used by the IKE daemon and can be tailored to a particular installation:

IKED_CODEPAGE

Use the IKED_CODEPAGE variable to specify the EBCDIC code page to be used when reading the configuration file. For more information about [IKE environment variables](#) and the supported code pages, see [z/OS Communications Server: IP Configuration Reference](#).

IKED_CTRACE_MEMBER

The IKED_CTRACE_MEMBER variable is used by the IKE daemon to locate a parmlib member for IKE daemon CTRACE customization. For more information on the [TCP/IP services component trace for the IKE daemon](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

IKED_FILE

The IKED_FILE variable is used by the IKE daemon in the search order for the IKE daemon configuration file. For details on the search order used for locating this configuration file, see step “1” on page 1073.

8. Setup the IKE daemon for TCP/IP stack initialization access control (optional).

See [“Multiple TCP/IP stacks” on page 1069](#).

9. Setup the IKE daemon for digital signature mode authentication (optional).

See [“Step 6: Setting up the IKE daemon for digital signature authentication \(optional\)” on page 1397](#).

10. Define AT-TLS policy to protect communication with an NSS server.

The IKE daemon requires that communication between the NSS server and the IKE daemon be secured using Application Transparent Transport Layer Security (AT-TLS). If a stack is configured as an NSS client, AT-TLS rules must be defined to secure this communication. Enable AT-TLS processing for a stack by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#).

Tip: Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with the NSS server. Failure to restrict the cipher suites to those requiring encryption can result in sensitive information flowing in the clear across an untrusted network.

Rule: AT-TLS policy must be defined for each stack through which the IKE daemon communicates with the NSS server.

A sample AT-TLS policy is located in `/usr/lpp/tcpip/samples/pagent_TTLS.conf`.

Rule: The RemotePortRange value in the TTLSRule statement must include the value specified on the NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the IKE daemon configuration file.

11. Define IP filter policy to enable communication with an NSS server (optional).

If a stack is configured as an NSS client, IP filter policy for that stack must be defined to enable this communication. The IKE daemon communicates with the NSS clients using the TCP protocol. By default, the NSS server listens on port 4159. The IKE daemon connects to the NSS client using an ephemeral port. Ephemeral ports are generally in the range 1024 – 65355.

Two types of IP filter policy can be defined for a z/OS stack:

- Default IP filter policy is defined in the TCP/IP profile. Updating default IP filter policy to permit communications between the IKE daemon and the NSS server is optional. Default IP filter policy is in effect only when IP security filter policy cannot be loaded or when the **ipsec -f default** command has been issued. For details about [TCP/IP profile](#), see [z/OS Communications Server: IP Configuration Reference](#).

The following example of a default policy contains IPSECRule definitions that allow IKE daemon traffic with the NSS server:

```
IPSEC LOGENable
; Rule      SrcAddr DstAddr  Logging Protocol  SrcPort  DestPort  Routing Secclass
; OSPF protocol used by Omproute
IPSECRule *      *      NOLOG   PROTO OSPF
; IGMP protocol used by Omproute
IPSECRule *      *      NOLOG   PROTO 2
; DNS queries to UDP port 53
IPSECRule *      *      NOLOG   PROTO UDP  SRCPort *  DESTport 53
; Administrative access
IPSECRule *      9.1.1.2  LOG                      SECClass 100
```

```

; IKE daemon access to the Network Security Server
IPSECRule * * LOG TCP SRCPort * DESTport 4159

; IKE daemon access to the Network Security Server
IPSEC6Rule * * LOG TCP SRCPort * DESTport 4159

ENDIPSEC

```

Rule: The DESTport value in the filter rules must include the value specified for the NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the IKE daemon configuration file.

- IP security filter policy is defined in Policy Agent configuration files. IP security filter policy must be updated to permit communications between the IKE daemon and the NSS server. For details about Policy Agent and policy applications, see [z/OS Communications Server: IP Configuration Reference](#).

The following example shows an IpFilterRule statement for IPv4, an IpFilterRule statement for IPv6, and an IpGenericFilterAction statement that allow the IKE daemon to communicate with the NSS server:

```

IpFilterRule          NssTrafficIPv4
{
  IpSourceAddr        all4
  IpDestAddr          all4
  IpService
  {
    SourcePortRange    1024 65535
    DestinationPortRange 4159
    Protocol            tcp
    Direction          bidirectional OutboundConnect
    Routing             local
  }
  IpGenericFilterActionRef permit-nolog
}

IpFilterRule          NssTrafficIPv6
{
  IpSourceAddr        all6
  IpDestAddr          all6
  IpService
  {
    SourcePortRange    1024 65535
    DestinationPortRange 4159
    Protocol            tcp
    Direction          bidirectional InboundConnect
    Routing             local
  }
  IpGenericFilterActionRef permit-nolog
}

IpGenericFilterAction permit-nolog
{
  IpFilterAction      permit
  IpFilterLogging      no
}

```

Rule: The DestinationPortRange value on the IpService statement must include the value specified on the NetworkSecurityServer port parameter or the NetworkSecurityServerBackup port parameter in the IKE daemon configuration file.

Starting the IKE daemon

After the necessary external security manager authorization has been defined (see “[Step 3: Authorizing the IKE daemon to the external security manager](#)” on page 1392), the IKE daemon can be started from an MVS procedure, from the z/OS shell, or using the AUTOLOG statement.

- You can start the IKE daemon procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(IKED).
- You can start the IKE daemon from the z/OS shell by starting OMVS and then issuing the iked command.

- You can use the AUTOLOG statement to start the IKE daemon automatically during TCP/IP initialization by inserting the name of the IKE daemon start procedure into the AUTOLOG statement in the PROFILE.TCPIP data set:

```
AUTOLOG
  IKED
ENDAUTOLOG
```

Tips:

- When implementing multiple stacks enabled for IP security, adding an AUTOLOG statement for the IKE daemon might not be optimal. If the IKE daemon is listed in an AUTOLOG statement of a stack's profile, the IKE daemon is cancelled if it is already running when that stack starts. In a multiple IP security stack environment, this could disrupt traffic on other IP security stacks. Use another method to automate starting the IKE daemon when the system is IPLed, such as using the COMMNDxx member of PARMLIB. For more information about the use and configuration of the [COMMNDxx](#) member of PARMLIB, see [z/OS MVS Initialization and Tuning Reference](#).
- If you start the IKE daemon from the z/OS shell and you stop the shell environment from scrolling, then when the daemon needs to display data to the shell it might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.

When running from an MVS procedure, the environment variables can be set using the STDENV DD statement in the IKE daemon procedure. For information concerning the environment variables used by IKE daemon, see step “7” on page 1074 in [“Steps for configuring the IKE daemon”](#) on page 1073.

The /var/ike/iked.pid is a temporary IKE daemon pid file that the IKE daemon creates. This file contains the process ID of the current invocation of the IKE daemon.

Restrictions:

- If /var/ike/iked.pid is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the IKE daemon.
- If /var/ike/iked.pid is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which /var/ike/iked.pid is stored cannot have write access to the directory. Additionally, write access to /var/ike/iked.pid must be limited to the owning UID or group, for example, --w--w----permissions.

Stopping the IKE daemon

The IKE daemon can be stopped as follows:

- From MVS, issue:

```
STOP procname
```

If the IKE daemon was started from a cataloged procedure, *procname* is the member name of that procedure. If the IKE daemon was started from the z/OS shell and the environment variable _BPX_JOBNAME was set, *procname* is the same as _BPX_JOBNAME. If the IKE daemon was started from the z/OS shell and _BPX_JOBNAME was not set, *procname* is based on the *userid*. If the *userid* is 8-character long, the *procname* is the *userid*. If the *userid* is less than 8-character long, the *procname* is *useridX*, where X is the sequence number set by the system. To determine the sequence number, from the SDSF LOG window on TSO, issue:

```
/d omvs,u=userid
```

This command shows the programs running under this user ID. For more information on [Commonly used environment variables](#), see [z/OS UNIX System Services Planning](#).

- From a superuser ID in the z/OS shell, issue the kill command to the process ID (PID) associated with the IKE daemon. The IKE daemon PID is recorded in /var/ike/iked.pid.

Controlling the IKE daemon

You can control the IKE daemon from the operator's console using the MODIFY command. MODIFY commands are available to perform the following functions:

- Rereading the configuration file

The MODIFY *procname*,REFRESH command is used to reread the IKE daemon configuration file. Not all IkeConfig statement parameters can be updated using this command. For information on which parameters can be dynamically changed, see the parameter descriptions for the IkeConfig statement of the [IKE daemon configuration file statements](#) in the [z/OS Communications Server: IP Configuration Reference](#).

- Displaying the configuration file parameters

The MODIFY *procname*,DISPLAY command is used to display configuration values currently being used by the IKE daemon.

For more information on the [MODIFY command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Verifying policy installation

This topic describes the console messages and commands that are used to verify policy installation.

Console messages

After the IP security policy has been configured, start the TCP/IP stacks, Policy Agent, and the IKED. A series of console messages is issued if the installation of IP security policy was successful.

The following console messages indicate that Policy Agent and IKE have completed initialization:

```
EZZ8432I PAGENT INITIALIZATION COMPLETE  
EZD1046I IKE INITIALIZATION COMPLETE
```

The following console messages indicate that the processing of IP security policy is complete:

```
EZZ8771I PAGENT CONFIG POLICY PROCESSING COMPLETE FOR TCPCS : IPSEC  
EZD1068I IKE POLICY UPDATED FOR STACK TCPCS
```

If there were errors in the configuration files, Policy Agent issues the following message to the console:

```
EZZ8438I PAGENT POLICY DEFINITIONS CONTAIN ERRORS FOR TCPCS : IPSEC
```

Look at the Policy Agent log to find and correct the error.

Displaying TCP/IP configuration

To display whether the TCP/IP stack is configured with IPCONFIG IPSECURITY, issue the **netstat -f** command and look for the following field in the IPv4 Configuration Table section:

```
IpSecurity: Yes
```

To display whether the TCP/IP stack is configured with IPCONFIG6 IPSECURITY, issue the **netstat -f** command and look for the following field in the IPv6 Configuration Table section:

```
IpSecurity: Yes
```

To display whether the TCP/IP stack is configured for Sysplex-Wide Security Associations, issue the **ipsec -f display** command. The DVIPSec field in the header of the command display shows whether or not the DVIPSEC keyword has been coded in the TCP/IP profile:

```
ipsec -f display | head -n 7
```

```
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 10:52:03 2010
Primary: Filter Function: Display Format: Detail
Source: Stack Policy Scope: Current TotAvail: 137
Logging: On Predecap: Off DVIPSec: Yes
NatKeepAlive: 20 FIPS140: No
Defensive Mode: Inactive
```

Displaying active filters with the ipsec command

Use the **ipsec -f display** command to display active filter rules, configured filter rules from IP security policy configuration files, and the default IP filter rules from the TCP/IP profile. The scope on the command, as indicated by the **-c** option, determines which source is queried:

-c policy

Shows IP filters as configured in the IP security policy configuration files.

-c profile

Shows default IP filters as configured in the TCP/IP profile.

-c current

Shows active IP filters in the stack. The active filters that are shown can be the default IP filters as defined in the TCP/IP profile, or IP filters as configured in the IP security policy configuration files, depending on which policy is active at the time the command is issued. The output of the display indicates the source of the current active filters.

The output of the command can be quite voluminous, so you might want to redirect the output of the display to a file.

The information in the report header of the report output indicates how many filters are active, and also indicates the source of the filters, whether from the default IP filter policy or the IP security policy from the Policy Agent.

```
ipsec -f display
```

```
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 10:53:12 2010
Primary: Filter Function: Display Format: Detail
Source: Stack Profile Scope: Current TotAvail: 14
Logging: On Predecap: Off DVIPSec: Yes
NatKeepAlive: 20 FIPS140: No
Defensive Mode: Inactive
```

If the source field shows **Stack Policy**, the IP security policy is installed and active.

If the source field shows **Stack Profile**, the IP security policy is either not installed or the **ipsec -f default** command was issued. Either issue the **ipsec -f reload** command, or correct the IP security policy configuration.

Filter displays can be abbreviated to include only specific named rules. To view a named filter rule, use the **-n** option as follows:

```
ipsec -f display -n Rule2Admin
```

```
CS V2R1 ipsec Stack Name: TCPCS Tue Feb 14 10:54:36 2012
Primary: Filter Function: Display Format: Detail
Source: Stack Policy Scope: Current TotAvail: 137
Logging: On Predecap: Off DVIPSec: Yes
NatKeepAlive: 20 FIPS140: No
Defensive Mode: Inactive

Anchor filters and dynamic filters

After a Security Association is negotiated, the **ipsec -f display** command shows the addition of two dynamic filters that were created when the Security Association was created, corresponding to the inbound and outbound anchor filters. Dynamic filters are placed ahead of the anchor filters in the filter table, so dynamic filters are searched first when IP filtering is performed. In the following sample output, note that two dynamic filters have been added to the filter table subsequent to the activation of a phase 2 Security Association. The Type field indicates whether the filter is a dynamic anchor filter or a dynamic filter:

```

ipsec -f dis -n Rule2Admin

The inbound dynamic anchor filter protects TCP traffic from source address 9.6.0.0/16, source port any, to destination address 9.3.3.3, destination port 21. The inbound NATT anchor filter protects TCP traffic from source address 9.5.5.5, source port any, to destination address 9.3.3.3, destination port 21. The two inbound NATT dynamic filters also protect TCP traffic from source address 9.5.5.5, source port any, to

destination address 9.3.3.3, destination port 21. However, the two NATT dynamic filters were negotiated for separate clients behind the security gateway. You can see that the first inbound NATT dynamic is for a host behind the security gateway using internal address 10.3.1.1 (value in the RmtIDpayload field).

The second inbound NATT dynamic is for a host behind the security gateway using internal address 10.3.2.2. The internal address of the data endpoint is what makes each NATT dynamic unique.

NAT resolution filters

Use the -h option on the **ipsec -f** command to display any NRFs associated with the displayed filters. After two clients behind the security gateway connect to host 9.3.3.3 using FTP, the NRFs might look like the following display. (The display is truncated to include only the NRFs.)

```

There are two NRF inbound/outbound entry pairs associated with the NATT anchor. In this example, two clients behind the security gateway have an FTP connection with host 9.3.3.3. The first outbound NRF entry is for:

```
source address 9.3.3.3, source port 21
destination address 9.5.5.5, destination port 34732
protocol TCP
```

The destination port is shown in the DestPort field. This value can be a translated value. The OrigRmtConnPort field indicates the original remote connection port, prior to remote port translation by Communications Server. In this example, the first outbound NRF shows that DestPort and OrigRmtConnPort are both 34732. For more information, see [“Remote port translation” on page 962](#).

The second outbound NRF entry is for:

```
source address 9.3.3.3, source port 21
destination address 9.5.5.5, destination port 65535
protocol TCP
```

The original remote connection port (OrigRmtConnPort) is 34732. Because the values in DestPort and OrigRmtConnPort do not match, you can tell that the value was translated by Communications Server's remote port translation function. For more information, see [“Remote port translation” on page 962](#).

The TunnelID field provides information on which phase 2 Security Association the traffic will be sent over. In this example, the phase two Security Associations are identified by the labels Y2 and Y3 respectively.

Displaying remote port translation with the ipsec command

As seen in [“NAT resolution filters” on page 1090](#), the remote data endpoint is represented by the security gateway's public IP address (9.5.5.5), not the client's IP address (10.3.1.1 or 10.3.2.2). Using the **ipsec -o display** command after the activation of two FTP connections in the branch office with NAT model, the port mappings are shown in the following display:

```
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:43:55 2010
Primary: NATT Port Trans Function: Display Format: Detail
Source: Stack Scope: Current TotAvail: 2

RmtIpAddress: 9.5.5.5
Protocol: TCP(6)
TransRmtConnPort: 34732
OrigRmtConnPort: 34732
RmtInnerIpAddress: 10.3.1.1
*****
RmtIpAddress: 9.5.5.5
Protocol: TCP(6)
TransRmtConnPort: 65535
OrigRmtConnPort: 34732
RmtInnerIpAddress: 10.3.2.2
*****

2 entries selected
```

In both entries, you can see that the remote IP address (RmtIpAddress) value is 9.5.5.5, the IP address of the branch office gateway, the protocol is TCP (6), and the original remote connection port (OrigRmtConnPort) is 34732. The first entry shows that the translated remote connection port (TransRmtConnPort) is also 34732. The remote inner IP address contains the private address of the client behind the security gateway that initiated the connection, 10.3.1.1. The second entry shows that the remote connection port was translated to a value of 65535 (TransRmtConnPort), and that the client initiating the connection is using private IP address 10.3.2.2.

[Table 54 on page 1094](#) details several places where one or both of the remote port values are displayed or used for a selection.

Table 54. Original and translated port values

Function	How remote port values are used	Which remote port, original or translated?
Netstat displays of connection data, such as Netstat ALL/-A, Netstat ALLConn/-a, and Netstat CConn/-c	The Netstat command has many options to display connection information, including the remote port value. In some cases, the Netstat command takes a remote port value as a selector.	Translated remote port
Netstat display of the VIPA connection routing table (netstat VCRT/-V)	This command displays the remote port value in the sport or Source field, depending on the flavor of the report generated, and allows you to select based on port.	Translated remote port
Packet trace	Packet trace displays packet data as it was received or sent. If the packet is authenticated but not encrypted, the port is visible in the packet trace data.	Original remote port
<p>IPSecurity syslog messages:</p> <ul style="list-style-type: none"> • EZD0814I packet permitted • EZD0815I packet denied by policy • EZD0821I packet denied, no tunnel • EZD0822I packet denied, tunnel inactive • EZD0832I packet denied by NAT traversal processing • EZD0833I packet denied, tunnel mismatch • EZD0836I packet permitted <p>Defensive filtering syslog messages:</p> <ul style="list-style-type: none"> • EZD1721I packet denied by defensive filter • EZD1722I packet would have been denied by defensive filter 	For an inbound packet, the sport field in these messages contains a remote port value. For an outbound packet, the dport field in these messages contains a remote port value. These messages also have an origport field.	The sport and dport fields contain the translated remote port, and the origport field contains the original remote port.

Table 54. Original and translated port values (continued)		
Function	How remote port values are used	Which remote port, original or translated?
Dynamic anchor, displayed with the ipsec -f command and the ipsec -t command	The dynamic anchor that is configured in the Policy Agent configuration file can specify the remote port as a single port, a range of ports, or all ports. This specification of the remote port controls the range of ports that the original port can be translated to. Both the original port and the translated port for a connection will fit the range of ports coded.	The configured remote port value is displayed. A packet's original port is used to match on this rule. Both the original port and translated port are included in the remote port value displayed.
NATT anchor, displayed with the ipsec -f command and the ipsec -t command	The NATT anchor, which is created as a result of the Security Association negotiation, contains a specific remote port or all ports.	Original remote port if specific port displayed
NATT dynamic, displayed with the ipsec -f command and the ipsec -t command	The NATT dynamic, which is created as a result of the Security Association negotiation, contains a specific remote port or all ports.	Original remote port if specific port displayed
NAT resolution filter (NRF), displayed with the ipsec -f command with the -h option	The NAT resolution filter is a connection level filter, and contains both the translated remote port and the original remote port.	Translated remote port and original remote port. A packet's translated port is used to match on this rule.
ipsec -t command	The ipsec traffic test command allows a remote port value to be specified as a filter selection criteria.	Original remote port

Displaying Security Associations with the ipsec command

Use the **ipsec** command to verify Security Associations.

Displaying IKE tunnel information with the ipsec command

Use the **ipsec -k display** command to display IKE tunnel information.

ipsec -k display

```

```

The setting of the AllowNat field indicates whether or not NAT traversal support was advertised to the IKE peer. If AllowNat is Yes, the negotiation might or might not have detected a NAT. If the NATInFrntLclScEndPnt field is Yes, a NAT device was detected in front of the local security endpoint. If the NATInFrntRmtScEndPt field is Yes, a NAT device was detected in front of the remote security endpoint.

Displaying IPsec tunnel information with the ipsec command

Use the **ipsec -y display** command to display IPsec tunnel information.

```

ipsec -y display -a Y39

```

The NAT Traversal Topology fields show additional information when a NAT was detected in the path between the IKE peers. The setting of the UdpEncapMode field indicates whether a UDP-encapsulated mode Security Association has or has not been negotiated. If NAT Traversal is supported by both IKE peers and one or more NATs are detected, UdpEncapMode is set to Yes. The RmtNATDetected field is Yes if a NAT is detected in front of the remote peer. The RmtIsGW field is Yes if the remote peer is acting as a security gateway.

Tip: Use the **-b** option of the **ipsec -y display** command to show the ports and protocols of the dynamic filter that are associated with the phase 2 Security Association. The following excerpt from the **ipsec -y display** using the **-b** option indicates a Telnet connection from a remote host:

```

AssociatedFiltProtocol: TCP(6)
AssociatedFiltSrcPort:  23
AssociatedFiltDestPort: 0

```

Displaying filter rules with the pasearch command

The configured IP filter rules and associated actions can also be viewed from the perspective of the Policy Agent. The **pasearch** command provides a way to view all Policy Agent configuration, of which IP security is a subset. In contrast to the information that is provided by the **ipsec** command, the detailed information that is provided by the **pasearch** command does not reflect the stack's active use of the IP security policy, but offers a relatively static view of configured IP security values that were generated from the IP security configuration file. For more information on [displaying policy based networking information](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Verifying filter action

To quickly determine which filter rule applies to a specific type of traffic, use the **ipsec** traffic test command (**ipsec -t**). This command returns all of the rules in the current filter table that match the given traffic type.

For example, to test which filter rule matches an incoming FTP connection request from remote IP address 9.1.1.2 to local IP address 9.1.1.1, issue the following command. The input values represent

the remote address, local address, protocol, remote port, local port, direction, and security class of the packet.:

```
ipsec -t 9.1.1.2 9.1.1.1 tcp 0 21 in 0
```

```

```

An incoming FTP connection request matches all of the rules shown in the example. The first rule that is returned does not always match a specific packet, depending on how much detail you provide as the input to the **ipsec -t** command. However, the Rule2Admin rule is the best match in this case, so the search for a matching filter ends there. The matching rule in this case is an ipsec rule, as indicated by the designation `Dynamic Anchor`. Therefore, IPSec processing is applied to this packet.

Tip: When using the **ipsec -t** command, provide as much detailed input as possible. The more detailed the input to the command, the more narrow the results of the search will be.

For detailed information about the use of the [ipsec command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Security Associations

This topic includes the following subtopics:

- Activating a Security Association
- Verifying the activation of a Security Association
- Verifying the use of an active Security Association
- Refreshing Security Associations
- Deactivating Security Associations

Activating a Security Association

Negotiations can be initiated in one of four ways:

- Remote activation

When a remote IKE peer initiates a negotiation with the local IKE daemon, no action is required. If the IP security policy has been configured correctly and is consistent with the policy of the remote IKE peer, a Security Association is established. No operator message is issued when a remote activation has occurred, but the syslog does contain a record of all IKE activity. The **ipsec -y display** command can also be used to view all of the active Security Associations.

- On-demand activation

An on-demand Security Association is activated when some outbound traffic matches an ipsec rule that allows on-demand activation. The `ondemand` field of the filter display indicates whether or not on-demand activation is allowed for that rule.

- Automatic activation

The local IKE daemon initiates a negotiation for an autoactivated Security Association when it connects to the TCP/IP stack. IKE also initiates a negotiation for an autoactivated Security Association when the **ipsec -f reload** command is issued, changing the active filter rule set from default IP filter rules to Policy Agent filter rules. No operator message is issued when an autoactivation has occurred, but the syslog does contain a record of all IKE activity. The **ipsec -y display** command can also be used to view all of the active Security Associations.

- Command-line activation

The **ipsec** command can be used as follows to activate a Security Association that has been defined by a LocalDynVpnRule statement:

```
ipsec -y activate -l ZoneC_VPN-EE1

CS V1R12 ipsec Stack Name: TCPCS Wed Feb 3 16:02:05 2010
Primary: Dynamic tunnel Function: Activate

Selection Data                                Status
ZoneC_VPN-EE1                                Activating
```

The output of the command indicates the status of the activation.

For detailed information about the use of the [ipsec command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Verifying the activation of a Security Association

After a Security Association has been activated, it can be displayed with the **ipsec -y display** command. To view all active Security Associations, issue the following command:

```
ipsec -y display
```

You can use the **ipsec** command to view all of the active phase 1 Security Associations, or limit the report to a single phase 1 Security Association by using the `-a` option.

For detailed information about the use of the [ipsec command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Verifying the use of an active Security Association

If filter logging is enabled for the selected filter rule, the log indicates whether a packet has been permitted with IPSec processing applied. Among the information available for a typical filter log entry are the rule name, the action, and the tunnel ID:

```
Feb 13 18:09:11 MVS175/TRMD TRMD1 TRMD.TCPCS2[28]: EZD0814I Packet
permitted: 02/13/2010 18:09:05.96 filter rule= Rule2Admin ext= 1 sipaddr=
9.1.1.2 dipaddr= 9.1.1.1 proto= tcp(6) sport= 3755 dport= 21 -=
Interface= 9.1.1.1 (I) secclass= 255 dest= local len= 52 vpnaction=
Silver-TransportMode tunnelID= Y58 ifcname= MPC4142L fragment= N
```

The **ipsec -y display** command also outputs a field with the number of bytes of traffic that have been protected by a particular Security Association.

For detailed information about the use of the **ipsec** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Refreshing Security Associations

When a Security Association is refreshed, the encryption keys change. Refreshing a Security Association periodically prevents the keys from being compromised by an outside party. Phase 1 and phase 2 Security Associations are refreshed automatically, based on the lifetime or life size that was configured for IKEv2 or negotiated between the two IKE peers for IKEv1. When a lifetime expiration causes an IKEv2 phase 1 Security Association to refresh, the encryption key changes but the peer is not reauthenticated. Changing the key without reauthenticating the peer reduces CPU cost.

Tip: For phase 1, these parameters are specified in the KeyExchangeOffer statement. For phase 2, these parameters are specified in the IpDataOffer statement.

You can also refresh Security Associations from the z/OS UNIX command line, but this should be necessary only in exceptional conditions because the IKE daemon is normally responsible for refreshing the keys at configured intervals. Exceptional conditions might include the compromise of a key or the failure to receive an informational IKE message from a remote host. For both IKEv1 and IKEv2 Phase 1 Security Associations, refreshes from the z/OS UNIX command line include both reauthentication and re-keying.

Phase 1

Each phase 1 Security Association is identified by a tunnel ID, a number with a prefix of K. To manually refresh a phase 1 Security Association, issue the **ipsec -k display** command to find the tunnel ID. Then issue the **ipsec -k refresh** command for that ID as follows:

```
ipsec -k refresh -a K1
```

```
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:48:04 2010
Primary: IKE tunnel Function: Refresh
```

Tunnel ID	Status
K1	Refreshing

For detailed information about the use of the **ipsec** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Phase 2

Each phase 2 Security Association is identified by a tunnel ID, a number with a prefix of Y. To manually refresh a phase 2 Security Association, issue the **ipsec -y display** command to find the tunnel ID. Then issue the **ipsec -y refresh** command for that ID as follows:

```
ipsec -y refresh -a Y2
```

```
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:48:04 2010
Primary: Dynamic tunnel Function: Refresh
```

Tunnel ID	LocalDynVpnRuleName	Status
Y2	ZoneC_VPN-EE1	Refreshing

The phase 2 Security Association can also be identified by the local dynamic VPN rule with which it is associated, if one exists, as follows:

```
ipsec -y refresh -l ZoneC_VPN-EE1
```

```
CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:48:04 2010
Primary: Dynamic tunnel Function: Refresh
```

Tunnel ID Y2	LocalDynVpnRuleName ZoneC_VPN-EE1	Status Refreshing
-----------------	--------------------------------------	----------------------

For detailed information about the use of the [ipsec command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Deactivating Security Associations

When a Security Association is deleted, all of the information that is stored in the Security Association is deleted from the TCP/IP stack and from the IKED, along with the dynamic filters that were created when the Security Association was created. After deletion, the Security Association is no longer available for use. Traffic that was protected by the old Security Association is denied until a new Security Association is subsequently activated.

When a parent phase 1 Security Association is deactivated, all of the associated phase 2 Security Associations are deleted as well. Be careful when deleting phase 1 Security Associations, because all traffic that uses the Security Association and its associated phase 2 Security Associations are dropped until new Security Associations can be negotiated.

- To delete a phase 1 Security Association and all of the phase 2 Security Associations it is protecting, issue the following command:

```
ipsec -k deactivate -a K1

CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:48:04 2010
Primary: IKE tunnel Function: Deactivate

Tunnel ID      Status
K1             Deactivating
```

- To delete all phase 1 Security Associations and all phase 2 Security Associations, use the **-a all** option as follows:

```
ipsec -k deactivate -a all

CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:48:04 2010
Primary: IKE tunnel Function: Deactivate

All IKE tunnels Deactivating
```

- To delete a phase 2 Security Association, issue the following command:

```
ipsec -y deactivate -a Y2

CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:48:04 2010
Primary: Dynamic tunnel Function: Deactivate

Tunnel ID      LocalDynVpnRuleName      Status
Y2             n/a                       Deactivating
```

The n/a in the LocalDynVpnRuleName field indicates that no local dynamic VPN rule name is associated with this Security Association. The Security Association was either remotely activated or was activated on-demand.

- To delete all phase 2 Security Associations, use the **-a all** option as follows:

```
ipsec -y deactivate -a all

CS V1R12 ipsec Stack Name: TCPCS Tue Feb 16 11:48:04 2010
Primary: Dynamic tunnel Function: Deactivate

All dynamic tunnels Deactivating
```

For detailed information about the use of the [ipsec command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Modifying active IP security policy

This topic describes the effects of changes to security-related files and of issuing the **ipsec -f default** command.

IP security policy files

The IP security configuration files for a TCP/IP stack that has the IPSECURITY parameter defined can be modified while the stack is active in the following ways:

- Policy Agent configuration, including IP security, is updated at each configured refresh interval that is specified on the TcpImage statement for local policies or on the DynamicConfigPolicyLoad statement for remote policies. The default is 30 minutes.
- If Policy Agent was started with the **-i** option and the configuration files are stored in a z/OS UNIX file, changes to any of the configuration files are detected and updated dynamically without user intervention. The **-i** option has no effect when the policies are stored in remote configuration files on the policy server.
- Policy Agent configuration, including IP security, can be updated at any time by issuing the MODIFY PAGENT,REFRESH command or the MODIFY PAGENT,UPDATE command from the console of the policy client.

Policy Agent image configuration files

For an active TCP/IP stack with IPSECURITY defined, the following conditions apply:

- Changing the file name that is identified by an existing IpSecConfig or DynamicConfigPolicyLoad statement causes Policy Agent to update and install the IP security policy as defined in the new file. If the new IP security policy file contains errors, the policy is not updated and the existing IP security policy remains in effect.
- For local IP security policies, removing an existing IpSecConfig statement from a Policy Agent image configuration file activates the default IP filter policy.
- For remote IP security policies, removing the PolicyServer statement (or the PolicyType IPsec parameter on that statement) from a Policy Agent image configuration file activates the default IP filter policy, assuming that no local IP security policy is defined using the IpSecConfig statement.

Policy Agent main configuration file

For an active TCP/IP stack with IPSECURITY defined, removing an existing TcpImage statement from the Policy Agent configuration file has the following effects on IP security policy:

- Existing IP filters remain.
- Existing Security Associations remain.
- Traffic continues to flow in the same way it did before the TcpImage statement was removed, including IPsec-protected traffic.
- New Security Associations cannot be activated.
- Existing Security Associations cannot be refreshed and are deleted when the refresh period expires.

If the intent of removing the TcpImage statement is to remove IP filters from the stack, an alternative is to modify the IP security policy to install a filter rule that permits all inbound and outbound traffic. Also, before restarting the stack, the IPSECURITY parameter should be removed from the IPCONFIG statement of the relevant stack.

Active Security Associations and the ipsec -f default command

Any active Security Associations that were negotiated for IPsec-protected traffic are not deleted when the **ipsec -f default** command is issued. However, they are deleted if, while the default policy is in effect, any associated IP filter rules from the IP filter policy are deleted or modified in such a way that

the filter rule no longer encompasses the scope of the Security Association. In that case, the Security Association will be deleted when the IP security policy is reloaded.

For example, Security Associations are not deleted by the following sequence of actions:

1. The **ipsec -f default** command is issued.
Security Associations remain active in the stack and in IKE, though unavailable for use.
2. No modification is made to the IP filter policy in the IP security configuration files.
Security Associations remain active in the stack and in IKE, though unavailable for use.
3. The **ipsec -f reload** command is issued.
Security Associations remain active in the stack and in IKE, and are available for use.

Security Associations are deleted by the following sequence of actions:

1. The **ipsec -f default** command is issued.
Security Associations remain active in the stack and in IKE.
2. The IpFilterRule statement that is associated with an active Security Association is deleted.
3. The IP security policy is updated by issuing the MODIFY PAGENT,REFRESH command from the console.
Existing Security Associations are deleted.
4. The **ipsec -f reload** command is issued.
Security Associations have been deleted.

In either case, Security Associations are never available for use when the default IP filter policy is in effect.

Displaying NSS client information

Use the NssStackConfig statement to configure a stack as an NSS client. Use the -w primary option on the **ipsec** command to determine which active stacks are configured as NSS clients, as well as their current status.

ipsec -w display

For complete details about the `ipsec` command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Sysplex-Wide Security Associations and IP security

z/OS IP security supports Sysplex-Wide Security Associations (SWSA). In a sysplex environment, SWSA distributes IPSec Security Associations (SAs) to the target stacks of distributed DVIPAs. To enable this support for IPv4 DVIPAs, you must code `IPCONFIG IPSECURITY` in the TCP/IP profile and `DVIPSEC` in the IPSEC block. To enable this support for IPv6 DVIPAs, you must code `IPCONFIG6 IPSECURITY`, in addition to `IPCONFIG IPSECURITY` and `DVIPSEC`.

You should add `DVLOCALFLTR`, the `DVIPSEC` subparameter, to the IPSEC statement block of the TCP/IP profile when intra-sysplex traffic should be protected by security associations. `DVLOCALFLTR` enables IP filtering and IPSec protection of TCP traffic between a client and an IPv4 dynamic VIPA that are defined on the same TCP/IP stack, when the traffic is forwarded to another TCP/IP stack. When the `DVLOCALFLTR` parameter is configured, ensure that the IPSec policy accounts for all local TCP traffic with an IPv4 dynamic VIPA endpoint. Traffic that does not match a configured IP filter rule is denied.

Restrictions:

- The IKEv1 protocol cannot be used to negotiate a tunnel between a client and an IPv4 dynamic VIPA that are defined on the same TCP/IP stack. You must use the IKEv2 protocol to negotiate a tunnel to protect the traffic. Use `HowToInitiate IKEv2` on the `KeyExchangePolicy` statement or a specific `KeyExchangeAction` statement to indicate that the IKEv2 protocol must be used when this system starts key negotiations.
- A tunnel cannot be negotiated if the source and destination IP addresses for client connections are the same dynamic VIPA. To help avoid this scenario, do not code a dynamic VIPA that can be used as a destination IP address on the `TCPCONFIG TCPSTACKSOURCEVIPA` or `SRCIP` statement in the TCP/IP profile.

In a sysplex environment, the IKE daemon can detect movement of a DVIPA to or from an IP security stack. To reestablish the Security Associations of a DVIPA, the `DVIPSEC` parameter must be specified in the TCP/IP profile of the stack from which the DVIPA is being moved and in the TCP/IP profile of the stack to which the DVIPA is being moved. For details about this movement, see [“Sysplex-Wide Security Associations”](#) on page 424. For information about the `IPCONFIG` statement, `IPCONFIG6`, and `IPSEC`

statement statements that need to be added to the TCP/IP profile to configure this support, see [z/OS Communications Server: IP Configuration Reference](#).

When a DVIPA is moved from one IP security stack in a sysplex to another IP security stack, and both stacks have the DVIPSEC option specified, an attempt is made to automatically reestablish Security Associations on the backup stack. The IKE daemon on the system that is assuming control of the DVIPA attempts to renegotiate new Security Associations to replace the ones that were on the system that previously owned the DVIPA. If these attempts fail due to configuration errors or connectivity errors, manual intervention might be required. Phase 1 Security Association or phase 2 Security Association negotiations that were in progress at the time of the DVIPA movement are lost. However, if these negotiations were for a refresh, a new negotiation is started in the process of assuming control of the DVIPA.

When a DVIPA is moved from one IP security stack in a sysplex to another IP security stack, and one or both stacks do not have the DVIPSEC option specified, the Security Associations that are associated with that DVIPA must be reestablished by issuing the **ipsec** command, on-demand activation, or by a peer initiation.

Guidelines:

- If a DVIPA is manually deleted and that address has no backup, the IKE daemon might not be able to terminate the tunnels in which the DVIPA is a security endpoint. To avoid this problem, use the **ipsec** command to deactivate the DVIPA's IKE tunnels before manually deleting the DVIPA.
- This support does not address the dynamic relocation of static filter rules and VPN policy definitions to the target system in the sysplex. It is up to you to ensure that the necessary filter rules and IP security policy definitions exist on all participating systems in the sysplex. If the necessary filter rules and IP security policy definitions do not exist, the IKE daemon might not be able to reestablish all Security Associations. For a description of the SWSA function, see [“Sysplex-Wide Security Associations” on page 424](#).

Rule: Because the renegotiation of a Security Association after a DVIPA move requires the sysplex stack to initiate an IKE negotiation, the sysplex stack must be allowed to initiate. You must code the Initiation attribute on the IpDynVpnAction statement as `localonly` or `either`.

NAT traversal and Sysplex-Wide Security Associations

The following topics describe Sysplex-Wide Security Associations (SWSA) in NAT traversal (NATT) configurations.

AES-GCM

When the AES-GCM combined-mode encryption and authentication algorithm is negotiated for an SA, decapsulation of all packets over that SA occurs on the distributing stack, and the decapsulated packets are forwarded to the target stack.

DVIPA recovery support

In NATT configurations where IKE can act only as the responder, sysplex distribution is possible but the recovery of the Security Associations when the DVIPA moves is not supported. There are two NATT configurations in which IKE can act only as the responder:

- When the IKE peer is a security gateway and a NAT is being traversed
- When the IKE peer is behind a NAPT

For more information about NATT configurations, as well as interoperability considerations, see [“Configuration scenarios supported for NAT traversal” on page 1064](#).

When only one client behind a NAPT has negotiated a Security Association, it is not always possible for the server to detect whether one-to-one address translation or many-to-one address port translation (NAPT) is being done. When multiple clients have active Security Associations, the server can detect that port translation is being done. If z/OS cannot determine that a Security Association is negotiated with a

remote peer behind a NAT, the Security Association is treated as if it is being negotiated with a remote peer using one-to-one address translation.

When IKE is limited to only a responder role, the Security Association must be reestablished by peer initiation. The interoperability considerations for establishing an initial phase 2 Security Association are relevant to the renegotiation of the phase 2 Security Association due to the movement of a DVIPA. For example, a host-to-host UDP-encapsulated tunnel mode Security Association protecting specific protocols or ports that was initially initiated from a non-z/OS client might not be able to be renegotiated when the z/OS system assuming control of the DVIPA initiates the negotiation. In this case, the Security Association must be reestablished by peer initiation.

FIPS 140 mode and Sysplex-Wide Security Associations

To enable FIPS 140 mode in a sysplex, you should enable FIPS 140 mode for all the TCP/IP stacks, IKE daemons, and network security services (NSS) daemons on all systems in the sysplex. If the FIPS 140 mode of the distributing TCP/IP stack in the sysplex is different than the FIPS 140 mode of the target TCP/IP stacks, distribution of some of the tunnels across the target TCP/IP stacks might not function as expected.

If the distributor is configured with FIPS 140 support, then all of the tunnels that it activates will adhere to the FIPS 140 restrictions (for example, DES encryption is not allowed). All target TCP/IP stacks can use the distributed tunnels and can process the distributed traffic, regardless of their FIPS 140 mode. The targets that are configured without FIPS 140 support might not adhere to the strict cryptographic module boundaries as defined by FIPS 140, but the Security Association will be successfully activated and used.

If the distributor is not configured with FIPS 140 support, it might activate Security Associations that do not adhere to the FIPS 140 restrictions. The distributor can successfully distribute those associations to target TCP/IP stacks that are not configured in FIPS 140 mode. However, if the distributor distributes those associations to target TCP/IP stacks that are configured in FIPS 140 mode, the data flowing over connections to those stacks is discarded because the associated Security Association or tunnel is not installed.

The distributor and its backup can be configured differently with respect to the FIPS 140 mode. When a backup takes over from a distributor, all the IP security tunnels are renegotiated by the backup. The renegotiated tunnels operate at the FIPS 140 mode that is defined on the backup distributor. This can change the operation of the tunnels as they are distributed by the backup. If the distributor is configured with FIPS 140 support and its backup is not, the backup might activate Security Associations that do not adhere to the FIPS 140 restrictions and distribution of them might fail.

For more information about enabling FIPS 140 mode in a sysplex environment, see [“Steps for configuring IP security to support FIPS 140 mode” on page 919](#).

Shadow Security Associations

When an IP security stack is the target of a DVIPA, it receives a copy (shadow) of any active Security Associations for the DVIPA. To display the shadow Security Associations, use the following command:

```
ipsec -y display -s
```

```

Sample IP security policy files

A sample stack-specific policy is located in /usr/lpp/tcpip/samples/pagent_IPSec.conf.

A sample common policy is located in /usr/lpp/tcpip/samples/pagent_CommonIPSec.conf.

Chapter 18. Network security services

A network security services (NSS) server provides network security services for one or more security disciplines. Supported disciplines are IPSec, which is a set of services that supports IPSec and IKE processing, and XMLAppliance, which is a set of services for XML appliances. For the IPSec discipline, these services include the IPSec certificate service and the IPSec remote management service. For the XMLAppliance discipline, the NSS server supports the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service. For information about configuring the IKE daemon to act as an NSS IPSec client on behalf of a TCP/IP stack, see [Chapter 17, “IP security,”](#) on page 911.

Terms and concepts for network security services

The following terms and concepts apply to the information about network security services (NSS):

certificate bundle

An X.509 bundle as defined in Section 3.6 of RFC 5996, *Internet Key Exchange Protocol: IKEv2*. A certificate bundle can contain multiple DER encoded certificates and certificate revocation lists (CRLs). You can use the **certbundle** command to create a certificate bundle.

Certificate revocation list (CRL)

A time-stamped list of revoked certificates that is signed by a certificate authority.

CRLDistributionPoints

An optional X.509 certificate extension that identifies one or more locations where the CRL for a certificate is.

hash and URL encoding

A certificate payload encoding that includes the hash of a certificate or bundle and the URL that identifies where that certificate or bundle can be retrieved from an HTTP server

IPSec certificate service

A service for NSS IPSec clients that provides IPSec digital signature and verification services.

IPSec discipline

A set of services provided to an NSS IPSec client. The services are the IPSec certificate service and the IPSec remote management service.

IPSec remote management service

A service for NSS IPSec clients that provides remote IPSec management capability.

Network security services (NSS)

A set of services that performs security enforcement or management. The services are provided in groupings called security disciplines.

NSS client

A client that requests network security services from an NSS server.

NSS daemon (NSSD)

The z/OS UNIX daemon that implements the NSS server functionality.

NSS IPSec client

An NSS client that is using the IPSec discipline. The z/OS IKE daemon can act as an NSS IPSec client for one or more TCP/IP stacks.

NSS server

Provides network security services for one or more NSS clients.

NSS XMLAppliance client

An NSS client that is using the XMLAppliance discipline.

security discipline

A specific grouping of network security services.

trust chain

The signing sequence of certificates for any particular certificate back to a root certificate authority.

XML appliance

A network appliance that processes XML messages efficiently and securely. XML appliances often offload XML parsing and transformations from host systems and implement a variety of XML security features.

XMLAppliance certificate service

A service for NSS XMLAppliance clients that provides key ring listing and certificate retrieval capability.

XMLAppliance discipline

A set of services provided to an NSS XMLAppliance client. The NSS server supports the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service.

XMLAppliance private key service

A service for NSS XMLAppliance clients that provides private key retrieval of private keys that are not protected by Integrated Cryptographic Service Facility (ICSF), RSA signature generation using ICSF-protected private keys, and RSA message decryption using ICSF-protected private keys.

XMLAppliance SAF access service

A service for NSS XMLAppliance clients that provides SAF user authentication and access control capability.

For additional IP security-related terms, see [Chapter 17, “IP security,” on page 911](#).

Network security services overview

Network security services (NSS) includes services that perform security enforcement or management. As shown in [Figure 142 on page 1112](#), NSS includes services provided by the NSS IPSec discipline and NSS XMLAppliance discipline. Each discipline includes a subset of services provided by NSS and is intended for use by a specific type of NSS client.

Figure 142. NSS services by discipline

NSS IPSec discipline overview

The NSS IPSec discipline includes the NSS IPSec certificate service and NSS IPSec remote management service.

The NSS server provides the NSS IPSec certificate service to perform digital signature and verification operations on behalf of an NSS IPSec client. The NSS IPSec certificate service is used by an NSS IPSec client during a phase 1 negotiation when digital signature authentication is required. Certificates and private keys for all NSS IPSec clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates and private keys on this key ring. When providing the NSS IPSec certificate service, the NSS server consults SERVAUTH profiles to verify that an NSS IPSec client is authorized to access the certificates that are involved. For details about these profiles, see step “9.d” on page 1117 and step “9.e” on page 1117, under “Steps for authorizing resources for NSS” on page 1114.

The NSS server uses the NSS IPSec remote management service to request IPSec monitoring data from an NSS IPSec client and to make IPSec control requests to an NSS IPSec client. Control requests include the ability to activate, deactivate, or refresh a Security Association, and to switch between default IP filter policy and IP security filter policy. Use the **ipsec** command and the IPSec network management interface (NMI) to make these requests. For details about the **ipsec** command, see [z/OS Communications Server: IP System Administrator's Commands](#). For details about the IPSec NMI, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

NSS XMLAppliance discipline

The NSS XMLAppliance discipline includes the NSS XMLAppliance SAF access service, the NSS XMLAppliance certificate service, and the NSS XMLAppliance private key service.

An NSS XMLAppliance client uses the NSS XMLAppliance SAF access service to perform SAF user authentication and access control checks. The NSS server consults SERVAUTH profiles for access control checks. For details about these profiles, see step “9.d” on page 1117 and step “9.e” on page 1117, under “Steps for authorizing resources for NSS” on page 1114.

The NSS XMLAppliance certificate service enables an NSS server to provide a list of authorized certificates on its key ring. Those certificates can then be retrieved on behalf of an NSS XMLAppliance client. Certificates for all NSS XMLAppliance clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates on this key ring. When the NSS server provides the NSS XMLAppliance certificate service, it consults SERVAUTH profiles to verify that an NSS XMLAppliance client is authorized to access the certificates involved. For details about these profiles, see step “9.d” on page 1117 and step “9.e” on page 1117, in “Steps for authorizing resources for NSS” on page 1114.

An NSS XMLAppliance client uses the NSS XMLAppliance private key service to retrieve authorized private keys stored in the SAF database of the NSS server. The private key service also enables the NSS server to perform RSA signature and RSA decryption operations using private keys protected by Integrated Cryptographic Service Facility (ICSF) on behalf of an NSS XMLAppliance client. An NSS XMLAppliance client can use a retrievable private key to sign and decrypt XML messages locally. XML appliances that are in less-trusted network zones can use a centralized NSS server to perform critical RSA operations using ICSF-protected private keys on behalf of the appliance. Certificates and private keys for all NSS XMLAppliance clients are stored on a single key ring. The NSS server must have access to this key ring and must have access to the certificates and private keys on this key ring. Retrieval of the private key is not allowed if the private key is stored in the ICSF public key data set (PKDS). When providing NSS XMLAppliance private key service, the NSS server consults SERVAUTH profiles to verify that an NSS XMLAppliance client is authorized to access the certificates and associated keys involved. For details about these profiles, see step “9.d” on page 1117, step “9.e” on page 1117, and step “9.g” on page 1118 under “Steps for authorizing resources for NSS” on page 1114.

Preparing to provide network security services

Before network security services can be provided, authorization to several resources must be defined to the external security manager. This topic also includes NSS server certificate label naming considerations, an NSS client authorization example, information on configuring and controlling the NSS server, and recovery considerations.

Steps for authorizing resources for NSS

Before network security services can be provided, authorization to several resources must be defined to the external security manager.

Before you begin

RACF is used as the external security manager in the following examples. RACF commands shown in these examples are also provided in the EZARACF member of the SEZAINST data set. In these examples, it is assumed that the NSS server is running under the user ID NSSD.

Procedure

Perform the following steps to authorize access to the appropriate resources:

1. Define and authorize the NSSD user ID.

The NSS server is a z/OS UNIX application that you can start from the z/OS UNIX shell or from an MVS started procedure. Before starting the NSS server, you must define the NSSD user ID to the external security manager with UID 0. If you start the NSS server from an MVS started procedure, the NSSD user ID must also be authorized to the STARTED class.

Issue the following commands:

```
ADDUSER NSSD DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
RDEFINE STARTED NSSD.* STDATA(USER(NSSD))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

2. Permit the NSSD user ID to SYS1.PARMLIB.

The NSS server uses the TCP/IP component trace (CTRACE) to perform service-level tracing. The default NSS server component trace parmlib member is stored in SYS1.PARMLIB. The NSSD user ID must be permitted to access SYS1.PARMLIB.

Issue the following command:

```
PERMIT SYS1.PARMLIB ID(NSSD) ACCESS(READ)
```

3. Define key ring controls.

Certificates used by NSS clients are stored on a SAF key ring. The RACDCERT command is used to manage a RACF key ring. The IRR.DIGTCERT FACILITY class resource is used to control access to the RACDCERT command. If these controls do not already exist, they must be defined as follows:

```
RDEFINE FACILITY IRR.DIGTCERT.ADD UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.ADDRING UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.CONNECT UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.GENCERT UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.GENREQ UACC(NONE)
```

For details about these controls, see [z/OS Security Server RACF Command Language Reference](#).

4. Give the user ID of the administrator that will manage the NSS server's key ring appropriate access to manage the key ring.

Issue the following commands:

```
PERMIT IRR.DIGTCERT.ADD CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.ADDRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
PERMIT IRR.DIGTCERT.CONNECT CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.GENCERT CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.GENREQ CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
```

After you permit access to the various IRR.DIGTCERT resources, update the FACILITY class as follows:

```
SETOPTS RACLIST(FACILITY) REFRESH
```

5. Give the NSSD user ID access to the key ring

You must provide appropriate access for the NSSD user ID to its own key ring using the RDATA LIB or FACILITY class. The RDATA LIB class is preferred as it allows for granular authorization to a specified key ring. The FACILITY class allows global authorization to all key rings and certificates. See [z/OS Security Server RACF Callable Services](#) for additional information.

To provide access using the RDATA LIB class:

```
a. Activate and RACLIST the RDATA LIB class if not already active:
SETOPTS CLASSACT(RDATA LIB) RACLIST(RDATA LIB)

b. Define an RDATA LIB profile for the NSSD key ring. Replace keyringname with the name of
the configured key ring.
REDEFINE RDATA LIB NSSD.keyringname.LST UACC(NONE)

c. Permit access to the RDATA LIB profile for the NSSD user ID.
PERMIT NSSD.keyringname.LST CLASS(RDATA LIB) ID(NSSD) ACCESS(READ)

d. When using RDATA LIB to control list access to the NSSD key ring, the administrator's ID
should also be permitted to the RDATA LIB profile.
PERMIT NSSD.keyringname.LST CLASS(RDATA LIB) ID(userid) ACC(UPDATE)

e. Refresh the RDATA LIB class
SETOPTS RACLIST(RDATA LIB) REFRESH
```

To provide access using the FACILITY class:

```
PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(NSSD) ACC(READ)
PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(NSSD) ACC(READ)
```

After you permit access to the various IRR.DIGTCERT resources, update the FACILITY class as follows:

```
SETOPTS RACLIST(FACILITY) REFRESH
```

6. Optionally, permit the NSS server to the BPX.DAEMON FACILITY class profile.

For information concerning the use of the BPX.DAEMON profile, see “[BPX.DAEMON FACILITY class profile](#)” on page 37.

If you decide to use this profile, permit the NSS server user ID to this profile using the following command, where the *userid* value is the user ID under which the NSS server runs:

```
PERMIT BPX.DAEMON CLASS(FACILITY) ID(userid) ACCESS(READ)
```

7. Enable the secured signon function.

The NSS server supports the use of PassTickets. To use this support, the secured signon function must be enabled, and at least one profile must be created for the NSS server.

The secured signon function of RACF is enabled by activating the PTKTDATA class as follows:

```
SETOPTS CLASSACT(PTKTDATA)
SETOPTS RACLIST(PTKTDATA) REFRESH
```

Profiles in the PTKTDATA class control the use of the secured signon function by an application. A secured signon application key is associated with each profile. This key is stored in the external security manager's database. When RACF is used as the external security manager, this key is stored in a masked or encrypted state.

With RACF, you can use a secured signon application key that is controlled at the following levels:

- All users who need access to the application
- A specific RACF group of users who need access to the application
- A specific RACF user, when connected to a specific RACF group

- A specific RACF user

The application name NSSD must be used when defining the secured signon keys for the NSS server. The following example shows a RACF command that you can issue to assign a secured signon key that can be used by all NSS clients that are authenticating to the NSS server:

```
RDEFINE PTKTDATA NSSD SSIGNON(KEYMASKED(E001193519561977)) UACC(NONE)
```

For specific information about enabling the secured signon function and defining profiles to be used by the single signon function, see [z/OS Security Server RACF Security Administrator's Guide](#).

8. Define SERVAUTH profiles to authorize NSS clients to network security services.

These profiles are on the same system as the NSS server. Many of these profiles are constructed using the name of an NSS client. NSS clients must authenticate to the NSS server using a valid user ID and password, or a valid user ID and PassTicket. This user ID must be given access to the SERVAUTH profiles created on behalf of the NSS client.

For details about how to define the IKE daemon as an NSS client, see [“Using network security services”](#) on page 1070.

Perform the following steps to authorize NSS clients:

a. Define a SAF user ID representing an NSS client to the external security manager.

An NSS client must present valid credentials to the NSS server before accessing any services. Valid credentials include a user ID and password, or a user ID and PassTicket if secured signon is enabled. A SAF user ID representing an NSS client must be defined to the external security manager.

Issue the following command:

```
ADDUSER userid DFLTGRP(OMVSGRP) OMVS(UID(x))
```

Rules:

- Multiple NSS clients can use a single user ID. However, each NSS client must have a unique client name.
- A SAF user ID must have an OMVS segment with either AUTOID or a specific UID(x) defined for the NSSD to authenticate it as an NSS client.

Guideline: Because SAF user IDs are used to authorize a client to the NSS services, avoid sharing a single user ID across NSS disciplines.

b. If you choose to define an NSSD profile in the APPL class with UACC(NONE), issue the following command to authorize each SAF user ID to the NSSD application:

```
PERMIT NSSD CLASS(APPL) ID(userid) ACC(READ)
SETROPTS RACLIST(APPL) REFRESH
```

c. Authorize the user ID associated with an NSS client for each of the network security services it will use.

To authorize an NSS client to use a network security service, you must create a SERVAUTH resource profile for that service that represents the NSS client. The user ID associated with the NSS client must be permitted READ access to that profile. [Table 55 on page 1116](#) shows the name of the SERVAUTH profile for each service, where *sysname* is the name of the z/OS system running the NSS server and *clientname* is the name by which the NSS server knows the NSS client.

Table 55. SERVAUTH profile names for NSS

Service	SERVAUTH profile name
IPSec certificate service	EZB.NSS.sysname.clientname.IPSEC.CERT

Table 55. SERVAUTH profile names for NSS (continued)	
Service	SERVAUTH profile name
IPSec remote management service	EZB.NSS.sysname.clientname.IPSEC.NETMGMT
XMLAppliance certificate service	EZB.NSS.sysname.clientname.XMLAPPLIANCE.CERT
XMLAppliance private key service	EZB.NSS.sysname.clientname.XMLAPPLIANCE.PRIVKEY
XMLAppliance SAF access service	EZB.NSS.sysname.clientname.XMLAPPLIANCE.SAFACCESS

You can authorize the NSS client to a SERVAUTH profile using the following commands:

```
RDEFINE SERVAUTH profile_name UACC(NONE)
PERMIT profile_name (SERVAUTH) ID(nssclient) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

Tip: You can use a wildcard in the profiles to reduce the number of profile entries that must be defined.

- d. Create a SERVAUTH resource profile for each NSS IPSec client certificate added to the NSS server's key ring, and give each NSS IPSec client's user ID access to the profiles created for its own certificates.

The name of such a resource profile is EZB.NSSCERT.*sysname.mappedlabelname*.HOST, where *sysname* is the name of the z/OS system running the NSS server and *mappedlabelname* is the mapped name of the certificate's label in the key ring. For details about determining a certificate label's mapped name, see [“NSS server certificate label naming considerations” on page 1120](#).

This can be accomplished with the following commands:

```
RDEFINE SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.HOST UACC(NONE)
PERMIT EZB.NSSCERT.sysname.mappedlabelname.HOST CLASS(SERVAUTH) ID(userid) ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

- e. Create a SERVAUTH resource profile for each certificate authority (CA) certificate that could be used by an NSS IPSec client, and give the NSS client's user ID access to the profiles.

When the digital signature mode of authentication is used, an NSS IPSec client can provide a remote security endpoint with information about certificate authorities that are trusted by the NSS client. The remote security endpoint should use this information as a hint to decide which of its certificates to use when creating its signature.

By default, an NSS IPSec client sends a remote security endpoint information about all the certificate authorities that the NSS IPSec client is authorized to advertise. This can result in an NSS IPSec client sending a large amount of data to a remote security endpoint. Use the CaLabel parameter on the RemoteSecurityEndpoint statement to reduce the amount of data sent to specific remote security endpoints. For details about the RemoteSecurityEndpoint statement, see [z/OS Communications Server: IP Configuration Reference](#).

A SERVAUTH resource profile is used to authorize NSS IPSec clients to use a CA. A SERVAUTH resource profile must be created for each CA certificate that could be used by an NSS IPSec client. The name of such a resource profile is EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH, where *sysname* is the name of the z/OS system running the NSS server and *mappedlabelname* is the mapped name of the certificate's label in the key ring. For details about determining a certificate label's mapped name, see [“NSS server certificate label naming considerations” on page 1120](#). An NSS IPSec client's user ID must be given access to this profile before it can use the corresponding CA certificate.

This can be accomplished with the following commands:

```
RDEFINE  SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH UACC(NONE)
PERMIT   EZB.NSSCERT.sysname.mappedlabelname.CERTAUTH CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

- f. Create a SERVAUTH resource profile for each certificate that an NSS XMLAppliance client could retrieve and give the user ID of the NSS XMLAppliance client access to the appropriate profiles.

In contrast to the IPSec discipline, the XMLAppliance discipline does not distinguish between host, site, or certificate authority certificates. For any given certificate request, the NSS server first checks the EZB.NSSCERT.*sysname.mappedlabelname*.HOST profile. If that check fails, the server then checks the EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH profile. If the NSS XMLAppliance client has read access to either profile, the server permits access to the certificate resource. It is up to the NSS server administrator to allow or deny access to each certificate, and it is up to the XML appliance administrator to determine how each certificate should be used. The user ID of an NSS XMLAppliance client must be given access to one of these profiles before it can use the corresponding certificate. For examples on how to define the required profiles and permit access, see step “9.d” on page 1117 and step “9.e” on page 1117, under “Steps for authorizing resources for NSS” on page 1114. For details about determining the mapped name of a certificate label, see “NSS server certificate label naming considerations” on page 1120.

- g. Create a SERVAUTH resource profile for the private key of each certificate to which an NSS XMLAppliance client requires access and give the user ID of the NSS XMLAppliance client access to the profiles.

Use the SERVAUTH resource profile to authorize NSS XMLAppliance clients to retrieve the private key from a certificate, and to locally perform any RSA operations that are based on the private key or to make ICSF calls requesting RSA operations on System z for ICSF-protected keys. You must create a SERVAUTH resource profile for each private key against which the XMLAppliance client needs to perform operations. The name of such a resource profile is EZB.NSSCERT.*sysname.mappedlabelname*.PRIVKEY, where *sysname* is the name of the z/OS system running the NSS server and *mappedlabelname* is the mapped name of the certificate label in the key ring. Ensure that the user ID of an NSS XMLAppliance client has appropriate access to this profile so that it can retrieve the private key or perform any RSA operations that are based on the private key. This can be accomplished with the following commands:

```
RDEFINE  SERVAUTH EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY UACC(NONE)
PERMIT   EZB.NSSCERT.sysname.mappedlabelname.PRIVKEY CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
SETROPTS RACLIST(SERVAUTH) REFRESH
```

For details about determining the mapped name of a certificate label, see “NSS server certificate label naming considerations” on page 1120.

- h. Create the following SERVAUTH profiles to enable users to remotely monitor (IPSEC.DISPLAY) or manage (IPSEC.CONTROL) NSS clients:

- EZB.NETMGMT.*sysname.clientname*.IPSEC.DISPLAY
- EZB.NETMGMT.*sysname.clientname*.IPSEC.CONTROL

For more information, see the information about the -z option of the **ipsec** command in “NSS client authorization example” on page 1121. For more details about **ipsec** command, see *z/OS Communications Server: IP System Administrator's Commands*. For details about the **IPSec NMI**, see *z/OS Communications Server: IP Programmer's Guide and Reference*.

9. If you are using the NSS XMLAppliance private key service with ICSF-protected private keys, authorize the NSS server to the Integrated Cryptographic Service Facility (ICSF).

ICSF is required when using the RSA operations in the XMLAppliance private key service. The XMLAppliance private key service uses ICSF in the following ways:

- Encrypting signature data for the XMLAppliance private key service RSA signature generation message flow.
- Decrypting data for the XMLAppliance private key service RSA decryption message flow.

ICSF provides cryptography support through various cryptographic hardware features. The cryptographic features that are available to your applications depend on your processor or server model. For information about which features are available on your hardware, see the information about callable service support by hardware configuration in [z/OS Cryptographic Services ICSF Overview](#). For details about configuring ICSF, see [z/OS Cryptographic Services ICSF Administrator's Guide](#).

When using a cryptographic coprocessor, the callable ICSF service names that are used by the XMLAppliance certificate service are as follows:

- CSNDDSG
- CSNDPKD

Requirement: If you plan to use the RSA operations within the XMLAppliance private key service, the NSS server must be permitted to access the ICSF cryptographic services (CSFSERV). Use the following commands to define the appropriate profiles in the CSFSERV class, give the NSS server access to the profiles, activate the CSFSERV class, and refresh the RACF profiles in storage:

```
RDEFINE service-name CLASS(CSFSERV) UACC(NONE)
PERMIT service-name CLASS(CSFSERV) ID(server-name) ACCESS(READ)
SETROPTS CLASSACT(CSFSERV)
SETROPTS RACLIST(CSFSERV) REFRESH
```

10. If XMLAppliance clients using the SAF access service are using certificates for access checks, enable RACF certificate name filtering.

The NSS XMLAppliance SAF access service can use RACF certificate name filtering to map an X.500 distinguished name to a RACF ID when performing SAF access checks. The DIGTNMAP class must be active to perform certificate name filtering. Activate the DIGTNMAP class with the following commands:

```
SETOPS CLASSACT(DIGTNMAP)
SETROPTS RACLIST(DIGTNMAP) REFRESH
```

Create a certificate name filter for each mapping of an X.500 distinguished name to a RACF ID using the following commands:

```
RACDCERT ID(userid) MAP SDNFILTER('x500dn')
SETROPTS RACLIST(DIGTNMAP) REFRESH
```

For specific details on enabling RACF certificate name filtering, see [z/OS Security Server RACF Security Administrator's Guide](#).

11. The NSSD uses ICSF callable services for ECDSA digital signature support. The services it uses are the PKCS11 private key sign service and the PKCS11 public key verify service. You can control access to these services with RACF, using the CSFSERV general resource class, and the CSF1PKS and CSF1PKV profiles.

If the CSFSERV class is defined, and the CSF1PKS and CSF1PKV profiles are defined, grant the NSSD user ID read access to the defined profiles using the following commands:

```
PERMIT CSF1PKS CLASS(CSFSERV) ID(NSSD) ACCESS(READ)
PERMIT CSF1PKV CLASS(CSFSERV) ID(NSSD) ACCESS(READ)
SETROPTS RACLIST(CSFSERV) REFRESH
```

See [z/OS Cryptographic Services ICSF Administrator's Guide](#) for more information about the CSFSERV general resource.

NSS server certificate label naming considerations

During the processing of certificate operations, the NSS server validates that an NSS client is authorized to access the certificates required to complete the operation. The NSS server consults SERVAUTH profiles to perform this validation. The profile names consulted by the NSS server are dynamically constructed by the NSS server using the following information:

- The system name on which the NSS server is running
- The label of the certificate this is used during a certificate operation
- The certificate operation that is being performed:
 - When processing a request to create a signature, the format of the profile that is consulted is EZB.NSSCERT.*sysname.mappedlabelname*.HOST.
 - When processing a request to obtain a list of CA certificates, the format of the profile consulted is EZB.NSSCERT.*sysname.mappedlabelname*.CERTAUTH.
 - When processing a request to retrieve a private key that is not protected by Integrated Cryptographic Service Facility (ICSF) or to use an ICSF-protected private key, the format of the profile consulted is EZB.NSSCERT.*sysname.mappedlabelname*.PRIVKEY.

The NSS server creates a mapped label name using the following algorithm:

- All lowercase alphabetic characters in a certificate's label are changed to uppercase. This is necessary because the class descriptor table for the SERVAUTH profile permits only uppercase profile names.
- The asterisk (*), percent sign (%), and ampersand (&) are replaced by a dollar sign (\$). This is necessary because these characters have special meaning when generic profile processing is active.
- All embedded blanks are also replaced by a dollar sign (\$). This is necessary because blanks are not allowed in SERVAUTH profile names.

Rules:

- The administrator of the NSS server must define profiles using the mapped label names generated by this algorithm. When the certificate's label name contains lowercase characters, the administrator must change each lowercase character to uppercase. When the certificate's label name contains the characters *, %, &, or a blank character, the administrator must replace each occurrence with a dollar sign (\$) character.
- When a certificate label contains the period character (.), ensure that the corresponding SERVAUTH profile contains matching qualifiers. For example, if you request a certificate with the label CERTIFICATE.123.ABC for a private key operation, the NSS server checks a SERVAUTH profile named EZB.NSSCERT.*sysname*.CERTIFICATE.123.ABC.PRIVKEY; defining a SERVAUTH profile named EZB.NSSCERT.*sysname*.CERTIFICATE.*.PRIVKEY does not permit access to the private key of the certificate.

Using this algorithm, it is possible that multiple certificates can result in the same mapped name. This is shown in [Table 56 on page 1120](#).

Table 56. Mapped label names	
Label	Mapped label
CERTIFICATE_123	CERTIFICATE_123
Certificate_123	CERTIFICATE_123
CERTIFICATE 123	CERTIFICATE\$123
CERTIFICATE%123	CERTIFICATE\$123
CERTIFICATE*123	CERTIFICATE\$123
CERTIFICATE&123	CERTIFICATE\$123
CERTIFICATE\$123	CERTIFICATE\$123

Tip: When creating certificates for the NSS server's key ring, avoid using lowercase alphabetic characters, blanks, and the characters *, %, and & in the certificate's label.

NSS client authorization example

Consider the configuration shown in [Figure 143 on page 1121](#).

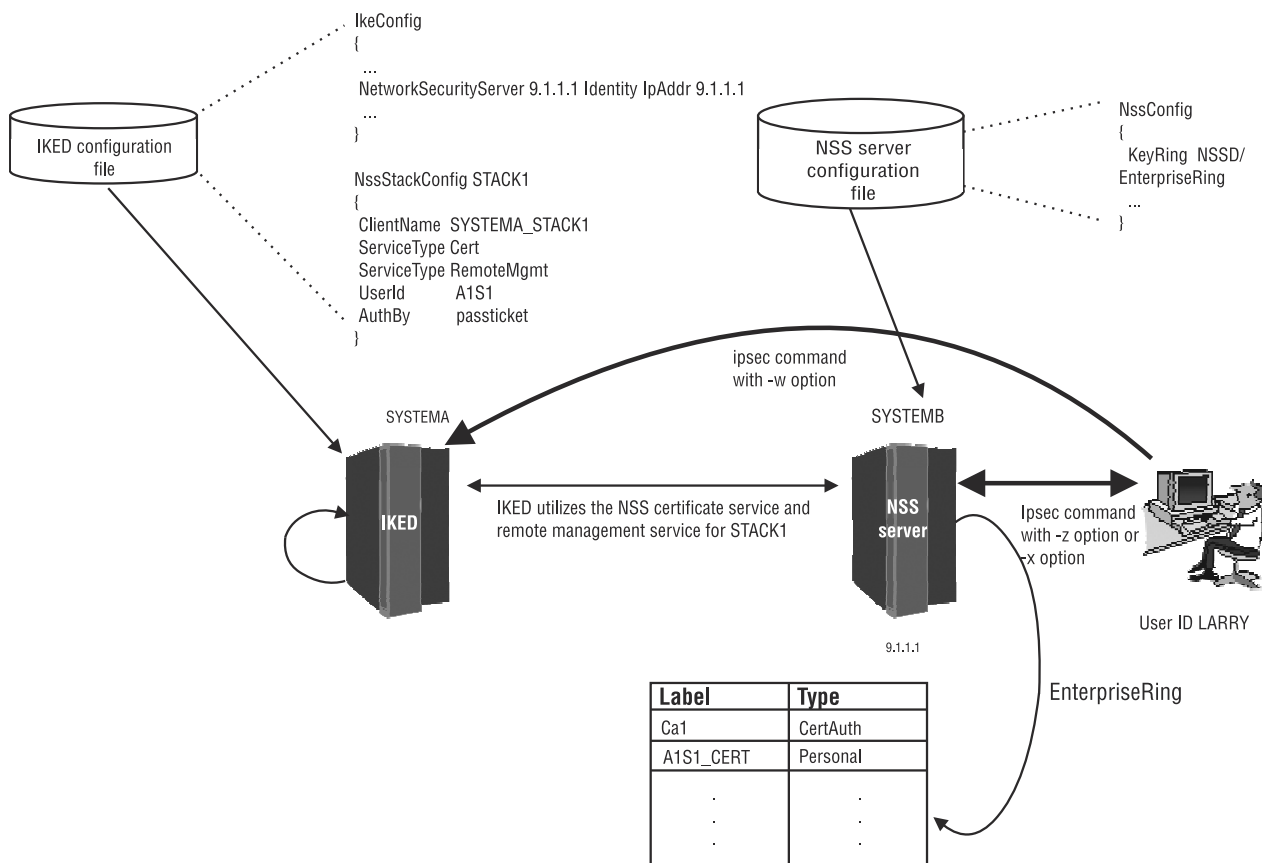

Figure 143. NSS client authorization example

In this example, note the following configuration:

- Stack STACK1 is defined as an NSS IPsec client in the IKE daemon configuration file on system SYSTEMA. The client name for STACK1 is SYSTEMA_STACK1. The user ID associated with SYSTEMA_STACK1 is A1S1. The user ID A1S1 must be defined to the external security manager on system SYSTEMB.
- Client SYSTEMA_STACK1 is configured to use the NSS certificate service. On system SYSTEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile:

```
EZB.NSS.SYSTEMB.SYSTEMA_STACK1.IPSEC.CERT
```

- Client SYSTEMA_STACK1 is configured to use the NSS remote management service. On system SYSTEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile:

```
EZB.NSS.SYSTEMB.SYSTEMA_STACK1.IPSEC.NETMGMT
```

- The NSS server on system SYSTEMB is configured to use the key ring EnterpriseRing. This key ring is owned by the NSSD user ID. Certificates for all NSS IPsec clients are stored on this key ring.

The NSS server's AT-TLS policy must also specify a key ring from which to obtain the NSS server's personal certificate for use during the TLS negotiation with an NSS client. The NSS server's AT-TLS policy can specify the same key ring as the NSS server's configuration file, or it can specify a different key ring. In either case, the AT-TLS policy should specify which personal certificate to use to represent the NSS server by using the CertificateLabel parameter on the TTLSCONNECTIONADVANCEDPARMS

statement. If this parameter is not configured, AT-TLS attempts to use the default certificate, if one exists, on the configured key ring. If no default certificate exists on the configured key ring and the CertificateLabel parameter is not configured, the TLS negotiation between the NSS client and the NSS server will fail.

The IKE daemon's AT-TLS policy also specifies a key ring. This key ring is used to locate the certificate that was used to sign the NSS server's personal certificate. If the IKE daemon's AT-TLS key ring does not contain this signing certificate, TLS negotiation will fail to verify the NSS server's certificate and the TLS negotiation between the NSS client and the NSS server will fail.

In this example, there is one Personal certificate stored on the key ring for client SYSTEMA_STACK1. On system SYSYEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile before the NSS server can use this certificate to create a signature for client SYSTEMA_STACK1:

```
EZB.NSSCERT.SYSTEMB.A1S1_CERT.HOST
```

In this example, there is also one CertAuth certificate stored on the key ring that should be advertised to IPsec peers by client SYSTEMA_STACK1. On system SYSYEMB, the user ID A1S1 must be given read access to the following SERVAUTH profile before the NSS server can inform client SYSTEMA_STACK1 that it can advertise this CERTAUTH certificate to its peers:

```
EZB.NSSCERT.SYSTEMB.CA.CERTAUTH
```

- The user LARRY will issue the **ipsec** command with the -z option to monitor and manage client SYSTEMA_STACK1. On system SYSTEMB, the user ID LARRY must be given read access to the following SERVAUTH profiles:

```
EZB.NETMGMT.SYSTEMB.SYSTEMA_STACK1.IPSEC.DISPLAY  
EZB.NETMGMT.SYSTEMB.SYSTEMA_STACK1.IPSEC.CONTROL
```

The user LARRY will also issue the **ipsec** command with the -x option to display information about the NSS server. On system SYSTEMB, the user ID LARRY must be given read access to the following SERVAUTH profile:

```
EZB.NETMGMT.SYSTEMB.SYSTEMB.NSS.DISPLAY
```

In addition, the user LARRY will issue the **ipsec** command with the -w option to display information from the IKE daemon about NSS IPsec clients. On system SYSTEMA, the user ID LARRY must be given read access to the following SERVAUTH profile:

```
EZB.NETMGMT.SYSTEMA.SYSTEMA.IKED.DISPLAY
```

Tip: A wildcard can be used in the profiles to reduce the number of profile entries that must be defined.

NSS server configuration considerations

This topic describes configuration issues specific to the NSS server.

Run-time environment

The NSS server is a z/OS UNIX application; it requires the z/OS UNIX file system. The NSS server can be started from an MVS started procedure, from the z/OS shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMNDxx member of PARMLIB. The NSS server must be started by a RACF-authorized user ID, and it must be in an APF-authorized library. For more information about how to start the NSS server, see [“Starting the NSS server” on page 1130](#).

The NSS server uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to the processing of NSS requests. CTRACE is used for detailed tracing and debugging.

The NSS server uses a standard message catalog. The message catalog must be in the UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

The NSS server uses ICSF and System SSL for encryption and key management services to provide certificate services to NSS IPsec clients. If the NSS IPsec clients are configured in FIPS 140 mode, you must also configure the NSS server in FIPS 140 mode so that it invokes ICSF and System SSL in FIPS 140 mode. This configuration is required for the entire system to be in FIPS 140 mode.

Language Environment run-time considerations

When starting the NSS server from a started or cataloged procedure, you should typically start it directly from the SEZALOAD data set using PGM=EZANSSD. However, there is a situation in which you might want to start the NSS server using BPXBATCH.

When the NSS server is started using PGM=EZANSSD, the STDENV DD card, if used, is passed directly to the NSS server program. Language Environment does not get access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM parameter, and the options must be specified before any NSS server options. However, the PARM parameter allows a maximum of 100 characters. If the Language Environment run-time options plus NSS server parameters that you want exceed 100 characters, consider using BPXBATCH to start the NSS server. When PGM=BPXBATCH is used, the Language Environment variable _CEE_RUNOPTS can be included on the STDENV DD card to specify run-time options in excess of 100 characters long.

Steps for configuring the NSS server

The network security services (NSS) server supports the IPsec and XMLAppliance disciplines. IPsec discipline services include the IPsec certificate service and the IPsec remote management service, and XMLAppliance discipline services include the XMLAppliance SAF access service, the XMLAppliance certificate service, and the XMLAppliance private key service.

Procedure

Perform the following steps to configure the NSS server:

1. Create the NSS server configuration file.

Use the IBM Configuration Assistant for z/OS Communications Server to establish NSS server settings. Establish the settings using the NSS perspective of the IBM Configuration Assistant for z/OS Communications Server, and then use the **Install Configuration File** button on the **Image Information** tab to store the generated NSS server configuration file on the z/OS system.

Tip: A sample configuration file is provided in /usr/lpp/tcpip/samples/nssd.conf.

The following search order is used by the NSS server to locate the configuration data set or file:

- a. If the environment variable NSSD_FILE has been defined, the NSS server uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.
- b. /etc/security/nssd.conf

You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the NSSD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

The NSS server configuration file allows the URL of a certificate or certificate bundle that is on an HTTP web server to be associated with the label of a certificate on the key ring of the network security server. See [“Using hash and URL certificate encoding types” on page 1127](#) for additional details.

2. Optionally, set the _BPX_JOBNAME environment variable.

When starting the NSS server from the z/OS shell, you should set the environment variable _BPX_JOBNAME. This enables a specific job name to be used when reserving ports for the NSS server.

This name can also be used with the STOP or MODIFY console commands. For more information about `_BPX_JOBNAME`, see [z/OS UNIX System Services Planning](#).

3. Authorize the NSS server to the external security manager, as described in [“Steps for authorizing resources for NSS”](#) on page 1114.

4. Configure and start syslogd.

The NSS server uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use z/OS File System as its underlying file system. For more information about syslogd, see [“Configuring the syslog daemon”](#) on page 235.

5. Optionally, update the NSS server environment variables.

The following environment variables are used by the NSS server and can be tailored to a particular installation.

NSSD_CODEPAGE

Use the NSSD_CODEPAGE variable to specify the EBCDIC code page to be used when reading the configuration file. For more information about NSSD environment variables and the supported code pages, see [z/OS Communications Server: IP Configuration Reference](#).

NSSD_CTRACE_MEMBER

Used by the NSS server to locate a parmlib member for NSS server CTRACE customization.

For more information about the [TCP/IP services component trace for the NSS server](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

NSSD_FILE

Used by the NSS server in the search order for the NSS server configuration file. For details about the search order used for locating this configuration file, see step [“1”](#) on page 1123.

NSSD_PIDFILE

Used by the NSS server in the search order for the NSS server PID file. The search order for the NSS server PID file is as follows:

- a. NSSD_PIDFILE environment variable
- b. `/etc/nssd.pid`

6. Set up the NSS server key ring.

The NSS server's key ring serves a similar purpose as the IKE daemon's key ring. It contains certificates that are used in the process of creating and verifying signatures that are exchanged during digital signature authentication. A personal certificate or site certificate contained on the key ring of the NSS server represents the identity of an NSS IPsec client, whereas a certificate contained on the IKE daemon's key ring represents a local stack's identity. Certificates for all NSS IPsec clients must be on this one key ring.

If a personal certificate or site certificate that is contained on the key ring of the NSS server is signed by a certificate authority, then the certificate of that certificate authority must also be connected to the key ring of the NSS server. If the certificate authority is a subordinate certificate authority (such as one that was created by another certificate authority) you should ensure that all the certificate authority certificates that make up the trust chain are connected to the key ring of the NSS server.

The same commands that are used to create and manage the IKE daemon's key ring also apply to the NSS server's key ring. For examples of how to create and manage the IKE daemon's key ring, see [Appendix E, “Steps for preparing to run IP security,”](#) on page 1391.

You must create a SERVAUTH resource profile for each NSS IPsec client certificate that is added to the key ring of the NSS server. For details, see step [“9.d”](#) on page 1117.

7. Update the TCP/IP profile and policy files.

You should update the TCP/IP profile to reserve the port on which the NSS server will listen. If IP security is enabled, consider updating the default IP filter rules in the TCP/IP profile to enable the NSS server to communicate with NSS clients. The IP security policy defined in Policy Agent configuration files must be updated to enable the NSS server to communicate with NSS clients. AT-TLS should be enabled and rules should be defined to protect NSS server communication with NSS clients.

For additional details concerning these tasks, see [“TCP/IP stack considerations”](#) on page 1125.

8. Update the NSS server cataloged procedure (if starting as a started procedure).

If the NSS server is to be started by a procedure, create the cataloged procedure by copying the sample in SEZAINST(NSSD) to your system. Specify NSS server parameters and change the data set names to suit your local configuration. For a [copy of the sample](#), see [z/OS Communications Server: IP Configuration Reference](#).

Results

If these steps are completed successfully, you should be able to start the NSS server. For details, see [“Starting the NSS server” on page 1130](#).

TCP/IP stack considerations

This topic describes TCP/IP stack considerations, including port reservation, IP filtering, and AT-TLS policy.

Port reservation

By default the NSS server uses TCP port 4159, but this value is configurable using the Port parameter of the NssConfig statement in the NSS server configuration file. For additional details about the [NssConfig](#), see [z/OS Communications Server: IP Configuration Reference](#).

Tip: Update the PORT statement in the TCP/IP profile to reserve the port that the NSS server will use when listening for client connections.

```
PORT
  4159 TCP NSSD
```

IP filtering

The NSS server communicates with NSS clients using the TCP protocol. The NSS server binds to all stacks using either INADDR_ANY or in6addr_any as the IP address. IP filters rules must be defined for any IP security stacks that contain an interface to which the NSS client will connect (for details about configuring the IKE daemon as an NSS client, see [Chapter 17, “IP security,” on page 911](#)). Remote IPsec clients use an ephemeral port when connecting to the NSS server. Ephemeral ports are generally in the range 1024–65355.

Two types of IP filter policy can be defined for a z/OS stack:

- You can define a default IP filter policy in the TCP/IP profile. Updating default IP filter policy to permit communications between the NSS server and NSS clients is optional. Default IP filter policy is in effect only when IP security filter policy cannot be loaded or when the **ipsec -f default** command has been issued.

For details about [TCP/IP profile](#), see [z/OS Communications Server: IP Configuration Reference](#).

The following default policy contains IPSECRule definitions that allow IPv4 and IPv6 NSS server traffic with NSS clients:

```
IPSEC LOGENable
; Rule      SrcAddr DstAddr   Logging Protocol  SrcPort   DestPort   Routing Secclass
; OSPF protocol used by Omproute
IPSECRule *      *        NOLOG   PROTO OSPF
; IGMP protocol used by Omproute
IPSECRule *      *        NOLOG   PROTO 2
; DNS queries to UDP port 53
IPSECRule *      *        NOLOG   PROTO UDP  SRCPort *  DESTport 53
; Administrative access
IPSECRule *      9.1.1.2   LOG
; Network security services (NSS) server access to the NSS client
IPSECRule *      *        LOG     TCP      SRCPort 4159 DESTport *
```

```

; Network security services (NSS) server access to the NSS client
IPSEC6Rule * * LOG TCP SRCPort 4159 DESTport *

ENDIPSEC

```

Rule: The SRCport value in the filter rules must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.

- You can define an IP security filter policy in Policy Agent configuration files. IP security filter policy must be updated to permit communications between the NSS server and NSS clients.

For details about defining IP security policy files, see the [Policy configuration files](#) topic in [z/OS Communications Server: IP Configuration Reference](#).

An example of an IpFilterRule statement for IPv4, an IpFilterRule statement for IPv6, and an IpGenericFilterAction statement that allows NSS clients to communicate with the NSS server is as follows:

```

IpFilterRule      NssTrafficIPv4
{
    IpSourceAddr      all4
    IpDestAddrSet     all4
    IpService
    {
        SourcePortRange      4159
        DestinationPortRange 1024 65535
        Protocol              tcp
        Direction             bidirectional InboundConnect
        Routing               local
    }
    IpGenericFilterActionRef permit-nolog
}

IpFilterRule      NssTrafficIPv6
{
    IpSourceAddr      all6
    IpDestAddrSet     all6
    IpService
    {
        SourcePortRange      4159
        DestinationPortRange 1024 65535
        Protocol              tcp
        Direction             bidirectional InboundConnect
        Routing               local
    }
    IpGenericFilterActionRef permit-nolog
}

IpGenericFilterAction permit-nolog
{
    IpFilterAction      permit
    IpFilterLogging      no
}

```

Rule: The DestinationPortRange value on the IpService statements must include the value specified on the port parameter of the NssConfig statement in the NSS server configuration file.

AT-TLS policy

Communications between the NSS server and NSS clients must be secured using Application Transparent Transport Layer Security (AT-TLS). You must define AT-TLS rules to secure this communication. Enable AT-TLS processing for a stack by specifying the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. Specific AT-TLS policy is configured in Policy Agent configuration files. For details about enabling AT-TLS and configuring AT-TLS policy, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149.

Tip: Define AT-TLS policy such that only cipher suites requiring TLS encryption are exchanged with NSS clients. Failure to restrict the cipher suites to those requiring encryption can result in sensitive information flowing in the clear across an untrusted network.

Rule: You must define AT-TLS policy for each stack through which the NSS server will communicate with an NSS client.

Requirement: The NSS server acts as the server during an SSL handshake. To act in the server role of an SSL handshake, the NSS server must have access to a private key and certificate verifying its ownership of that private key. For information about creating and managing keys and certificates for servers using AT-TLS, see Appendix B, “TLS/SSL security,” on page 1359.

A sample AT-TLS policy is located in `/usr/lpp/tcpip/samples/pagent_TTLS.conf`.

Rule: The `LocalPortRange` value on the `TTLSRule` statement must include the value specified on the `port` parameter of the `NssConfig` statement in the NSS server configuration file.

Using hash and URL certificate encoding types

During an IKE flow, security endpoints can authenticate each other by exchanging certificate information in certificate payloads and by performing digital signature operations on that certificate information. When the IKED negotiates an IKEv2 phase 1 Security Association on behalf of a network security client, the IKED uses the network security server for these digital signature operations. Encoded certificate information that is received from a remote security endpoint is forwarded to the network security server. Encoded certificate information that is sent to a remote security endpoint by the IKED is obtained from the network security server.

There are several encoding types defined for use in IKEv1, but the only encoding type that must be supported by an IKEv1 implementation is an X.509 certificate signature. Two additional certificate encoding types must be supported by an IKEv2 implementation:

- Hash and URL of an X.509 certificate
- Hash and URL of an X.509 bundle

Generally a hash and URL of a certificate or certificate bundle is considerably smaller than the certificate or the bundle that it represents. Less data is exchanged between IKE peers and between the IKED and the network security server. Although smaller message sizes might improve the efficiency of network resources, using hash and URL encoding requires more processing. The NSSD must communicate with an HTTP server to retrieve the certificate using the URL, and it must validate the certificate using the hash. This communication, when needed, increases the amount of time it takes to complete an IKEv2 phase 1 negotiation.

If you want the NSSD to create hash and URL certificates to send to peers, you must create files on an HTTP server that contain the certificates and the certificate bundles. You must also include the URLs of those files in the NSSD configuration file. See [“Enabling the NSSD to generate hash and URL certificate encoding” on page 1127](#).

Rule: Even if you put a certificate or a certificate bundle on an HTTP server and add the URLs to the NSSD configuration file, you still need to store that certificate on the key ring of the NSSD.

The NSSD can accept hash and URL encoded certificates that it receives from its peers. In that case, the NSSD uses the URLs sent by the peers to locate the certificates. The NSSD caches data that it retrieves from an HTTP server using a URL. See [“Enabling the NSSD to process received hash and URL certificate encoding” on page 1128](#).

Even when URL information is configured for the NSSD, it is ultimately the responsibility of the network security client to decide whether the network security server should use hash and URL encoding. See [“Controlling the use of hash and URL certificate encoding” on page 1128](#).

Enabling the NSSD to generate hash and URL certificate encoding

To enable the NSSD to generate hash and URL certificate encoding, perform the following steps:

1. Export the certificates in CERTDER format from RACF.

Use the `RACDCERT EXPORT` command with the `CERTDER` format option to create a data set that contains the binary DER encoding of a certificate on a key ring. If the HTTP server is running on the local system, copy the data set to the location specified by the `CertificateURL` parameter value. If the HTTP server is running on a remote system, transfer the data set to the appropriate location using a

utility such as FTP. For more details about the RACDCERT command, see [z/OS Security Server RACF Command Language Reference](#).

Tip: Do not export the private key when you export the certificate from RACF.

2. Populate the HTTP server with exported certificates.
3. Identify the resources to the NSSD using the CertificateURL parameter.

The CertificateURL parameter in the configuration file of the NSS server associates a certificate on the key ring of the NSS server with a URL that identifies an HTTP server and a file on that server that contains the binary DER encoding of the certificate. For more details about the CertificateURL parameter, see [z/OS Communications Server: IP Configuration Reference](#).

4. Create the certificate bundles that you need by issuing the **certbundle** command.

Use the **certbundle** command to create a file or data set that contains a certificate bundle. If the HTTP server is running on the local system, copy the file or data set to the location specified by the CertificateBundleURL parameter value. If the HTTP server is running on a remote system, transfer the file or data set to the appropriate location using a utility such as FTP. For more details about the **certbundle** command, see [z/OS Communications Server: IP System Administrator's Commands](#). For more details about creating certificate bundles, see [“Creating certificate bundles” on page 1128](#).

5. Populate the HTTP server with the certificate bundle files.
6. Identify the resources to the NSSD using the CertificateBundleURL parameter.

The CertificateBundleURL parameter in the configuration file of the network security server associates a certificate on the key ring of the network security server with a URL that identifies an HTTP server and a file on that server that contains the certificate in a certificate bundle. For more details about the CertificateBundleURL parameter, see [z/OS Communications Server: IP Configuration Reference](#).

Enabling the NSSD to process received hash and URL certificate encoding

To enable the NSSD to process received hash and URL certificate encoding, perform the following steps:

1. Ensure that HTTP traffic is not impeded by IP filter rules.

Tip: If IP filtering is enabled on the system where the network security server is running, ensure that the correct filter rules are in place to allow communication with the HTTP servers that are identified on a CertificateURL or CertificateBundleURL, as well as any HTTP servers used by the remote security endpoint of the network security client. This communication typically uses the TCP protocol with an ephemeral source port and a destination port of 80.

2. Use the URLCacheInterval parameter on the IPSecDisciplineConfig statement in the NSSD configuration file to determine the maximum amount of time that URL data is cached before being re-fetched from an HTTP server. For more details about the URLCacheInterval parameter, see [z/OS Communications Server: IP Configuration Reference](#).

Controlling the use of hash and URL certificate encoding

To control the use of hash and URL certificate encoding, configure IP security policies to accept hash and URL encoded certificates by setting the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements in the IP security policy configuration file of network security clients. For more details about the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements, see [z/OS Communications Server: IP Configuration Reference](#).

Creating certificate bundles

Certificate bundles are used to store a group of related certificate information. A certificate bundle contains zero or more certificates and zero or more certificate revocation lists (CRLs). When an IKEv2 negotiation uses a digital signature authentication method, this certificate information can be exchanged using a certificate bundle. When information is exchanged using a certificate bundle, a URL that identifies the certificate bundle and a hash of the data in the certificate bundle is sent to the remote security

endpoint. The remote security endpoint then retrieves the certificate bundle from an HTTP server, and uses the bundle when it validates the digital signature.

A certificate bundle can hold in a single location all relevant information about an entire trust chain. The following types of information can be included in a certificate bundle:

- The certificate that was used to create a digital signature
- The certificates of certificate authorities in the trust chain
- Certificate revocation lists (CRLs)

Although consolidating this information in one place has advantages, consolidation might cause the remote security endpoint to retrieve unneeded information. Often the remote security endpoint already has knowledge of most of the certificates in the trust chain and is capable of retrieving CRL information using another method. In such cases, it might be more efficient to use individual certificates, rather than a certificate bundle.

You can use the **certbundle** command to create one or more files, each of which contains one certificate bundle. A certificate bundle options file is required as input to the **certbundle** command. The certificate bundle options file identifies how many certificate bundles are created, as well as the contents of each certificate bundle.

Guidelines:

- All certificate information in a certificate bundle file should be for the same trust chain.
- You should not include CRL information in a certificate bundle except when there is no other way for the remote security endpoint to retrieve the CRL information. Because certificate authorities periodically issue new CRLs, CRL information that is stored in a certificate bundle must be constantly updated to contain the most recent CRL information.

Rule: Do not put the certificate for the root certificate authority in a certificate bundle. An IKE implementation cannot accept a certificate for the root certificate authority from an untrusted source and, because certificate bundles are considered an untrusted source, any root certificates they contain are unusable. In addition, putting this certificate in the certificate bundle needlessly increases the size of the certificate bundle.

Steps for creating certificate bundles

You can use certificate bundles to consolidate all relevant information about an entire trust chain. The types of information that can be included in a certificate bundle are the certificate that was used to create a digital signature, the certificates of certificate authorities in the trust chain, and certificate revocation lists (CRLs).

Before you begin

Obtain from the certificate authority any certificate revocation lists (CRLs) that you want to put in a certificate bundle.

Procedure

Perform the following steps to create certificate bundles:

1. Store the CRLs that you are going to include in a certificate bundle in a file or data set.
2. Create a certificate bundle options file. See [The z/OS UNIX certbundle command options file in z/OS Communications Server: IP System Administrator's Commands](#) for more information.
3. For each certificate bundle that you are creating, define a CertBundleOptions statement:
 - a) Use the KeyRing parameter to identify the key ring containing any certificates that you want to include.
 - b) Use the CertificateChain parameter to specify the label of the certificate that is lowest in any complete trust chain that you want to include (excluding the root CA). The CertificateChain parameter generates a certificate bundle file that contains an optimal set of certificates.

- c) Use the CertificateLabel parameter to specify the label of any individual certificates that you want to include. Use the CertificateLabel parameter only when you need to include fewer certificates than the entire chain.
 - d) Use the CRLFile parameter to identify the files that contain any CRLs that you want to include.
 - e) Use the BundleFile parameter to identify the name of the certificate bundle file that you are creating.
4. Provide read access to the key rings that are specified in the certificate bundle options file to the user ID under which the **certbundle** command is issued. See [z/OS Security Server RACF Command Language Reference](#) for details concerning access to key rings.
 5. Issue the **certbundle** command, specifying the certificate bundle options file that you just created.

Controlling the NSS server

This topic describes starting and stopping the NSS server, modifying the configuration file, and displaying configuration file parameters.

Starting the NSS server

The NSS server can be started in the following ways:

- Using an MVS procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(NSSD).
- From the z/OS shell, by starting OMVS and then issuing the **nssd** command.
- Using the COMMNDxx member of PARMLIB. This allows the NSS server to be automatically started when the system is IPLed. For information about the use and configuration of the COMMNDxx member of PARMLIB, see [z/OS MVS Initialization and Tuning Reference](#).
- Using the AUTOLOG statement in the TCP/IP profile.

Tips:

- You should not start the NSS server using the AUTOLOG statement in a stack's profile. If the NSS server is listed in a stack's AUTOLOG statement, the server is cancelled if it is already running when that stack starts. This results in the NSS server losing any cached information that it has in place for NSS clients previously connected through all stacks, and could increase the overall recovery time when a TCP/IP stack recycles.
- If you start the NSS server from the z/OS shell and you stop the shell environment from scrolling, then when the **nssd** command needs to display data to the shell, the NSS server might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.
- When running from an MVS procedure, set the environment variables using the STDENV DD statement in the NSS server procedure.

Restriction: Only one instance of the NSS server can run on a z/OS image. If you attempt to start a second instance, the NSS server will fail.

Stopping the NSS server

Stop the NSS server from MVS by issuing the following command:

```
STOP procname
```

If the NSS server was started from a cataloged procedure, the *procname* value is the member name of that procedure. If the NSS server was started from the z/OS shell and the environment variable `_BPX_JOBNAME` was set, the *procname* value is the same as the `_BPX_JOBNAME` value. If the NSS server was started from the z/OS shell and `_BPX_JOBNAME` was not set, the *procname* value is based on the *userid*. If the *userid* is 8 characters long, the *procname* is the *userid*. If the *userid* is less than 8 characters

long, the *procname* is *useridX*, where *X* is the sequence number that is set by the system. To determine the sequence number, from the **ISPF LOG** window on TSO, issue the following command:

```
/d omvs,u=userid
```

This command displays the programs running under the specified user ID. For more information about `_BPX_JOBNAME`, see [z/OS UNIX System Services Planning](#).

To stop the NSS server from the z/OS shell, issue the **kill** command (from a superuser ID) to the process ID (PID) that is associated with the NSS server. By default, the NSS server PID is recorded in `/etc/nssd.pid`. You can change the default location using the `NSSD_PIDFILE` environment variable.

Using the NSS server MODIFY command

The NSS server provides a modify command to take the following actions:

- Reread the configuration file.

Use the `MODIFY procname,REFRESH` command to flush all cached URLs and reread the NSS server configuration file. Not all NSS server configuration parameters can be updated using this command. For information about which parameters can be dynamically changed, see the parameter descriptions for the `NssConfig` and `IPSecDisciplineConfig` statements in [z/OS Communications Server: IP Configuration Reference](#).

- Display the configuration file parameters.

Use the `MODIFY procname,DISPLAY` command to display configuration values currently in use by the NSS server.

- Display the contents of the URL cache.

Use the `MODIFY procname,DISPLAY,URLCACHE` command to display the current contents of the URL data cache maintained by the NSS server.

For more information on the `MODIFY` command, see [z/OS Communications Server: IP System Administrator's Commands](#).

NSS server failover considerations

NSS IPSec clients can use the NSS certificate service when negotiating phase 1 Security Associations. Network monitoring applications can use the NSS remote management service to display information about NSS IPSec clients. The NSS server should be treated as an application that requires high availability, an application that is able to recover quickly from an outage that impacts the ability of the NSS server to respond to IPSec clients.

Recovery configurations for the NSS server include:

- For recovery of NSS server workload by another NSS server within a sysplex, configure NSS IPSec clients to connect to the NSS server on a non-distributed dynamic VIPA. TCP/IP stacks configured as backup for the dynamic VIPA must have the necessary external security manager definitions and certificates to support the NSS IPSec clients, and an NSS server must be running on the z/OS system hosting the TCP/IP stack configured as backup.

Guideline: Do not configure NSS IPSec clients to connect to a distributed DVIPA address on the NSS server. If a distributed DVIPA is used, the **ipsec** command and IPSec NMI can manage only NSS IPSec clients that have been distributed to the system on which the **ipsec** command is being run or to the system on which the IPSec NMI is invoked.

- Alternatively, you can configure an IKE daemon running as an NSS IPSec client to connect to a backup NSS server with the `NetworkSecurityServerBackup` parameter on the `IkeConfig` statement in the IKE daemon configuration file. When the IKE daemon is unable to connect to the primary NSS server, or when it loses its connection with the primary server, the IKE daemon attempts to connect to the server configured as backup. This recovery configuration can be used regardless of sysplex configurations. The backup server must be configured with all necessary external security manager definitions and

certificates to support the NSS IPSec clients. For additional details about the [IkeConfig statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

NSS server capacity considerations

A single NSS server instance can support a maximum of 500 concurrent NSS client connections, in addition to 10 concurrent NMI client connections.

NSS server certificate revocation support

The NSS server supports the checking of certificate revocation lists (CRLs) when verifying a signature. The NSS server obtains the CRL of a certificate from an HTTP repository, determining the location of the CRL using the CRLDistributionPoints extension of the certificate. The NSS server searches each distribution point entry in the CRLDistributionPoints extension that contains a reason field pertaining to the all-reasons special value and that references the CRL by using an HTTP URL scheme. The search continues until a CRL that matches the certificate attributes is retrieved or until all distribution points containing an HTTP URL scheme are processed. If a certificate does not contain a CRLDistributionPoints extension or the CRLDistributionPoints extension does not contain at least one suitable distribution point that contains an HTTP URL scheme, then the NSS server is unable to retrieve the CRL.

The NSS server also supports the retrieval of certificate bundles, which can also contain a CRL. If a CRL cannot be retrieved using the CRLDistributionPoints extension of a certificate, the NSS server looks for a CRL in any certificate bundle that has hash and URL information provided by the network security client. The network security client obtains certificate bundle hash and URL information from certificate payloads sent by a remote security endpoint.

Managing network security services

Use the **ipsec** command to display information about NSS IPSec clients that are connected to the NSS server. You can also use this command to manage NSS IPSec clients that are enabled to use the NSS IPSec remote management service and that are currently connected to the NSS server.

Use the **-x** primary option on the **ipsec** command to display connection information about NSS IPSec clients connected to the NSS server.

ipsec -x display

```

Use the **-z** option on the **ipsec** command to specify the name of an NSS client rather than a name of a local TCP/IP stack. When the **-z** option is specified, the **ipsec** command obtains information about the NSS client from the NSS server. The **-z** option is valid only on the system that is running the NSS server. The NSS client that is identified by the **-z** option must be connected to the NSS server. The NSS client must also be enabled to use the NSS remote management service. The following example uses the **-z** option to display phase 2 Security Association information about the NSS client client4, where the name client4 was obtained from the previous **ipsec -x display** command.

ipsec -y display -z client4

```

For details about the `ipsec` command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Chapter 19. Defensive filtering

An external security information and event manager, by analyzing and correlating messages from multiple sources and systems in the network, can take action to block attacks by installing defensive filters in your TCP/IP stack. A defensive filter is an IP filter rule to discard packets, separate from IP security filters, and is typically installed for a short duration (for example, 30 minutes) to block a specific attack or a pattern of attacks. If traffic being blocked by a defensive filter should be blocked on a long-term basis, update your configured IP security policy to add an IP security deny rule.

A defensive filter uses a combination of the following characteristics to target traffic to be discarded:

- IP source or destination address
- IP protocol
- Source or destination port
- ICMP type or code
- Direction of flow
- Type of traffic: Routed or local

For example, a defensive filter might be installed to block all TCP traffic from IP address 10.1.1.1 that is destined for the Telnet server. The characteristics of this filter are the following characteristics:

- IP source address is 10.1.1.1.
- IP protocol is TCP.
- Destination port is 23.
- Direction of flow is inbound.
- Traffic is local.

Defensive filters are given higher priority than IP security filters. That is, IP filter processing first checks any installed defensive filters for a match against a packet, before checking the IP security filters. When a defensive filter is added to a TCP/IP stack, it is placed at the top of the filter search order.

[Figure 144 on page 1136](#) provides an overview of defensive filtering.

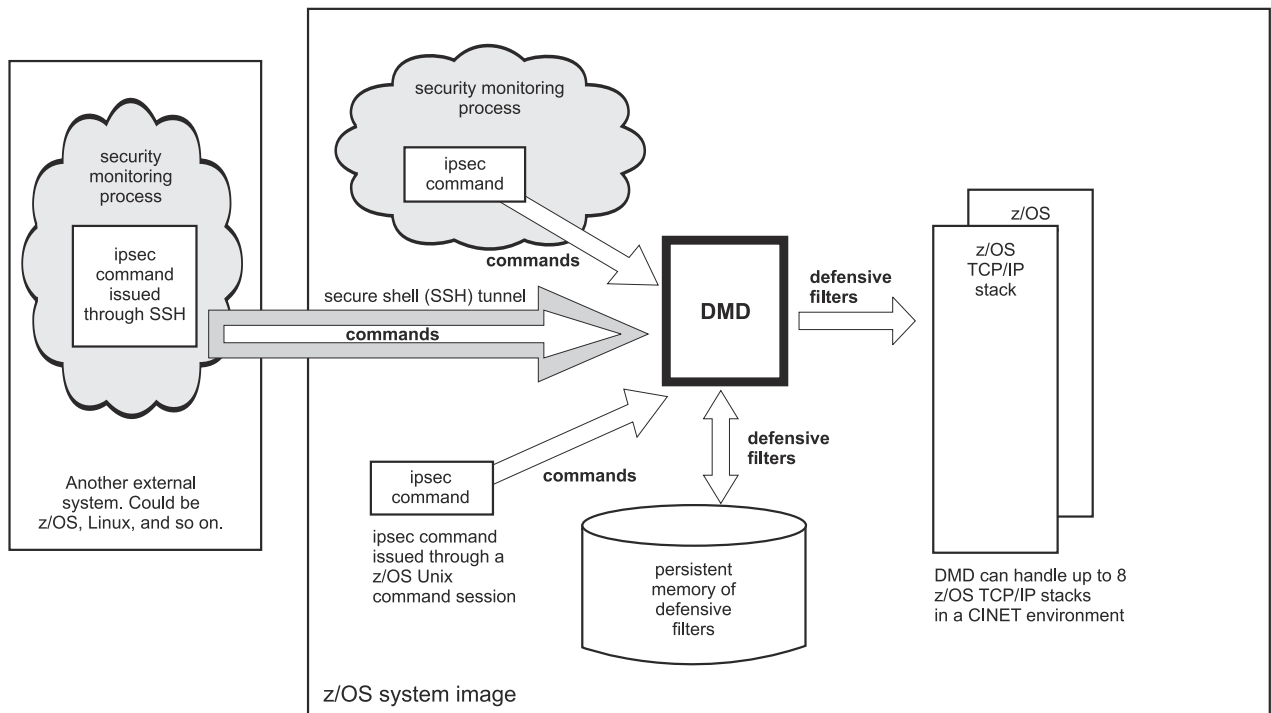

Figure 144. Defensive filtering overview

Defensive filters are added and managed using the z/OS UNIX **ipsec** command with the -F primary option.

- Defensive filters are typically added as an automated action resulting from an external security information and event manager's analysis. The manager issues the set of **ipsec** commands that install the required defensive filters.
- You can also add a defensive filter by manually issuing the **ipsec** command.
- After a defensive filter is created, you can use the **ipsec** command to update some attributes of the filter, such as its lifetime, and also to display and delete defensive filters.

For more information about the [ipsec command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Requirements:

- You must enable the IP security function for defensive filters to be installed in a stack. If you do not have the IP security function enabled, see [“Enabling the IP security function”](#) on page 1143.
- The Defense Manager daemon (DMD) plays an integral role in managing defensive filters, and must be active for defensive filters to be added, updated, or deleted. One instance of the DMD manages all eligible stacks on a z/OS image. An eligible stack is one that is enabled for IP security and that is included in the DMD configuration file with a mode of Active or Simulate. For information about configuring the DMD, see [“Steps for configuring the DMD”](#) on page 1144. You can refresh most of the DMD configuration parameters so that options can be changed without recycling the DMD.

Guideline: The DMD can support a maximum of 10 concurrent **ipsec** command connections.

Restriction: Remote management of defensive filters using a network security services (NSS) server is not supported. Management of defensive filters is provided only through the local **ipsec** command.

Global and stack-specific defensive filters

A defensive filter has either a global or stack-specific scope.

- A global defensive filter, identified by the -G option on the **ipsec** command, is installed in all eligible stacks on the z/OS image.

- A stack-specific defensive filter is installed in the stack specified by the `-p stackname` option on the **ipsec** command, if the stack is eligible.

When a defensive filter is created, the DMD installs the defensive filter in the eligible stacks and maintains a copy of the filter. The DMD maintains a persistent record of all active defensive filters, global and stack-specific, and the stacks into which those filters are installed.

This persistence enables the DMD to maintain the correct set of installed defensive filters across startup and shutdown activities for TCP/IP stacks, as well as across startup and shutdown of the DMD itself. If the DMD is already running when an eligible TCP/IP stack starts, the DMD installs all applicable defensive filters, global and stack-specific, to that stack. If, when the DMD starts up, it detects that eligible stacks are already running, it ensures that they have or receive the correct set of defensive filters.

After a global defensive filter is created and installed in one or more stacks, you can update it as a global filter, resulting in all copies of the filter being updated. You can also update it in an individual TCP/IP stack, resulting in only that stack's copy of the filter being updated. Similarly, you can delete a global defensive filter globally or only from an individual TCP/IP stack.

Defensive filter names

A defensive filter receives its name from the `-N DefensiveFilterName` option when the filter is created. All copies of a global defensive filter have the same name. Global filters and stack-specific filters share the same filter namespace, so a filter name cannot be used for both a global filter and a stack-specific filter. The creation of a stack-specific filter fails if the filter name conflicts with a global filter of the same name, or if there is already a stack-specific filter of the same name in the target stack. The creation of a global filter fails if the filter name conflicts with a global filter of the same name, or if there is already a stack-specific filter of the same name in any stack. This check includes filter names that are in the DMD's persistent memory, even if the corresponding stack is not active.

Tip: If you are manually creating defensive filters, avoid conflicts between global and stack-specific filter names by choosing a distinct naming convention for each, such as starting all global filter names with a G.

Defensive filter modes

Each defensive filter has a mode setting of block or simulate. The defensive filter's mode is set when the filter is created or updated by the **ipsec** command.

By default, defensive filters are in block mode, causing traffic to be discarded. A defensive filter in simulate mode simulates a block and lets you monitor the impact of enabling defensive filters without discarding traffic.

When a packet matches a defensive filter and the mode is simulate, a message is logged indicating that the packet would have been discarded, but the packet is not discarded and IP filtering continues. The packet can subsequently match a defensive filter that is in block mode and be discarded, but the packet will not match another simulation filter.

The DMD configuration file also provides the mode settings Active, Simulate, or Inactive on the `DmStackConfig` statement.

- Active enables defensive filtering and honors the mode setting of the individual filters.
- Simulate enables defensive filtering and overrides the mode setting of the individual filters; simulate mode is used for all defensive filters installed in the stack.
- Inactive disables defensive filtering.

Table 57 on page 1138 summarizes the interaction between the mode setting on the `DmStackConfig` statement and the mode setting in individual filters set by the **ipsec** command.

Table 57. Interaction between the mode setting on the DmStackConfig statement and the mode setting in individual filters

		Mode setting on the DmStackConfig statement		
		Active	Simulate	Inactive
Individual filter mode set by the ipsec command	Block	Block the packet	Simulate blocking the packet	No defensive filters
	Simulate	Simulate blocking the packet	Simulate blocking the packet	No defensive filters

Tips:

- You might want to specify Mode Simulate on the DmStackConfig statement when you are first implementing defensive filtering. All defensive filters in the TCP/IP stack will be treated as if the mode was simulate. When a packet matches a defensive filter, syslog message EZD1722I is generated and IP filtering continues. Defensive filters added to this stack retain the mode setting with which they were added, block or simulate. In most cases, you should use the default mode, block, on the individual filter.
- After completing defensive filter testing in simulate mode, specify Mode Active on the DmStackConfig statement. If there are defensive filters installed in the stack when the mode is changed from simulate to active, the mode on the individual defensive filters is used.
- If defensive filtering is active (DmStackConfig statement with Mode Active) and you want to implement and test additional automation, you can revert to an overall mode of simulate for the whole stack. However, you might want only defensive filters added by the new automation to have a mode of simulate. The automation action can add individual defensive filters with a mode of simulate using the mode keyword on the **ipsec -F add** command. After testing, you can update the automation action to add defensive filters with a mode of block using the mode keyword on the **ipsec -F add** command.

For more information about the [DmStackConfig statement](#), see [z/OS Communications Server: IP Configuration Reference](#). For more information about adding or updating a defensive filter with the -F option of the **ipsec** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Allowing administrative access

Defensive filters are checked before IP security filters. To ensure that an administrator is not blocked by a defensive filter, you can exclude the administrator's IP address from defensive filter processing by specifying the administrator's address on the Exclude parameter of the DmStackConfig statement in the DMD configuration file. For more information about the [DmStackConfig statement](#) and its parameters, see [z/OS Communications Server: IP Configuration Reference](#).

Filter-match logging

When a packet matches a defensive filter during IP filter processing, a message can be logged indicating that the packet was discarded based on this filter. When a defensive filter is added, filter-match logging can be enabled or disabled for the filter; it is enabled by default. The filter-match logging setting can be updated with the **ipsec** command for an existing defensive filter.

When a defensive filter is simulating a block, filter match logging is always performed to indicate that a packet would have been discarded based on the defensive filter.

You can limit the number of filter-match messages generated for a defensive filter by specifying a log limit for the defensive filter in one of the following ways:

- Use the loglimit keyword on the **ipsec** command when you add a defensive filter.
- Use the loglimit keyword on the **ipsec** command to update a defensive filter.
- Set a default value for one or more TCP/IP stacks using the DefaultLogLimit parameter on the DmStackConfig statement in the DMD configuration file. The DefaultLogLimit value is used when a filter

is added without specifying a `loglimit` value. For more information about the `DmStackConfig` statement and its parameters, see [z/OS Communications Server: IP Configuration Reference](#).

The log limit limits the average rate of filter-match messages generated in a 5-minute interval for a defensive filter. For example, a `loglimit` value of 100 limits the average rate of filter-match messages to 100 messages per 5-minute interval. A burst of up to 100 messages is allowed while maintaining the long-term average of 100 messages per 5-minute interval.

A count is kept of suppressed messages. At the end of the 5-minute interval, if there are suppressed filter-match messages, `EZD0837I` or `EZD0838I` is generated to report the number of suppressed messages.

TRMD

The Traffic Regulation Manager daemon (TRMD) is responsible for logging defensive filter events that are detected by the stack. These events include filter-match logging and the creation, deletion, and updating of defensive filters.

TRMD and `syslogd` provide the logging service for defensive filtering. In a Common INET environment, you must configure one instance of TRMD for each stack on a z/OS system. For information about configuring TRMD, see [“TRMD” on page 906](#).

Disabling defensive filters for a single stack

To disable defensive filtering for a TCP/IP stack, while you continue to support defensive filtering for other stacks on the system, take the following actions:

1. Update the DMD configuration file and change the mode of the stack to `Inactive` on the `DmStackConfig` statement.
2. Issue the `MODIFY REFRESH` command for the DMD.

Results:

- All defensive filters are removed from the stack.
- The DMD's persistent memory of defensive filters for the stack is cleared.
- Additional defensive filters cannot be added to this stack.

Tips:

- If you cannot update your DMD configuration file, you can issue the `MODIFY FORCE_INACTIVE` command for the DMD to disable defensive filtering for the stack. However, a later `MODIFY REFRESH` command will use the DMD configuration file, so if you want defensive filtering to remain disabled, you should update the DMD configuration file as soon as possible.
- Removing the `DmStackConfig` statement from the DMD configuration file does not delete existing defensive filters from the stack. If you remove the `DmStackConfig` statement, the defensive filters remain in the stack until they expire. To remove the defensive filters from the stack immediately, add the `DmStackConfig` statement back to the DMD configuration file and specify mode `Inactive`, or issue the `MODIFY FORCE_INACTIVE` command for the stack.

Relationship between intrusion detection services and defensive filters

Communication Server's intrusion detection services (IDS) support enables you to detect scans of your TCP/IP stack and possible attacks. It also provides traffic regulation for TCP connections and UDP sockets. One action that can be taken when a scan or attack is detected, or traffic regulation is enforced, is to generate a message to report the event.

An external security information and event manager that is configured to receive messages from the TCP/IP stack's IDS function can analyze the messages and correlate the information with other information that it has received. Communication Server's IDS messages can be one of a number of inputs

that an external security information and event manager uses to make the decision to add a defensive filter to the stack. If the external security information and event manager detects an attack, it can add defensive filters to the stack to block the attack. Defensive filter support can be enabled without enabling Communication Server's IDS support.

For more information about IDS support, see [Chapter 16, “Intrusion detection services,”](#) on page 877.

Comparison of IP security filters and defensive filters

Table 58 on page 1140 compares IP security filters and defensive filters.

<i>Table 58. Comparison of IP security filters and defensive filters</i>			
Topic	IP security filters (policy)	IP security filters (default)	Defensive filters
Configuring	Configured in a Policy Agent flat file.	Configured in the TCP/IP profile.	Not configured. The ipsec command is used to create defensive filters, either automatically or manually.
Installing in the TCP/IP stack	Installed by the Policy Agent.	Installed by TCP/IP profile processing.	Installed by the Defense Manager daemon (DMD).
Filter search order	The order in the configuration file.	The order in the configuration file.	Defensive filters are searched before IP security filters. When a defensive filter is created, it is installed at the top of the search order.
Displaying a filter	Use pasearch and ipsec -f display . The ipsec -f display -c current command displays all installed filters, both defensive filters and IP security filters.	Use ipsec -f display -c profile .	Use ipsec -F display .

Table 58. Comparison of IP security filters and defensive filters (continued)

Topic	IP security filters (policy)	IP security filters (default)	Defensive filters
Filter display order	<p>The order in the configuration file.</p> <p>The pasearch command displays IP security filters as complex filter rules, not split filters as they are in the stack.</p> <p>The ipsec -f display command displays IP security filters as split filters, like they are in the stack.</p> <p>IPv4 IP security filters are shown first, followed by IPv6 IP security filters.</p>	<p>The order in the configuration file.</p> <p>The ipsec -f display command displays IP security filters as split filters, like they are in the stack. A single profile filter in the configuration file is split into an inbound and outbound filter in the stack.</p> <p>IPv4 IP security filters are shown first, followed by IPv6 IP security filters.</p>	<p>The ipsec -F display command displays defensive filters from the stack in four groups:</p> <ul style="list-style-type: none"> • IPv4 inbound filters • IPv4 outbound filters • IPv6 inbound filters • IPv6 outbound filters <p>Within each group, the filters are displayed from most recently installed to least recently installed.</p> <p>The ipsec -F display -G command displays global defensive filters from the DMD. The global filters are displayed from most recently installed to least recently installed.</p>
Deleting a filter	<p>Remove the filter rule from the configuration file. When Policy Agent detects the configuration file change, the filter rule is removed from the stack. Policy Agent detects the change in one of the following ways:</p> <ul style="list-style-type: none"> • If Policy Agent was started with the -i startup option, an immediate refresh picks up the change. • You issue a MODIFY REFRESH command. • You issue a MODIFY UPDATE command. • Policy Agent checks for configuration changes using an update interval defined in the policy configuration file. 	<p>Use a VARY TCP/IP,,OBEYFILE command with a data set that contains a new IPSEC statement with the filter rule removed.</p>	<p>Use ipsec -F delete.</p> <p>Defensive filters are also deleted when their lifetime expires.</p>

Table 58. Comparison of IP security filters and defensive filters (continued)			
Topic	IP security filters (policy)	IP security filters (default)	Defensive filters
Updating a filter	Update the filter rule in the configuration file. When the Policy Agent detects the configuration file change, the filter rule is updated in the stack.	Use a VARY TCPIP,,OBEYFILE command with a data set that contains a new IPSEC statement with the filter rule updated.	Use ipsec -F update . A defensive filter's lifetime, mode, and logging values can be updated.
Specifying time conditions	Specify time conditions in the policy. The Policy Agent installs an IP security filter when it becomes active, and deletes the filter when it becomes inactive due to time.	Not supported.	Not supported. Defensive filters have a lifetime that is minutes in length. A defensive filter is deleted when its lifetime expires.
Simulation mode	Not supported.	Not supported.	Controlled by the DMD configuration file and the ipsec -F add and ipsec -F update commands.
Global filters	IP security filters defined in a CommonIPSecConfig file are added to all eligible stacks.	Not supported.	Defensive filters added with the -G option of the ipsec command are added to all eligible stacks on the z/OS system.
Filter-match logging	<ul style="list-style-type: none"> Controlled by settings in the policy flat file. Message generated for each packet that matches the filter, if logging enabled. 	<ul style="list-style-type: none"> Controlled by settings in the TCP/IP profile. Message generated for each packet that matches the filter, if logging enabled. 	<ul style="list-style-type: none"> Set when the filter is added or updated with the ipsec command. Messages can be limited by using the loglimit parameter on the ipsec -F add or ipsec -F update commands, or by using the DefaultLogLimit parameter in the DMD configuration file.

The DMD run-time environment

The DMD is a z/OS UNIX application; it requires the z/OS UNIX file system. You can start the DMD from an MVS started procedure, from the z/OS UNIX shell, with the AUTOLOG statement in the TCP/IP profile, or by using the COMMNDxx member of parmlib. The DMD must be started by a RACF-authorized user ID, and it must be in an APF-authorized library. For more information about how to start the DMD, see [“Starting the DMD”](#) on page 1147.

The DMD uses the MVS operator's console, syslogd, CTRACE, and STDOUT for its logging and tracing. The MVS operator's console and STDOUT are used for major events such as initialization, termination, and error conditions. Syslogd is used for logging events related to the processing of defensive filter requests. CTRACE is used for detailed tracing and debugging.

The DMD uses a standard message catalog. The message catalog must be in the UNIX file system. The directory location for the message catalog path is set by the environment variables NLSPATH and LANG.

The DMD and Language Environment run-time options

When you start the DMD from a started or cataloged procedure, you typically start it directly from the SEZALOAD data set using PGM=EZADMD. However, you can also start the DMD using BPXBATCH.

When you start the DMD using PGM=EZADMD, the STDENV DD card, if used, is passed directly to the DMD. Language Environment does not have access to the STDENV environment variables. As a result, any Language Environment run-time options set in the STDENV DD data set using the _CEE_RUNOPTS environment variable are ignored. In this case, Language Environment run-time options must be passed on the PARM parameter, and the options must be specified before any DMD options. However, the PARM parameter allows a maximum of 100 characters. If the Language Environment run-time options plus the DMD parameters that you want to specify exceed 100 characters, consider using BPXBATCH to start the DMD. When you use PGM=BPXBATCH to start the DMD, you can include the Language Environment variable _CEE_RUNOPTS on the STDENV DD card to specify run-time options in excess of 100 characters long.

For more information about how to start the DMD, see [“Starting the DMD” on page 1147](#).

Enabling defensive filtering

To enable defensive filtering, first take both of the following actions:

- Enable the IP security function.
See [“Enabling the IP security function” on page 1143](#).
- Configure the Defense Manager daemon (DMD).
See [“Steps for configuring the DMD” on page 1144](#).

After configuring the DMD and enabling IP security, start the DMD. For details, see [“Starting the DMD” on page 1147](#).

Enabling the IP security function

The IP security function must be enabled for defensive filters to be installed in a stack. If you do not have the IP security function enabled and want to use defensive filters, perform the following steps.

1. Specify the IPSECURITY parameter on the IPCONFIG statement in the TCP/IP profile.
2. If you have IPv6 traffic in your network and want to use defensive filters for IPv6, specify the IPSECURITY parameter on the IPCONFIG6 statement in the TCP/IP profile.
3. Configure a default IP security filter policy in the TCP/IP profile using the IPSEC statement in the TCP/IP profile.

Tip: To permit all IPv4 traffic, you can configure a single rule for the IPSEC statement that allows all traffic. The following example allows all IPv4 traffic, without logging filter matches.

```
IPSEC
; Rule      SourceIp      DestIp      Logging      Prot      SrcPort      DestPort      Routing      Secclass
;
; Permit all local and routed IPv4 traffic, no logging.
IPSECR *      *      NOLOG      PROTO *      ROUTING EITHER
ENDIPSEC
```

For more information about the [IPSEC statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

4. Optionally, configure a more comprehensive IP security policy in a flat file for the Policy Agent to install and manage.

You can configure IPsec encryption and authentication only in a Policy Agent flat file.

Tip: You can use the IBM Configuration Assistant for z/OS Communications Server to create an IP security policy flat file.

For more information about configuring an IP security policy, see [Chapter 14, “Policy-based networking,”](#) on page 813 and [Chapter 17, “IP security,”](#) on page 911.

Attention: You must configure an IP security policy if you enable the IP security function. If you specify IPSECURITY in your TCP/IP profile and do not configure an IP security policy, all inbound and outbound traffic will be discarded.

Steps for configuring the DMD

The Defense Manager daemon (DMD) plays an integral role in managing defensive filters, and must be active for defensive filters to be added, updated, or deleted.

Procedure

Perform the following steps to configure the DMD:

1. Authorize the DMD to the external security manager.

See [“Steps for authorizing resources for the DMD and the ipsec command”](#) on page 1146.

2. Create the directories that the DMD needs.

- a) Create the directory `/var/dm` for use by the DMD. The DMD user ID must have permission to create, delete, read, and write files to this directory.
- b) If you set the PID file location with the `DMD_PIDFILE` environment variable, ensure that the path portion of the file name exists and that the DMD user ID has permission to create and write files to that directory. If you use the default PID file location, `/var/dm/dmd.pid`, you have already created the directory and given the DMD user ID the appropriate access in the previous step.
- c) Create the directory that will hold the persistent defensive filters for each stack, as well as the global defensive filters.

The DMD configuration file parameter `DefensiveFilterDirectory` points to this directory. The default value is `/var/dm/filters`. Ensure that the DMD user ID is authorized to create, delete, read from, and write to files in this directory. The directory should have sufficient space to support at least 1 MB of data for each TCP/IP stack, plus another 1 MB for the global filter definitions. For more information about the `DefensiveFilterDirectory` parameter in the [DMD configuration file](#), see [z/OS Communications Server: IP Configuration Reference](#).

3. Create the DMD configuration file.

Take one of the following actions:

- Use the IBM Configuration Assistant for z/OS Communications Server.

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the DMD configuration file.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the GUI to create DMD configuration files for any number of z/OS images with any number of TCP/IP stacks per image.

- Configure the file manually.

A sample configuration file is in `/usr/lpp/tcpip/samples/dmd.conf`.

For a description of the [DMD configuration file](#), see [z/OS Communications Server: IP Configuration Reference](#).

If the DMD was defined to the external security manager with a nonzero UID, ensure that the DMD has permission to read the configuration file. The DMD user ID must have both read access to the configuration file and execute access to the directory containing the configuration file.

Tip: You can create the configuration file in the /var/dm directory and use the DMD_FILE environment variable to specify the configuration file. You set up the /var/dm directory in step 2 to allow DMD to create, delete, read, and write files to this directory.

The following search order is used by the DMD to locate the configuration data set or file:

- a. If the environment variable DMD_FILE is defined, the DMD uses the value as the name of an MVS data set or z/OS UNIX file to access the configuration data.
- b. /etc/security/dmd.conf

You can specify statements in the configuration file using a variety of EBCDIC code pages. Use the DMD_CODEPAGE environment variable to specify the code page that you want to use. The default code page is IBM-1047.

4. Optionally, set the _BPX_JOBNAME environment variable.

When you start the DMD from the z/OS UNIX shell, set the environment variable _BPX_JOBNAME. This enables a specific job name to be used with the STOP or MODIFY console commands. For information about [Commonly used environment variables](#), see [z/OS UNIX System Services Planning](#).

5. Configure and start syslogd.

The DMD uses the local4 facility when writing messages to syslogd. For performance purposes, syslogd should use z/OS File System as its underlying file system. For more information about syslogd, see [“Configuring the syslog daemon” on page 235](#).

6. Optionally, update the DMD environment variables.

The DMD uses the following environment variables. You can modify them for your installation.

DMD_CODEPAGE

Use the DMD_CODEPAGE variable to specify the EBCDIC code page to be used when reading the configuration file. For details about the [supported code pages](#), see [z/OS Communications Server: IP Configuration Reference](#).

DMD_CTRACE_MEMBER

Used by the DMD to locate a parmlib member for DMD CTRACE customization. For more information about the [TCP/IP services component trace for the DMD](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

DMD_FILE

Used by the DMD in the search order for the DMD configuration file. For details about the search order used for locating this configuration file, see step [“3” on page 1144](#).

DMD_PIDFILE

Used by the DMD in the search order for the file that should contain the DMD process ID (PID). The search order for the DMD PID file is as follows:

- a. DMD_PIDFILE environment variable
- b. /var/dm/dmd.pid

7. If you are starting the DMD as a started procedure, update the DMD cataloged procedure.

Create the cataloged procedure by copying the sample in SEZAINST(DMD) to your system. Specify the DMD parameters and change the data set names to suit your local configuration. A copy of the [DMD cataloged procedure](#) can also be found in [z/OS Communications Server: IP Configuration Reference](#).

If the DMD was defined to the external security manager with a nonzero UID and the cataloged procedure specifies an HFS file containing environment variables, ensure that the DMD has permission to read the HFS file.

Results

You know you are done when you can start the DMD. For details, see [“Starting the DMD” on page 1147](#).

Steps for authorizing resources for the DMD and the ipsec command

You need to define and authorize the DMD user ID, permit the DMD user ID to SYS1.PARMLIB, and define the SERVAUTH profiles necessary to be able to add, update, delete, and display defensive filters

Before you begin

RACF is used as the external security manager in the following examples. However, you can use any SAF-compliant security product. RACF commands shown in these examples are also provided in the EZARACF member of the SEZAINST data set. In these examples, it is assumed that the DMD is running under the user ID DMD.

Procedure

Perform the following steps to authorize access to the appropriate resources:

1. Define and authorize the DMD user ID.

The DMD is a z/OS UNIX application that you can start from the z/OS UNIX shell or from an MVS started procedure. Before starting the DMD, you must define the DMD user ID to the external security manager. If you start the DMD from an MVS started procedure, the DMD user ID must also be authorized to the STARTED class. In the following example, the DMD user ID is defined with UID 0:

```
ADDUSER DMD DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
RDEFINE STARTED DMD.*          STDATA(USER(DMD))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

You can define the DMD with a nonzero UID. For additional steps that you must take when the DMD UID is nonzero, see [“Steps for configuring the DMD” on page 1144](#).

2. Permit the DMD user ID to SYS1.PARMLIB.

The DMD uses the TCP/IP component trace (CTRACE) to perform service-level tracing. The default DMD component trace parmlib member is stored in SYS1.PARMLIB. The DMD user ID must be permitted to access SYS1.PARMLIB.

Issue the following command:

```
PERMIT SYS1.PARMLIB ID(DMD) ACCESS(READ)
```

3. Define SERVAUTH profiles to control the users that are allowed to manage defensive filters.

For information about defining the SERVAUTH profiles needed for a user to be able to add, update, delete, and display defensive filters, see [“Step 4: Authorizing the ipsec command to the external security manager” on page 1393](#). Additional information about [ipsec command](#) is available in [z/OS Communications Server: IP System Administrator's Commands](#).

Steps for granting authority to start DMD

You need to authorize one or more user to start DMD.

Before you begin

RACF is used as the external security manager in the following procedure. However, you can use any SAF-compliant security product. RACF commands shown in these examples are also provided in the EZARACF member of the SEZAINST data set.

Procedure

Perform the following steps to authorize a user ID to start DMD:

1. Activate and RACLIST the OPERCMDS class, if it is not already active.

```
SETROPTS CLASSACT(OPERCMD5)  
SETROPTS RACLIST (OPERCMD5)
```

2. Define a SAF profile to protect the MVS.SERVGR.DMD resource in the OPERCMD5 class.

```
RDEFINE OPERCMD5 (MVS.SERVGR.DMD) UACC(NONE)
```

3. Permit the appropriate user IDs CONTROL access to the profile.

```
PERMIT MVS.SERVGR.DMD CLASS(OPERCMD5) ACCESS(CONTROL) ID(userid)
```

4. Refresh the OPERCMD5 class

```
SETROPTS RACLIST(OPERCMD5) REFRESH
```

Starting the DMD

You can start DMD in any of the following ways:

- By using an MVS procedure from the MVS operator console. A sample start procedure is provided in SEZAINST(DMD).
- By issuing the **dmd** command from the z/OS UNIX shell.
- By using the COMMNDxx member of parmlib. This member enables the DMD to be automatically started after an IPL of the system. For information about configuring and using the [COMMNDxx](#) member of parmlib, see [z/OS MVS Initialization and Tuning Reference](#).
- By using the AUTOLOG statement in the TCP/IP profile. For information about the [AUTOLOG](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

Tips:

- Do not start the DMD using the AUTOLOG statement in a stack's profile if you are running in a CINET environment with more than one stack configured. If a stack is configured using AUTOLOG to start and stop the DMD each time the stack starts and stops, it is difficult to maintain a stable running instance of the DMD in a multi-stack environment. In a multi-stack environment, you should use another method to automate starting the DMD when the system is started, such as using the COMMNDxx member of parmlib.
- When you start the DMD from an MVS procedure, set the environment variables using the STDENV DD statement in the DMD procedure.
- If you start the DMD from the z/OS shell and you stop the shell environment from scrolling, when the daemon needs to display data to the shell, it might stop and wait indefinitely for the shell to scroll and make output buffer space available for the data.

Restriction: Only one instance of the DMD can run on a z/OS image. If you attempt to start a second instance, the second DMD will fail.

Stopping the DMD

Stop the DMD in one of the following ways:

- From MVS, stop the DMD by issuing the following command:

```
STOP procname
```

where *procname* is one of the following values:

- If the DMD was started from a cataloged procedure, the *procname* value is the member name of that procedure.
- If the DMD was started from the z/OS UNIX shell and the environment variable `_BPX_JOBNAME` was set, the *procname* value is the same as the `_BPX_JOBNAME` value.

- If the DMD was started from the z/OS UNIX shell and `_BPX_JOBNAME` was not set, the *procname* value is based on the *userid*. If the *userid* is 8 characters long, the *procname* is the *userid*. If the *userid* is less than 8 characters long, the *procname* is *useridX*, where *X* is the sequence number that is set by the system. To determine the sequence number, from the **ISPF LOG** window on TSO, issue the following command:

```
/d omvs,u=userid
```

This command displays the programs that are running under the specified user ID. For more information about [Commonly used environment variables](#), see [z/OS UNIX System Services Planning](#).

- From the z/OS shell, issue the **kill** command from a superuser ID for the process ID (PID) that is associated with the DMD. By default, the DMD PID is recorded in `/var/dm/dmd.pid`. You can change the default location using the `DMD_PIDFILE` environment variable.

Using the DMD MODIFY command

The DMD provides a MODIFY command to take the following actions:

- Reread the configuration file.

Use the `MODIFY procname,REFRESH` command to reread the DMD configuration file. You can use this command to update some DMD configuration file parameters. For information about the DMD configuration file parameters that can be dynamically changed, see [z/OS Communications Server: IP Configuration Reference](#).

- Display the configuration file parameters.

Use the `MODIFY procname,DISPLAY` command to display configuration values currently in use by the DMD.

- Disable defensive filtering.

Use the `MODIFY procname,FORCE_INACTIVE,stackname` command to disable defensive filtering for stack *stackname*. All defensive filters for the stack are removed from the DMD's persistent memory and from the stack. No additional defensive filters are added to the stack while the stack's mode is inactive. The change to the stack's mode persists until the next successful `MODIFY procname,REFRESH` command.

For more information about the `MODIFY` command for DMD, see [z/OS Communications Server: IP System Administrator's Commands](#).

Chapter 20. Application Transparent Transport Layer Security data protection

The Transport Layer Security (TLS) protocol evolved from the Secure Sockets Layer (SSL) protocol and was originally defined in RFC 2246. The protocol enables client and server applications to communicate in a way that is designed to prevent eavesdropping, tampering, and message forgery. To implement TLS protocols, typically, applications must be modified to incorporate a TLS toolkit. Modifying applications requires significant development overhead, ongoing maintenance for each application, and application-specific knowledge of the parameters needed to implement TLS for that application.

Application Transparent Transport Layer Security (AT-TLS) consolidates TLS implementation in one location, reducing or eliminating application development overhead, maintenance, and parameter specification. AT-TLS is based on z/OS System SSL, and transparently implements these protocols in the TCP layer of the stack. As shown in [Figure 145 on page 1149](#), most applications do not need any awareness of the security negotiations and encryption done by TCP/IP on its behalf. However, you might want some applications to be aware of AT-TLS or have control over the security functions being performed by TCP/IP. For example, if the application is a server requesting client authentication, you might want the application to get the partner certificate or the user ID associated with the partner certificate, or the application might negotiate in cleartext with its partner to decide whether a secure session is necessary. If both agree to a secure session, the application needs to tell AT-TLS to set up a secure session. The `SIOCTTLCTL` ioctl provides the interface for the application to query or control AT-TLS.

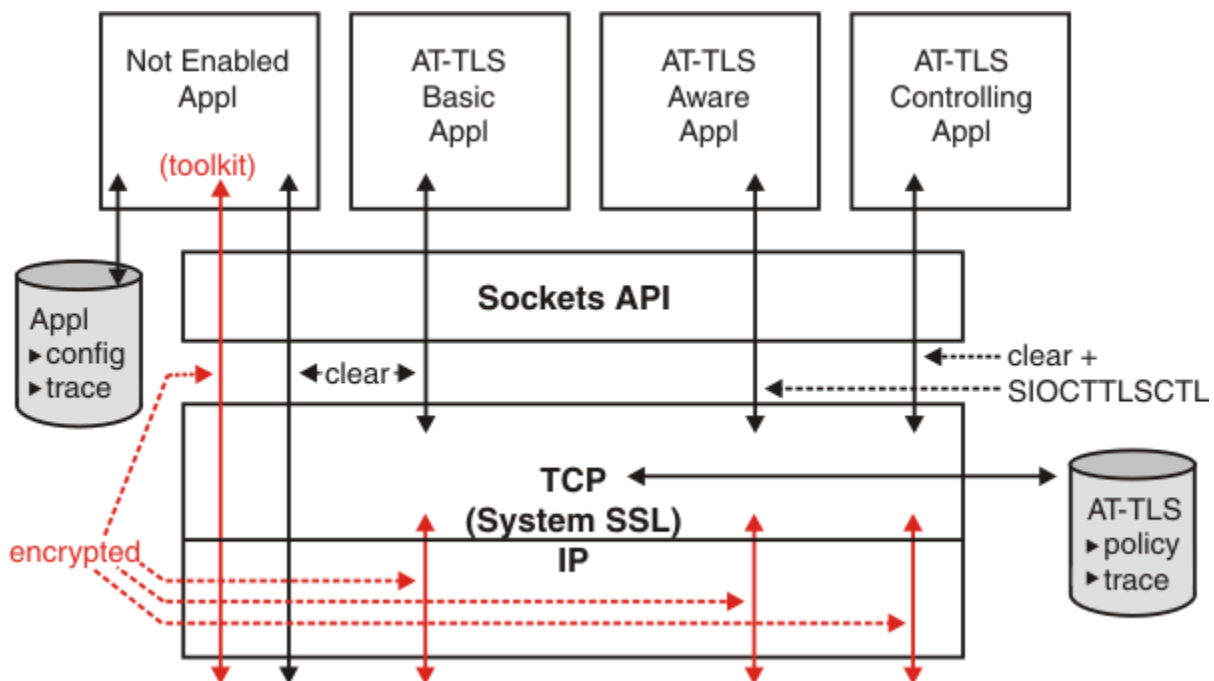

Figure 145. Application Transparent TLS

In all cases, an application using a socket enabled with AT-TLS continues to send and receive text data in the clear while encrypted data flows over the network. This allows the use of TLS with applications that cannot be modified or that cannot incorporate one of the available tool kits. The partner application must also support TLS protocols, either by using AT-TLS or an available TLS toolkit.

AT-TLS configuration in PROFILE.TCPIP

AT-TLS support is controlled by the TTLS or NOTTLS parameter on the TCPCONFIG statement in PROFILE.TCPIP. AT-TLS is enabled by specifying TTLS. The information required to negotiate secure

connections is provided to the stack by AT-TLS policies configured in Policy Agent. When AT-TLS is enabled and a newly established connection is first used, the TCP layer of the stack searches for a matching AT-TLS policy installed from the Policy Agent. If no policy is found, the connection is made without AT-TLS involvement.

TCP/IP stack initialization access control

A TCP/IP stack initializes before Policy Agent installs configured policies into the stack. This leaves a window of time where connections that should be covered by AT-TLS are clear text connections. The RACF resource EZB.INITSTACK.*sysname.tcpname* in the SERVAUTH class is used to block stack access, except for the user IDs permitted to the resource. While in this initialization window, any socket request from an unauthorized application receives the same errno (EAGAIN with JrTcpNotActive) received prior to the stack coming up.

Checking is done only if the TCP/IP profile activates AT-TLS. If there is no profile in the SERVAUTH class covering this resource name, all socket requests fail, including those from Policy Agent. Checking ceases the first time that the Policy Agent indicates AT-TLS policy is complete, or if a TCP/IP profile change deactivates AT-TLS.

When the limited access window begins, non-scrollable message EZZ4248E is written to the system console stating that TCP/IP is waiting for Policy Agent to install AT-TLS policies. The message is released when the restriction ends. You can delay the start of AUTOLOG procedures during this window of time by specifying the optional DELAYSTART parameter with the TTLS subparameter on the AUTOLOG entry for that procedure; when specified, the procedure will start after the EZZ4248E message is deleted and message EZZ4250I is issued indicating that AT-TLS services are available.

You must permit a limited set of administrative applications to the profile to ensure full initialization of the stack. If Policy Agent is dependent on other applications in your environment, they must also be permitted. You can permit other applications that do not require AT-TLS and that you want to start prior to general applications. At a minimum, the following applications should be permitted to the profile:

- Policy Agent
- OMROUTE
- SNMP agent and subagents
- NAMED

For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.

Options for configuring AT-TLS security

AT-TLS is configured using a set of configuration statements and parameters coded into a flat file, which is parsed by the Policy Agent to establish the AT-TLS policy for each TCP/IP stack. In a complex environment, this file can become large. For this reason, there are two alternatives for creating the Policy Agent files.

Option 1: Use the IBM Configuration Assistant for z/OS Communications Server

The IBM Configuration Assistant for z/OS Communications Server, an optional GUI-based tool, provides a guided interface for configuring TCP/IP policy-based networking functions. You can use the IBM Configuration Assistant for z/OS Communications Server to generate the Policy Agent files.

The IBM Configuration Assistant for z/OS Communications Server is a z/OS Management Facility (z/OSMF) task. z/OSMF provides a web browser interface for a variety of z/OS system management functions. When you invoke the IBM Configuration Assistant for z/OS Communications Server in z/OSMF, the IBM Configuration Assistant for z/OS Communications Server runs natively in the z/OS system and you can access it through a web browser.

Through a series of wizards and online help panels, you can use the IBM Configuration Assistant for z/OS Communications Server to create AT-TLS configuration files for any number of z/OS images with any number of TCP/IP stacks per image. Using the IBM Configuration Assistant for z/OS Communications Server, there are three types of reusable objects:

- Traffic descriptors that define the local application, by describing the TCP traffic with ports or identifying the application using its jobname.
- Security levels that define the different ways to protect data, such as the encryption level.
- Requirement maps that map traffic descriptors to security levels. A single requirement map should contain a complete set of security requirements that will govern the level of security for multiple IP traffic types.

For each TCP/IP stack, you create a set of connectivity rules that indicate the data endpoints and indicate which requirement map will govern security between the data endpoints.

The IBM Configuration Assistant for z/OS Communications Server comes with a number of IBM-supplied traffic descriptors, security levels, and requirement maps that are easily applied, or you can use the IBM-supplied definitions as the basis for your own set of reusable objects.

The IBM Configuration Assistant for z/OS Communications Server can dramatically reduce the amount of time that is required to create AT-TLS policy files, contributing to ease of configuration and maintenance. Because of the inherently complex nature of z/OS security, using the GUI can help you ensure that you have a consistent and easily manageable interface for implementing AT-TLS security.

This information primarily describes option 2, manual configuration. However, if you are using the IBM Configuration Assistant for z/OS Communications Server, reading this information will help you understand security concepts and the relationship between Policy Agent and AT-TLS function.

Option 2: Manual configuration

You can manually create the AT-TLS policy configuration files by coding all the required statements in a z/OS UNIX file or MVS data set. There are a large number of configuration options provided by AT-TLS policy statements that permit advanced users to carefully fine-tune AT-TLS policy on a per-stack basis. This information describes the procedure for creating an AT-TLS policy by manually creating and editing the configuration files. For details about the [AT-TLS policy statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

Specifying the AT-TLS configuration file based on Policy Agent role

The Policy Agent can act as a policy server, a policy client, or neither. For more information on these different roles, see [“Policy types and infrastructure overview”](#) on page 813. Regardless of which option is used to configure AT-TLS policies, the resulting configuration files need to be specified using different statements, depending on the role of the Policy Agent.

- If you are using the Policy Agent as a policy client that retrieves AT-TLS policies from the policy server, specify the configuration files using the `DynamicConfigPolicyLoad` statement on the policy server.
- If you are using the Policy Agent as a policy client, but the policy client does not retrieve AT-TLS policies from the policy server, specify the configuration files using the `TTLSTLSConfig` statement on the policy client.
- If you are not using a policy client/policy server environment, specify the configuration files using the `TTLSTLSConfig` statement on the single Policy Agent.

When this information refers to configuration files, keep in mind where the files should exist, based on the role of the Policy Agent.

AT-TLS policy configuration

AT-TLS policy is provided to the stack by the Policy Agent. The Policy Agent main configuration file contains a `TcpImage` statement for each stack that is to receive policy, and can optionally contain a `CommonTTLSTLSConfig` statement that identifies a local shared AT-TLS policy file.

The TcpImage statement identifies the z/OS UNIX file or MVS data set that contains policy for that stack. This policy file can contain a TTLSSConfig statement to identify the z/OS UNIX file or MVS data set that contains the local AT-TLS policy. The TTLSSConfig statement is required for each stack that is to receive AT-TLS policy. If both a TTLSSConfig statement and a CommonTTLSSConfig statement are defined, the specified CommonTTLSSConfig file is processed before the TTLSSConfig policy file specified for that stack.

On the policy server, use the DynamicConfigPolicyLoad statement to specify the remote AT-TLS policies. On the policy client, use the PolicyServer statement to retrieve the remote AT-TLS policies from the policy server.

Within the AT-TLS policy file, AT-TLS rules define a set of conditions that are compared to connections when policy is mapped during connect, or at the first select for readable or writable, poll for readable or writable, send, receive, or SIOCTTLSSCTL ioctl. If a rule match is found, AT-TLS transparently provides TLS protocol control for the connection based on the security attributes specified in the actions associated with the rule.

AT-TLS rules

A TTLSSRule statement consists of a set of conditions that are compared against the connection being checked. When a match is found, policy lookup stops and the connection is assigned the actions associated with the rule. The rule conditions are:

- LocalAddr - Local IP address or addresses
- RemoteAddr - Remote IP address or addresses
- LocalPortRange - Local port or ports
- RemotePortRange - Remote port or ports
- Jobname - Job name of the owning application or wildcard job name
- Userid - User ID of the owning process or wildcard user ID
- Direction - Inbound if applied to a passive socket (established by accept), Outbound if applied to an active socket (established by connect), or Both

Direction and at least one other condition must be specified. Other rule considerations include:

- If a condition is not specified, that condition is not considered when comparing the rule and the connection for a match.
- Multiple values can be specified for the IP address and port conditions, either directly in the condition or as a referenced group.
- IPv6 addresses are valid in all environments.

Each TTLSSRule statement can also have a priority. Priority values can be integers in the range 1 - 2000000000, with 2000000000 being the highest priority. When assigning priorities, you should skip some values to allow for future rule insertion between existing rules. Policy Agent orders rules in alphabetical order within priority.

Tip: If connections can map to more than one rule, always use priority and leave priority space between rules.

AT-TLS actions

A TTLSSRule statement can reference up to three actions:

- The TTLSSGroupActionRef parameter includes the name of a globally defined TTLSSGroupAction statement
- The TTLSEnvironmentActionRef parameter includes the name of a globally defined TTLSEnvironmentAction statement
- The TTLSSConnectionActionRef parameter includes the name of a globally defined TTLSSConnectionAction statement

The `TTLSTLSGroupActionRef` parameter is required, and the `TTLSTLSGroupAction` statement must specify `TTLSEnabled ON` or `TTLSEnabled OFF`. If `TTLSEnabled OFF` is specified, no additional specifications are needed. Otherwise, the AT-TLS environment action is required and the AT-TLS connection action is optional. Each action represents a scope of control.

When an AT-TLS action statement is deleted or replaced, it is considered stale. New connections will not map to a stale action. Connections that mapped to an action that later becomes stale continue to use the resources associated with the stale action until the connection closes.

AT-TLS group action

This action defines whether AT-TLS is enabled, allows trace settings, and provides the ability to set unique Language Environment variables for the Language Environment process that will be started for the action. Many `TTLSTLSRule` statements can reference the same `TTLSTLSGroupAction` statement. In a simple implementation of AT-TLS, you need to specify only `TTLSEnabled ON` on the `TTLSTLSGroupAction` statement.

The AT-TLS group action represents a single Language Environment process and enclave, and initializes one instance of the System SSL DLL. Global attributes are owned by this action. Each AT-TLS group has a main task, a logging task, and a dynamic pool of pthreads that handle System SSL secure environment and secure connection management. When a stale group has no remaining connections, the pthreads, tasks, and Language Environment process are removed.

Guideline: Use as few AT-TLS group actions as necessary.

AT-TLS environment action

This action requires a key ring name (either RACF or gskkyman format), and the handshake role (client or server) this half of the connection will assume. Cipher suites and trace settings can also be set. There are several advanced parameters available if needed, but in a simple implementation of AT-TLS, you need to specify only a key ring and the handshake role.

The AT-TLS environment action is used to create System SSL environments. A key ring and SSL Session ID (SID) cache are examples of attributes owned by a System SSL environment. The AT-TLS environment action initializes a System SSL environment within the Language Environment process that was created to represent an AT-TLS group action. Several System SSL environments can exist within a single AT-TLS group. The same `TTLSEnvironmentAction` statement can be used to create similar System SSL environments in the same or different groups. AT-TLS dynamically creates instances of System SSL environments as needed. AT-TLS deletes System SSL environments when they have had no connections using them for a period of ten to twenty minutes. If the `TTLSEnvironmentAction` statement used to create a System SSL environment becomes stale, AT-TLS deletes the environment when it has no remaining connections. Connections associated with the same server application or same client user ID can share a System SSL environment. Connections that share an existing System SSL environment avoid the processing required to initialize an environment, such as opening a key ring. Connections between the same partners can also reuse recent session information in the SID cache, allowing them to use the SSL short handshake that requires less processing. System SSL connection resources are released when the connection closes.

AT-TLS connection action

The AT-TLS connection action represents attributes at the connection level. This action is optional, and is needed only when a subset of connections within an AT-TLS environment must have different parameters. Handshake role, security version, cipher suites, and tracing are examples of attributes that can be changed at the connection level. In a simple implementation of AT-TLS, you do not need to specify this action.

System SSL connections are initialized within a System SSL environment. Use the AT-TLS connection action to override attributes specified at the SSL environment layer. System SSL connection resources are released when the connection closes.

Getting started with AT-TLS

Assume you have a TCP client and server application pair running on z/OS platforms. This application handles sensitive data, and you want this application to be used only with the TLS protocol. The server application runs under the job name of XYZSRV, and creates a passive TCP socket bound to IP address INADDR_ANY and port 5000. The client application runs as a command, issued by TSO or z/OS UNIX interactive users, and connects to port 5000.

To complete AT-TLS security setup for this sample environment, you need to create both server and client key rings. The server key ring needs to contain a server certificate, and any certificates used to sign it. The server needs access to the private keys of the server certificate. The client key ring needs the root certificate used to sign the server certificates. For a TLS/SSL primer and some step-by-step examples, see [Appendix B, “TLS/SSL security,” on page 1359](#). For more information on using RACDCERT to administer certificates, see [z/OS Security Server RACF Security Administrator's Guide](#). For detailed information on managing key rings and certificates with gskkyman, see [z/OS Cryptographic Services System SSL Programming](#).

Configuring the server system

On each z/OS system where you run the server application, see [Table 59 on page 1154](#) for the tasks needed to configure the server.

Table 59. AT-TLS configuration for the server system	
Task	Specification
Create key ring	Create server key ring with server certificate and necessary certificate authority certificates.
Create Policy Agent files	<ol style="list-style-type: none">1. Create a Policy Agent main configuration file containing a TcpImage statement for the server stack.2. Create a Policy Agent image configuration file for the server stack.3. If AT-TLS policies are to be retrieved from the policy server, create image-specific AT-TLS configuration files, and optionally, common AT-TLS configuration files, on the policy server.

Table 59. AT-TLS configuration for the server system (continued)	
Task	Specification
Add AT-TLS configuration	<ol style="list-style-type: none"> For local AT-TLS policies, add a TTLSConfig statement to the Policy Agent image configuration file, identifying the TTLSConfig policy file location: <pre>TTLSConfig serverpath</pre> For remote AT-TLS policies, add a PolicyServer statement to the policy client image configuration file: <pre>PolicyServer { ClientName name PolicyType TTLS { ... } ... }</pre> <p>Add a DynamicConfigPolicyLoad statement to the policy server main configuration file:</p> <pre>DynamicConfigPolicyLoad clientname { PolicyType TTLS { PolicyLoad serverpath } ... }</pre>
Add statements to the AT-TLS policy file	<p>Add the AT-TLS policy statements to the <i>serverpath</i> file:</p> <pre>TTLSRule XYZServerRule { LocalPortRange 5000 JobName XYZSRV Direction Inbound TTLSGroupActionRef XYZGroup TTLSEnvironmentActionRef XYZServerEnvironment } TTLSGroupAction XYZGroup { TTLSEnabled On } TTLSEnvironmentAction XYZServerEnvironment { TTLSKeyRingParms { # Assuming SERVER is the owner of the keyring server_key_ring. Keyring SERVER/server_key_ring } HandshakeRole SERVER Trace 7 }</pre>
Set up InitStack access control	<ol style="list-style-type: none"> Define the EZB.INITSTACK.sysname.tcpname profile for each AT-TLS stack. Permit administrative applications to use the stack before AT-TLS is initialized. <p>For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.</p>
Enable AT-TLS	Set TCPCONFIG TTLS in PROFILE.TCPIP.

Configuring the client systems

On each z/OS system where you run the client application, see [Table 60 on page 1156](#) for the tasks needed to configure the client.

Table 60. AT-TLS configuration for the client system	
Task	Specification
Create key ring	<p>Create/specify a key ring for each client:</p> <ul style="list-style-type: none">• When using TLS server authentication without client authentication, there are two approaches for defining your client-side key rings. As you decide between these approaches it is important to know that a complete copy of a key ring's contents will be loaded into TCP/IP above-the-bar private memory for each user that opens a connection under the protection of an AT-TLS client rule that uses that key ring. If the key ring in question contains a lot of certificates and a non-trivial number of users will use the key ring, it could consume a large amount of above-the-bar TCP/IP private memory.<ol style="list-style-type: none">1. Specify the virtual CERTAUTH key ring (*AUTH*/*) for the client AT-TLS rule. This virtual key ring contains every trusted certificate authority (CA) certificate in the RACF database, thus eliminating the need to create client-specific key rings with the required CA certificates.2. Create a client key ring for each client user ID using the specified key ring name that only contains the necessary CA certificates. Due to the way the key ring name is specified in the client-side AT-TLS policy (defined in a later step), when it is time to open the key ring,, System SSL looks for a key ring of the specified name that is owned by the user ID under which the client is executing. While requiring more administration than the virtual key ring, this approach could be a good alternative if there are a large number of trusted CA certificates in the RACF database.• When using TLS server authentication with client authentication, create a client key ring for each client user ID using the specified key ring name. This key ring must contain the client certificate and private key, the CA certificates in the client's trust chain, as well as any CA certificates required to validate the server's certificate. Due to the way the key ring name is specified in the client-side AT-TLS policy (defined in a later step), when it is time to open the key ring, System SSL looks for a key ring of the specified name that is owned by the user ID under which the client is executing.
Create Policy Agent files	<ol style="list-style-type: none">1. Create a Policy Agent main configuration file containing a TcpImage statement for the client stack.2. Create a Policy Agent image configuration file for the client stack.3. If AT-TLS policies are to be retrieved from the policy server, create image-specific AT-TLS configuration files, and optionally, common AT-TLS configuration files, on the policy server.

Table 60. AT-TLS configuration for the client system (continued)

Task	Specification
Add AT-TLS configuration	<ol style="list-style-type: none"> For local AT-TLS policies, add a TTLSConfig statement to the Policy Agent image configuration file, identifying the TTLSConfig policy file location: <pre>TTLSConfig clientpath</pre> For remote AT-TLS policies, add a PolicyServer statement to the policy client image configuration file: <pre>PolicyServer { ClientName name PolicyType TTLS { ... } ... }</pre> <p>Add a DynamicConfigPolicyLoad statement to the policy server main configuration file:</p> <pre>DynamicConfigPolicyLoad clientname { PolicyType TTLS { PolicyLoad clientpath } ... }</pre>
Add statements to the AT-TLS policy file	<p>Add the AT-TLS policy statements to the <i>clientpath</i> file:</p> <pre>TTLSRule XYZClientRule { RemotePortRange 5000 Direction Outbound TTLSGroupActionRef XYZGroup TTLSEnvironmentActionRef XYZClientEnvironment } TTLSGroupAction XYZGroup { TTLSEnabled On } TTLSEnvironmentAction XYZClientEnvironment { TTLSKeyRingParms { # The Keyring value is not qualified with the key ring owner. # This allows the rule to be used by multiple clients with # different user IDs. # For rules that are only used under one specific client user # ID, the user ID # of the key ring owner can be specified in the Keyring parameter # as USERID/client_key_ring. # Specifying the owning user ID can simplify diagnostics. Keyring client_key_ring } HandshakeRole CLIENT Trace 7 }</pre>

Table 60. AT-TLS configuration for the client system (continued)	
Task	Specification
Set up InitStack access control	<ol style="list-style-type: none"> 1. Define the EZB.INITSTACK.<i>sysname.tcpname</i> profile for each AT-TLS stack. 2. Permit administrative applications to use the stack before AT-TLS is initialized. <p>For examples of the security product commands needed to create this resource profile name and grant users access to it, see member EZARACF in sample data set SEZAINST.</p>
Enable AT-TLS	Set TCPCONFIG TTLS in PROFILE.TCPIP.

Steps for starting AT-TLS and verifying its operation

After configuring the server and client systems, use these steps to start and verify AT-TLS.

Before you begin

- Perform the tasks in [AT-TLS configuration for the server system](#) and [AT-TLS configuration for the client system](#).
- Review your syslogd configuration to verify that messages written by Policy Agent and TCP/IP stacks are saved in the wanted files. AT-TLS syslogd messages are written to the daemon facility by default.
- Start syslogd.

You are now ready to start the sample AT-TLS environment and verify its operation.

Procedure

Perform the following steps to start AT-TLS and verify its operation:

1. Start the TCP/IP stacks.
2. Start the administrative applications required to successfully run Policy Agent, such as OMROUTE and LDAP.
3. If System SSL needs to access Integrated Cryptographic Services Facility (ICSF), start ICSF. For information about [Using cryptographic features with System SSL](#), see [z/OS Cryptographic Services System SSL Programming](#).
4. Start Policy Agent on all participating systems and verify that there were no policy errors in processing the policy files.
5. Verify that the participating TCP/IP stacks have received AT-TLS policy and released console message EZZ4248E.
6. Start server application and verify that it starts without errors.
7. Start client applications. Review the AT-TLS trace messages in the syslogd output on both the client and server systems. Verify that connections are mapping to the intended policy and no handshake errors occur. The info messages EZD1281I TTLS Map and EZD1283I TTLS Initial Handshake show the policy used and result of TLS handshake negotiation. The error message EZD1286I TTLS Error shows any failures.

Results

For information on [common AT-TLS startup errors](#), see [z/OS Communications Server: IP Diagnosis Guide](#).

Application compatibility with AT-TLS

Most applications can use AT-TLS. However, some applications should not be configured to use AT-TLS. Any application that is already configured to use SSL or TLS protocols should not use AT-TLS. Use of AT-TLS would result in encrypting data that is already encrypted. The receiving partner would not be able to decipher the data that had been encrypted twice. If the application can be configured to use clear text or the application uses the `SIOCTTLCTL` ioctl, AT-TLS can provide support.

The only TCP/IP application supplied with z/OS Communications Server that already supports the TLS protocol is the FTP client, which provides two modes of TLS support. One uses native calls to System SSL and the other uses AT-TLS. To configure the FTP client to use AT-TLS, code the `TLSMECHANISM ATTLS` statement in `FTP.DATA`. For more information, see [“Steps for migrating the FTP client to use AT-TLS” on page 728](#).

AT-TLS does not support web servers using the Fast Response Cache Accelerator (FRCA) support in TCP/IP. AT-TLS ignores policy for connections using FRCA. The sockets are treated as if they did not match any AT-TLS rules.

AT-TLS does not support applications that use the Pascal sockets API. AT-TLS ignores all Pascal sockets. The sockets are treated as if they did not match any AT-TLS rules. TCP/IP applications that use the Pascal API include:

- TSO TN3270E Telnet client
- LPD server

Policy considerations

Policy is a powerful tool for configuring and managing your applications that use AT-TLS. Before configuring the AT-TLS policy, review the [table in the Policy Agent and policy applications topic in z/OS Communications Server: IP Configuration Reference](#).

Reusable objects

With several of the AT-TLS rule conditions and action parameters, you can reference named objects. If you are going to use the same definition in several rules or actions, it is easier to create a single named object and refer to it, rather than repeating the definition. This also makes changing these definitions easier and more accurate. For example, the `IpAddrGroup` statement can be used to identify groups of IP addresses that are used in several rules. You might find it useful to define `TTLSRule` statements that reference an IP address group with a name, such as `LocalHost`. In each stack's AT-TLS policy file, you would define that IP address group with all of the addresses local to that stack. That single reference can then be used throughout the policy to easily represent all local IP addresses, without re-coding the local addresses in each rule condition.

Common AT-TLS configuration file

The common AT-TLS configuration file should contain all of the policy that is common to multiple stacks. When the policy agent reads a policy file for a given stack, the contents of the common AT-TLS configuration file are logically added before the contents of the stack-specific file. Rules and actions in the common AT-TLS configuration file can reference objects, such as a local `IpAddrGroup` statement, that are defined in the stack-specific AT-TLS configuration file. Rules and actions in the stack-specific file can also reference objects that are defined in the common file.

If Policy Agent encounters multiple objects of the same type and name, the last occurrence is the one that is used. You can take advantage of this by defining an object that is used on many stacks in the common file, and then overriding it in the stack-specific file of a specific stack.

Exempting specific connections from AT-TLS

In some cases, you might want to have the majority of users of an application using AT-TLS, but then exempt a small group of users. You might find that it is simpler to define a broad AT-TLS policy for the

application, and then define a higher priority rule for the exempt users. The simplest way to do this is to define a `TTLSTLSGroupAction` statement with the `TTLSEnabled` parameter set to `OFF`. The exempt user rule would then reference this action. When the `TTLSTLSGroupAction` statement specifies the `TTLSEnabled` parameter as `OFF`, the `TTLSEnvironmentActionRef` parameter on the corresponding rule is not required.

Action refresh

When Policy Agent is stopped and restarted, or when policy files are changed, policy objects that are currently in use might be deleted or replaced. When an AT-TLS action is deleted or replaced, connections using the old object continue processing without change. Connections that search AT-TLS policy after the change use the new action objects. A change to an AT-TLS group action causes a new Language Environment process to be created, along with new SSL environments for each user or application environment associated with that group. A change to an AT-TLS environment action causes new SSL environments to be initialized within each group with which that environment is associated. System SSL reopens key rings and certificates, and creates an empty session ID cache when it initializes an SSL environment.

There are cases when a change is made that is not reflected by a change in the action. For example, the default certificate in a key ring might change. The key ring name has not changed, but there is a need to open a new environment. Simply refreshing policy will not refresh the AT-TLS environment action in AT-TLS, because no values within the action have changed. To force a refresh in AT-TLS, some parameter must be changed. The `EnvironmentUserInstance` parameter can be used for this purpose. Incrementing the instance number forces a refresh of AT-TLS without changing any of the security parameters. Similarly, changes to the contents of the environment file named in a group action will not be applied until the group action is changed. The `GroupUserInstance` parameter can be used to force an AT-TLS refresh of the group, creating a new Language Environment process using the new environment file contents.

Sometimes after you have made a change to an AT-TLS policy, the changed policies are not automatically reinstalled by the Policy Agent; new connections might fail until the policies are reinstalled. If you see AT-TLS connection setup errors with message `EZD1286I` or `EZD1287I` after you made an AT-TLS configuration change, you can force all AT-TLS policies to be reinstalled by refreshing the Policy Agent. From the MVS console, issue the `MODIFY procname,REFRESH` command. For more information about controlling the refresh of policies using the [TcpImage and PEPInstance statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Achieving the basic level of security

To achieve the basic level of security, take the following actions:

1. Pick the handshake roles.
2. Specify the key ring.

Picking the handshake roles

Every secure connection must have one end using the `HandshakeRole Client`, and the other end using the `HandShakeRole Server` or `HandShakeRole ServerWithClientAuth`.

In the SSL and TLS protocols, the client side sends a `ClientHello` handshake record and the server side responds with a `ServerHello` handshake record. If both sides send `ClientHello` records, the handshake fails. If both sides wait for a `ClientHello`, the handshake times out.

The role played in the handshake is independent of whether the application is used as the client, server, or peer. It is also independent of which application does the `listen()` and `accept()` and which does the `connect()`. The primary consideration for deciding which role an application should play is certificate management.

- An application designated as `HandshakeRole Server` must have a user or site certificate on its key ring. It must have access to the private keys of its user or site certificate. It might also need other certificates on its key ring, required for authentication.

The partner application designated as HandshakeRole Client must have a key ring that contains the root certificates required to authenticate the server's certificate. The client does not need access to the private keys of any certificate. Clients can share this key ring.

- An application designated as HandshakeRole ServerWithClientAuth might need additional root certificates on its key ring to authenticate client certificates. The server decides whether a client must present a user certificate and what constitutes an acceptable certificate.

The partner application designated as HandshakeRole Client decides whether to present a user certificate when challenged. To present a user certificate, it must have a private key ring with that user certificate. It must have access to the private keys of the user certificate. The client key ring must also contain the root certificates required to authenticate the server's certificate.

When the HandshakeRole parameter is set to ServerWithClientAuth, a certificate request is sent to the client during the handshake. The client can send its certificate to the server, which can then validate the certificate. The level of validation done by the server is controlled by the setting of the ClientAuthType parameter. The following chart summarizes the differences between the parameter settings:

Table 61. ClientAuthType parameter settings		
ClientAuthType	Client certificate required or optional	Certificate validation
PassThru	Optional	None
Full	Optional	Certificate is validated against keyring, if provided
Required	Required	Certificate is validated against keyring
SAFCheck	Required	Certificate is validated against keyring and must be associated with a user ID in the security product

If the certificate fails validation, the secure connection does not initialize successfully. The default setting for ClientAuthType is Required. For applications that do not issue AT-TLS ioctl calls to obtain the certificate or user ID of the client, the Required setting ensures that any client that connects provides a valid client certificate. The ClientAuthType setting of PassThru should be used only for applications that will get the certificate from AT-TLS using the SIOCTTLCTL ioctl call and implement their own security methods to validate the certificate. The ClientAuthType setting of Full can be used for applications that want to validate the client certificate if provided, but do not require a client certificate to establish a secure connection. The ClientAuthType setting of SAFCheck provides an additional level of security when using client authentication by requiring AT-TLS to derive a user ID associated with the certificate. An application can then get the user ID from AT-TLS using the SIOCTTLCTL ioctl after the secure connection has been established. The user ID can be used to either verify the user ID presented by the client during the application's protocol flows or eliminate the need for a user ID to be sent by the client.

Specifying the key ring

A fully-qualified SAF key ring name is specified as *userid/keyring*. A value that begins with a forward slash is interpreted as the path name of a gskkyman key ring. A PKCS #11 token name is specified as **TOKEN*/token-name*. **TOKEN** indicates that the specified key ring is actually a token name.

When creating AT-TLS rules for cases where the protected connections will always use the same SAF keyring, owned by the same user ID, you should specify the fully qualified key ring name in the form *userid/keyring* on the Keyring parameter. Coding the user ID on the Keyring parameter can be helpful when diagnosing TLS handshake issues. However, for cases where multiple TLS client user IDs each have their own key ring using a common keyring name, you can omit the userid and forward slash so that only the keyring name itself is specified. When the user ID is omitted, AT-TLS and System SSL assume the currently executing user ID owns the keyring when the TLS handshake takes place. This allows multiple

clients that use a common key ring name to share the same AT-TLS rule. Note that doing this, however, adds diagnostic steps to determine which key ring was being used in case an error occurs.

Configuring more sophisticated security

This topic describes decisions you can make to achieve more elaborate levels of security.

Cipher suite specification

You can specify the exact list of TLS cipher suites to be allowed for TLS sessions. You should not include any cipher suites that you do not want to allow. The order of the cipher suite list is important, as it determines the priority order for selecting a cipher suite during a TLS handshake. In general, System SSL selects cipher suites according to the server's order of usage preference. The first cipher suite in the server's list that is present in the client's list and is also supported for the selected TLS protocol version is selected. Other implementations might work differently.

AT-TLS does not pass any cipher suites to System SSL by default. For the list of cipher suites supported and the default order used if none is specified, see [z/OS Cryptographic Services System SSL Programming](#).

Guideline: Code TTLSCipherParms statements to support newer cipher algorithms, such as elliptical curve cipher suites, AES Galois Counter Mode (GCM) cipher suites, or cipher suites that use SHA2-based digests.

Tip: If you configure your AT-TLS policies using the Network Configuration Assistant (NCA), you can select a recommended cipher suite list.

Requirement: Integrated Cryptographic Service Facility (ICSF) must be active for elliptic curve ciphers and for ciphers using AES-GCM or Cha-Cha Poly algorithms.

If the CSFSERV class is defined, the user ID that is associated with the AT-TLS application must have READ access to the following resources in that class:

- CSF1DVK
- CSF1GAV
- CSF1GKP
- CSF1PKS
- CSF1PKV
- CSF1SKD
- CSF1SKE
- CSF1TRC
- CSF1TRD
- CSFOWH

For more information about [elliptic curve cryptography support](#), see [z/OS Cryptographic Services System SSL Programming](#).

Limiting Key Exchange Elliptic Curves for TLSv1.0, TLSv1.1, and TLSv1.2

When using an Ephemeral Elliptic Curve Diffie Hellman cipher (TLS_ECDHE_XXX), each side of the connection being negotiated generates an elliptic curve key pair and exchanges the public key as part of the TLSv1.0, TLSv1.1, or TLSv1.2 handshake process. The elliptic curve is selected by the TLS server using a list of supported elliptic curves provided by the TLS client.

For a TLS client, the list of supported elliptic curves is defined using the ClientECurves parameter on the TTLSignatureParms statement. This list represents the curves supported by the TLS client for the key exchange in the client's preferred order. This list also represents certificate elliptic curves supported when a server is using an elliptic curve public key certificate.

For a TLS server, the list of allowed curves is defined using the `ServerKexECurves` parameter on the `TTLSSignatureParms` statement. This list represents the allowed key exchange curves with no defined order.

Example:

For a TLS client that supports `secp256r1` (0023) and `secp384r1` (0024) and prefers that `secp256r1` be used, `ClientECurves` would be configured as:

```
ClientECurves 00230024
```

If the TLS server supports `secp384r1` (0024), `x25519` (0029) and `secp256r1` (0023), `ServerKexECurves` would be configured as:

```
ServerKexECurves 002400290023
```

The TLS server selects the first elliptic curve in the client's list which is included in the server's supported list. In this example, the key exchange process for a connection between the client and server would use `secp256r1` (0023).

For more information on configuring `ClientECurves` and `ServerKexECurves`, see [TTLSSignatureParms statement in z/OS Communications Server: IP Configuration Reference](#).

Protocol versions

TLSv1.2 and TLSv1.3 provide stronger security than SSLv2, SSLv3, TLSv1.0 and TLSv1.1. By default, SSLv2, SSLv3, TLSv1.0 and TLSv1.1 are not enabled in AT-TLS policy. To use older applications that do not support the newer protocols, set `SSLv2`, `SSLv3`, `TLSv1.0` or `TLSv1.1on`.

If you plan to use the TLSv1.3 protocol, you must ensure that you specify at least one TLSv1.3 cipher suite.

Using TLSv1.3 protocol support

The TLS Version 1.3 protocol is a major revision to the TLS protocol that is intended to provide better security and reduce the number of handshake messages.

Note: Be aware that the CPU consumption of the TCP/IP address space will likely increase when you enable TLSv1.3. While TLSv1.3 provides stronger cryptographic protection for your TCP connections, it inherently uses more cryptographic operations and therefore consumes more CPU than TLSv1.2 when using comparable cipher suites and key exchange algorithms. The magnitude of the CPU increase depends on a variety of factors, including the cipher suites you were using under TLSv1.2 (or earlier), the z/OS operating system level (earlier OS versions may not have as many optimizations as later versions), and the level of hardware you are using (earlier versions of hardware may have less cryptographic acceleration than newer versions).

To use TLSv1.3, there are certain configuration requirements:

- **Cipher specifications:** The cipher specifications that are valid for TLSv1.2 and earlier protocols are not supported for TLSv1.3. AT-TLS supports three TLSv1.3 cipher suites: `TLS_AES_128_GCM_SHA256`, `TLS_AES_256_GCM_SHA384`, and `TLS_CHACHA20_POLY1305_SHA256`. For an AT-TLS rule that enables TLSv1.3, you must specify one or more of these cipher suites.

Guideline: When multiple TLS protocol versions are supported, it is recommended that you include the TLSv1.3 cipher specifications at the beginning of the cipher suite list.

- **Supported groups or curves for certificate selection (TLSv1.0 and later):** A supported groups or curves list is configured for the client with the `ClientECurves` parameter. It is sent to the server in a supported groups extension. The client's list is used by the server to select a group or curve for use during the key exchange process and to guide selection of the server's certificate when elliptic curve-based certificates are used.

- Key share groups: TLSv1.3 uses client and server key shares to facilitate the encryption of TLSv1.3 handshake messages and to determine the key exchange algorithms. When using TLSv1.3, each TLS partner must provide its key share.

Key share group settings are configured in AT-TLS policy. For a client, the key share groups or curves for which a key share should be generated are specified with the `ClientKeyShareGroups` parameter. The client generates a key share for each group in the `ClientKeyShareGroups` list that is also in the `ClientECurves` list. The order of the key shares in the `key_share` extension sent to the server is based on the `ClientECurves` order.

For a server, the supported key share groups or curves are specified with the `ServerKeyShareGroups` parameter. When the server receives the client's `key_share` extension, the server will use the client's preference order in selecting a group that is also supported for the server. The selected group is used to encrypt the remaining portions of the TLSv1.3 handshake.

- Signature and hash algorithms: The list of signature and hash algorithms supported by the TLS client and server are specified in order of preference using the `SignaturePairs` parameter. These algorithms are used in the TLSv1.3 handshake for digital signatures of X.509 certificates and TLS handshake messages. The client sends its supported list to the server in the supported groups extension to guide the server's certificate selection and the selection of an algorithm for use in protecting TLSv1.3 handshake messages. If the server is enabled for client authentication, the server sends its supported list to the client in the supported groups extension for the same type of guidance.

Tip: When different algorithm pairs need to be specified for the key exchange and certificate selection, `SignaturePairsCert` can be configured to guide the certificate selection.

Rule: When using RSA certificates for TLSv1.3 handshakes, `SignaturePairs` should include the RSASSA-PSS signature algorithms for generating the signatures for TLSv1.3 handshake messages.

- Middlebox compatibility mode: When TLSv1.3 was under development by the IETF, there were issues with some network-based devices that act as TLS proxies. These devices, called "middleboxes" were not able to properly parse pure TLSv1.3 handshake messages. To accommodate these middleboxes, RFC 8446 (TLSv1.3 specification) defined a compatibility mode. The AT-TLS parameter `MiddleBoxCompatMode` can be set on to enable compatibility mode. It is disabled by default.

For more details on TLSv1.3 selection of signature algorithm pairs, groups and curves, and X.509 certificates and other considerations, see [z/OS Cryptographic Services System SSL Programming](#).

Certificate validation

You can specify that certificates should be validated by using the following methods:

- Only the method described in RFC 2459
- Only the method described in RFC 3280
- Only the method described in RFC 5280
- Any of the methods that are described in RFC2459, RFC3280 and RFC5280

If 128-bit minimum or 192-bit minimum Suite B profiles are configured, the certificates will be validated as described in RFC 5280 and RFC 5759.

Validating a host name against a certificate

Validating a host name against a partner certificate

After a successful TLS negotiation, an application-aware or application-controlling AT-TLS application can request that the partner certificate be checked to ensure that it matches a provided host name. This is done with the `SIOCTTLSTLSIOCTL` ioctl with request type of `TTLSTLS_QUERY_ONLY` and a `TTLSTLS_Host_Status` get request in the `TTLSTLSHeader`. See [Coding the SIOCTTLSTLSIOCTL ioctl in z/OS Communications Server: IP Programmer's Guide and Reference](#).

The host name value is validated against the DNS entry in the Subject Alternative Name (SAN) extension first and, only if that is not present, is the host name validated against the subject DN's common name.

For additional details on the validation that is done by System SSL see [gsk_validate_hostname\(\)](#) in [z/OS Cryptographic Services System SSL Programming](#).

Enabling an AT-TLS client to verify the server identity during the TLS handshake

An AT-TLS client can be configured to validate the server identity based on the server's certificate as part of the TLS handshake. The validation is done based on the comparison logic defined by RFC 6125 Representation and Verification of Domain-Based Application Service Identity within Internet Public Key Infrastructure Using X.509 (PKIX) Certificates in the Context of Transport Layer Security (TLS).

The server's DNS domain name is configured in the AT-TLS client rule using one or both of the following parameters:

- HostReferenceIdDNS
- HostReferenceIdCN

These parameters can be configured on the `TTLSEnvironmentAdvancedParms` or the `TTLSTLSConnectionAdvancedParms` statement.

If the server certificate contains a Subject Alternative Name (SAN) extension with one or more DNS domain names, the configured `HostReferenceIdDNS` list is used to ensure that the server to which the client connected is the expected one. This is done by comparing the values configured on the `HostReferenceIdDNS` parameter with the values in the certificate's SAN extension.

If the server certificate does not contain a SAN extension with DNS domain name values, the certificate's subject DN Common Name (CN) is used for verification. The values configured on the `HostReferenceIdCN` parameter are compared with the CN value in the subject DN.

Note: The `HostReferenceIdCN` parameter is only used for verification when the certificate does not contain a SAN extension with DNS values.

The configured values for the verification must be fully qualified DNS domain names. By default, the server certificate values are also expected to be fully qualified DNS domain names. However, the `HostRefWildcardValidation` parameter can be configured to support an asterisk as a wildcard character within the first label of a server certificate value.

If an AT-TLS rule includes a `HostReferenceIdDNS` or `HostReferenceIdCN`, the TLS handshake will fail with `GSK_ERR_SERVER_REF_ID_NO_MATCH` if the server identity cannot be verified.

If you use the IBM Configuration Assistant for z/OS Communications Server to configure AT-TLS policies, see *IBM Configuration Assistant for z/OS Communications Server online help*.

If you manually configure AT-TLS policy files, see [z/OS Communications Server: IP Configuration Reference](#) for details on configuring the `HostReferenceIdDNS`, `HostReferenceIdCN`, and `HostRefWildcardValidation` parameters.

See *Server certificate Domain-based validation* in [z/OS Cryptographic Services System SSL Programming](#) for additional details.

FIPS 140-2 support

You can configure AT-TLS to support FIPS 140-2. Specify either `On`, `Level1`, `Level2`, or `Level3` for the `FIPS140` statement of the `TTLSTLSGroupAction` statement.

For information about configuring System SSL to run in FIPS 140-2 mode, see the [System SSL and FIPS 140-2](#) topic in [z/OS Cryptographic Services System SSL Programming](#).

Restriction: The FIPS 140-2 standard does not define support for TLSv1.3 or the new cipher suites defined for it. Enabling both the TLSv1.3 protocol and FIPS support will result in an error.

Requirement: ICSF must be active before starting AT-TLS groups configured to support FIPS140. For information about configuring ICSF to support FIPS 140-2, see the topic about [Operating in compliance with FIPS 140-2](#) in [z/OS Cryptographic Services ICSF Writing PKCS #11 Applications](#).

If the RACF CSFSERV class is defined, the user ID associated with the TCP/IP stack and any application user ID that is using the TTLSGroup must be given READ access to the CSFRNG resource within the CSFSERV class. If the CSFSERV class is defined and Diffie-Hellman is being used, the application user ID must be given READ access to the CSF1TRC, CSF1DVK, CSF1GKP, CSF1GSK, CSF1GAV, and CSF1TRD resources within the CSFSERV class.

Certificate revocation support

Applications requiring validation of the partner's certificate can optionally check to see if the certificate has been revoked. Certificate revocation checking can be done using a certificate revocation list (CRL) obtained from a LDAP or HTTP server or by using the certificate revocation status obtained from an OCSP responder. You can configure any combination of certificate revocation by using the following AT-TLS policy statements:

- TTLSGskHttpCdpParms
- TTLSGskLdapParms
- TTLSGskOcspParms

Guideline: Connections that are used by System SSL to contact the CRL service should not fall under an enabled AT-TLS policy because these connections can be made before AT-TLS policy is installed.

Encryption key refresh

All of the TLS protocol versions except SSLv2 support some form of dynamic key refresh (also call "cipher reset"). The SSLv3, TLSv1, TLSv1.1, and TLSv1.2 protocols allow the encryption key to be renegotiated during a secure connection. TLSv1.3 supports dynamic key updates without renegotiation. Refreshing the encryption key provides a higher level of security for long-running connections. The AT-TLS default is to not reset the cipher.

To enable cipher reset through AT-TLS, you can specify a time interval in the range 1–1440 minutes using the ResetCipherTimer parameter. The cipher reset is requested when the timer expires and the next application read or write is completed. The time interval is restarted when the cipher has been changed. The specific behavior for a cipher reset depends on the TLS protocol version of the connection:

- For TLSv1.2 and prior versions, both ends of the secure connection must agree to perform another handshake to renegotiate the cipher. By default, both the client and server must support RFC 5746 renegotiation. The HandshakeRole Client end must initiate this handshake. The HandshakeRole Server end can send an alert to the client requesting another handshake. The client is free to ignore or postpone the request. The server is free to refuse a handshake request sent by the client for another handshake.
- For TLSv1.3, either TLS endpoint can initiate a key update for the traffic it encrypts and sends to the partner, which typically results in the partner sending a key update for the traffic in the opposite direction in response.

Additional security customization considerations

This topic provides additional information that you might want to use to customize security for your environment.

Handshake timer

Certain configuration or application protocol mismatches can lead to stalled connections. The TLS handshake protocol always expects the end of the connection configured as HandshakeRole Client to send the first message. One connection stall scenario results when both ends of the connection are configured as HandshakeRole Server and wait for a ClientHello record from the other end. Another connection stall scenario results when the end of the connection that normally sends the first application data is configured as HandshakeRole Server, but the partner application is not configured to use a secure connection. The HandshakeRole Server end is waiting for a ClientHello, and the nonsecure end is waiting for application data.

You can use the `HandshakeTimeout` action parameter to control the time that AT-TLS should wait during TLS handshake negotiation before resetting the connection. AT-TLS times two different handshake intervals, handshake start and handshake completion. The handshake start interval is intended to detect configuration problems that result in neither partner sending data. The handshake completion interval is intended to detect problems that might stall a handshake in one of the TLS protocol implementations.

The handshake start interval begins when AT-TLS is ready to begin a TLS handshake, and ends when the hello handshake record is received from the partner. On the initiating or active side of the connection, the handshake start interval used is five times the specified `HandshakeTimeout` value, because it includes:

- The network time for the `ClientHello` record to reach the partner if `HandshakeRole` is `Client`.
- The time a connection spends on the partner's listen backlog.
- The time before the partner causes the connection to be mapped.
- The time spent on the partner AT-TLS work queue.
- The time spent by the partner initializing a new System SSL environment, if necessary.
- The network time for the partner's `ServerHello` or `ClientHello` record to be returned.

On the listening or passive side of the connection, the handshake start interval used is the specified `HandshakeTimeout` value, because it includes only the network time for one or both hello records. Handshake start interval timeouts result in AT-TLS return code 5004 and a connection reset.

The handshake completion interval begins when the hello handshake record is received from the partner, and ends when the System SSL `gsk_secure_connection_init()` service returns to AT-TLS. The handshake completion interval used is the specified `HandshakeTimeout` value on either active or passive connections. Handshake completion interval timeouts result in AT-TLS return code 5005 and a connection reset.

The `HandshakeTimeout` action parameter has a default value of 10 seconds. If you determine that you are getting handshake time-outs that are caused by network delays or application workload rather than configuration or application errors, you should increase the value. On the other hand, if you determine that handshakes normally complete much faster in your environment and you would like to detect the occasional incorrectly configured partner more quickly, you can decrease the value.

Diagnostic traces

In addition to the steps for diagnosing AT-TLS problems described in [z/OS Communications Server: IP Diagnosis Guide](#), you might need to collect a System SSL trace when you are diagnosing an AT-TLS problem. The only method for collecting this trace is by using `GSKSRVR CTRACE`, as described in [z/OS Cryptographic Services System SSL Programming](#). You cannot use the `GSK_TRACE` environment variable because it causes an abend if it is used with AT-TLS. When you use `GSKSRVR CTRACE` to diagnose AT-TLS problems, the job name that you specify on the `JOBNAME` parameter of the `CTRACE` command should be the TCP/IP job name rather than the application job name.

If you are not using any other features provided by the `GSKSRVR` started task, then you can use the sample procedure provided in the `SGSKSAMP` library without any changes.

Diagnosis considerations

Applications that implement SSL or TLS can control whether non-encrypted application data is included in diagnostic traces. Lower layers have access to only encrypted data. When using AT-TLS, the TCP, PFS, and SOCKAPI layers have access to non-encrypted data. The AT-TLS default is to suppress this data in `CTRACE` records generated by these layers to protect the application's users. If you need to see this data in these records to diagnose a problem, you can set `CtraceClearText ON`.

AT-TLS writes messages to `syslogd` using the jobname of the TCP/IP started task. The AT-TLS default behavior is to write `syslogd` messages to the daemon facility. Other TCP/IP functions, such as the SNMP TCP/IP subagent, also use the job name of the TCP/IP started task and specify the daemon facility name when writing records to `syslogd`. Because the job name and syslog facility name of the AT-TLS records and the TCP/IP function records are the same, filters cannot be used to direct the AT-TLS records to a different output file. If you want AT-TLS records to go to a different output file, configure `SyslogFacility Auth` on

the `TTLSTLSGroupAdvancedParms` statement to direct the messages from that group to the Auth facility. The job name will remain the job name of the TCP/IP started task. You can then set up filtering based on the job name of the TCP/IP started task and the auth facility in the `syslogd` configuration file to direct AT-TLS records to a different output file.

The Trace value is interpreted by AT-TLS as a bit map. Each of the options is assigned a value that is a power of 2. You should add together the values of each option that you want to activate.

The default Trace value is 2, which provides error messages to `syslogd`. While you are deploying a new policy, you might find it beneficial to specify a Trace value of 6 or 7. This provides connection info messages, in addition to error messages in `syslogd`. The info messages provide positive feedback that connections are mapping to the intended policy.

Trace options event (8), flow (16), and data (32) are intended primarily for diagnosing problems. Trace values larger than 7 can cause a large number of trace records to be dropped instead of being sent to `syslogd`.

Tip: Use a `TTLSTLSConnectionAction` with a higher Trace value to diagnose problems in a production environment. You can temporarily define a high priority `TTLSTLSRule` with conditions that cover only a small number of problem connections. This temporary rule can reference the same `TTLSTLSGroupAction` and `TTLSTLSEnvironmentAction` that your production rule references, and a `TTLSTLSConnectionAction` with the Trace level you want for diagnosis.

TLS function negotiation

TLS protocols enable the TLS client and TLS server to negotiate additional functionality for a connection. If either the TLS client or TLS server does not understand a function, the function is not used on the connection. However, the TLS client or TLS server might require that the function be supported by the remote partner. If the remote partner does not support the function, the connection can be closed. Each function can be configured as Required, Optional, or Off.

- Required

The connection ends if the remote endpoint does not accept the TLS function.

- Optional

The function is negotiated on the connection, but the connection does not end if the remote partner does not support the function.

- Off

The function is not supported on the connection. If the remote partner requires this function, the remote partner closes this connection.

Guideline: For TLS servers, configure the functions as Optional to prevent remote partners that require this extension from being unable to connect.

Wireless performance

AT-TLS supports the following negotiated functions:

- Maximum SSL fragment length

This TLS function negotiates the maximum size of unencrypted data that can be sent in a single SSL fragment. Without this function, 16 K is the maximum fragment length. A TLS client can negotiate a size of 512, 1 K, 2 K or 4 K. Some clients need to use the smaller size because of memory or bandwidth limitations.

- Truncated HMAC

TruncatedHMAC is supported for TLSv1, TLSv1.1 and TLSv1.2. TLS cipher suites use the MAC construction HMAC with either MD5 or SHA-1 (RFC 2104) to authenticate record layer communications. The truncated HMAC function saves bandwidth by truncating the HMAC to 80 bits.

Certificate selection

When AT-TLS supports a server, the certificate designated as the default for the key ring is used. Use the `CertificateLabel` parameter to explicitly identify a different certificate that you want to use to represent the server during TLS handshakes.

If the TLS server needs to support multiple host names and multiple certificates, you can use the Server Name Indication function. The Server Name Indication function enables you to define pairs of certificate labels and host names. Use the `ServerHandshakeSNIList` parameter to specify these pairs for a server. To use these pairs, the TLS client must support the Server Name Indication function as well. The TLS client includes a host name during the TLS handshake, which allows the matching certificate to be used.

When AT-TLS supports a client, you can use the `ClientHandshakeSNIList` parameter to specify the host name to be included in the TLS handshake.

Note: For TLSv1.2 and TLSv1.3 handshakes, additional factors such as the configured signature algorithm pairs or client ecurves can also influence the selection of the server certificate. For more about these factors see [“Using TLSv1.3 protocol support”](#) on page 1163.

Session caching

The SSLv2, SSLv3, TLSv1, TLSv1.1, and TLSv1.2 protocols can cache session information based on the TLS Session ID (SID). TLS connections can request that a previous session be resumed. When session information is found in the cache, connections can use the TLS abbreviated handshake, which requires less processing.

In a similar manner, the TLSv1.3 protocol can cache session information based on a session ticket. TLS connections can request that a previous session be resumed. When session information is found in the cache, connections can use an abbreviated handshake which avoids public key encryption.

The number of SIDs or session tickets cached, the length of time that a SID or session ticket is held in the cache, and whether SIDs or session tickets in the cache are available across the sysplex can be configured using the `TTLGskAdvancedParms` statement.

Session ticket generation and caching for TLS Version 1.3 can be enabled for the client and server using the `TTLGskAdvancedParms` statement. The maximum size of the session ticket accepted by the client, the algorithm used by the server to encrypt the session ticket, the number of session tickets that the server sends after an initial handshake completes, and the maximum time for which a session ticket is valid for session resumption can also be configured using the `TTLGskAdvancedParms` statement.

For sysplex caching of session IDs or session tickets, the GSKSRVR must be started.

For additional information on session caching, see [Session ID \(SID\) and session ticket cache](#) and [SSL started task](#) in *z/OS Cryptographic Services System SSL Programming*.

AT-TLS access control considerations

Access to key rings and certificates is verified by System SSL when SSL environments are initialized. Access to certificate private keys is verified by ICSF when asymmetric encryption services are requested that require the private keys. AT-TLS invokes System SSL services that cause these access control checks to occur on tasks created in the TCP/IP address space. TCP/IP replicates the security environment of the user running the application that owns the socket at the time AT-TLS policy is mapped, before invoking these System SSL services. As such, the access control checks use the socket application's security credentials and not those of the TCP/IP stack.

Several common application models were considered to determine the most appropriate time for replicating the security environment. Replication occurs when AT-TLS policy is mapped. Policy mapping occurs during processing of the first occurrence of `connect`, `SIOCTLCTL` `IOCTL`, `select` for socket readable or writable, `poll` for socket readable or writable, or call that sends or receives data over the socket. This defers security environment replication for applications such as `INETD` until after the `accept()`, `fork()`, `setuid()`, and `exec()` sequence of services has established the server application process.

In the CICS socket environment, transaction security environments are not visible to AT-TLS support. The CICS job and all of its transactions appear to the stack as a single server application with a single z/OS UNIX process ID running in the security environment of the CICS job. All AT-TLS policy lookups, System SSL key ring authorization checks, and ICSF private key authorization checks are processed using the identity of the CICS job. Connections established, whether active or passive, can perform TLS handshake processing as either the client or server. All of the connections established by a single CICS job are able to share the session ID or session ticket cache in the SSL environment. The CICS job should use a private key ring with a server certificate. The key ring used must contain the chain of root certificates needed to validate the server certificate it presents to the client. If the server requires client authentication, it must also have any other root certificates necessary to validate client certificates presented on its key ring.

Application model considerations

AT-TLS support provides for several typical socket application models. Socket applications with significantly different models might not benefit from AT-TLS.

Client application model

As shown in Figure 146 on page 1170, this type of application runs entirely within the security environment of a single user. Many users might use the application, but each usage is independent, runs in a separate process, and should not share System SSL information with other processes. All socket calls for each usage of the application are made from the same z/OS UNIX process. Most connections are active connections initiated with the `connect()` service by this application to a server. Some client applications, such as web browsers, repeatedly connect to servers at the same or different IP addresses.

Some client applications, such as FTP or REXEC, support a second parallel connection with the server. This is often a passive connection, established by binding to an ephemeral port and listening for a single connection back from the server's IP address. For a description of an alternative method of mapping policy for these special cases, see [“Secondary connection application model”](#) on page 1174.

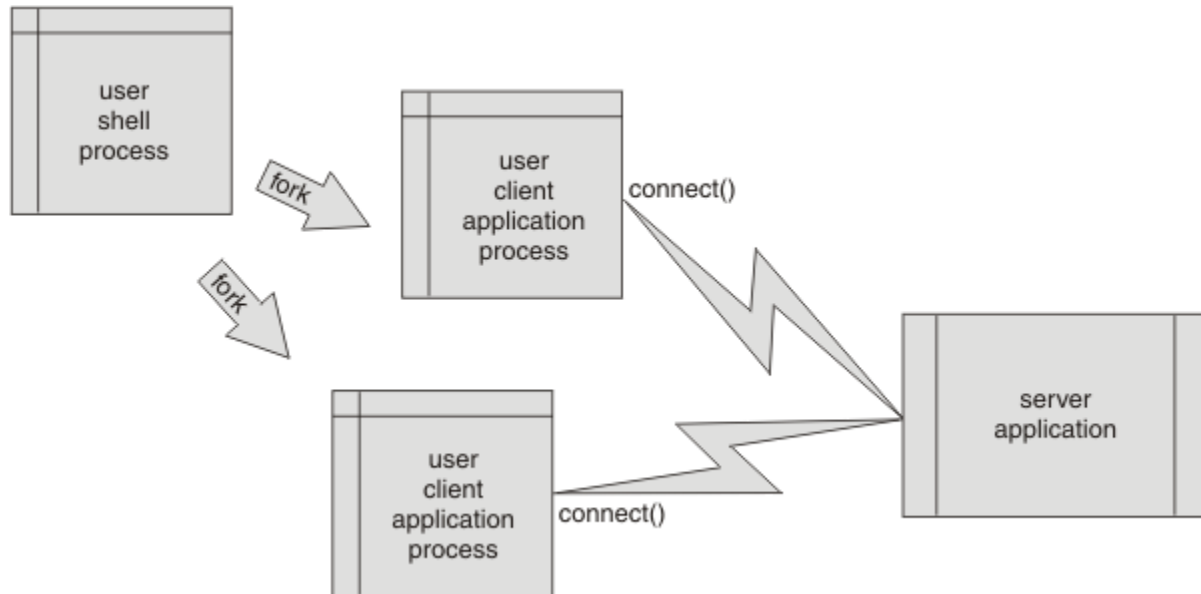

Figure 146. Client application model

All connections established by this application, whether active or passive, perform TLS handshake processing as a client. All of the connections established by a single process under the same user ID should be able to share the session ID or session ticket cache associated with the `TTLSEnvironment`.

If the server does not require client authentication, this client can use a virtual CERTAUTH keyring (`*AUTH/*`) or shared key ring containing only the root certificates needed to validate the server's certificate.

If the server does require client authentication, each user ID needs to own a key ring that contains:

- the root certificate needed to validate the server's certificate
- the user's client certificate and private key
- the certificate authority certificates for the client's own trust chain

Tip: SAF key ring names are qualified with the owning user ID and are specified as *userid/keyring*. If the user ID is not explicitly specified on the AT-TLS key ring parameter, when it is time to open the keyring, System SSL will look for a key ring with the specified name that is owned by the user ID under which the client is executing. Therefore, specifying a key ring name without the owning user ID on the AT-TLS key ring parameter allows you to define a single `TTLSEnvironmentAction` keyring parameter that represent all clients. As long as each of those client user IDs own a key ring of the specified name, System SSL will use the client's own key ring.

Server application model

As shown in Figure 147 on page 1171, this type of application runs entirely within a single z/OS UNIX process. Connections can be either passive connections returned from a listening socket by the `accept()` service, or active connections initiated with the `connect()` service. Communication partners can be client applications or peer servers. Connections can be processed by subtasks or pthreads within the server process. The initial read or write of data on the connection is done under the primary security environment of the server process. Some server applications allow a client to log in with a user ID on the server system and can place this client-specified identity on the subtask or pthread used to access resources on behalf of the client. The user ID associated with the server is used for AT-TLS purposes, regardless of this ability to change to the client-specified identity.

Figure 147. Server application model

Connections established by this application, whether active or passive, can perform TLS handshake processing as either a client or server. All of the connections established by a single process, under the same user ID and performing the handshake as a client or as a server, should be able to share a session ID or session ticket cache in the SSL environment. The server process should use a private key ring with the server's personal certificate and associated private keys. The key ring used must also contain the chain of signing (Certificate Authority) certificates needed to validate the server certificates it presents to its client. If the server requires client authentication, its key ring must also have any other root certificates necessary to validate the client certificates presented during TLS handshakes.

Forked server application model

As shown in [Figure 148 on page 1172](#), this type of application is forked by a daemon application, such as INETD, to handle a single passive connection to a socket that the daemon is listening on. The daemon invokes the `bind()`, `listen()`, and `accept()` services on the parent socket. It then forks a new process to handle each child connection, optionally changes the new process to a different identity, and optionally execs a configured server application. The server application reads and writes data on the child connection.

Some server applications support a second parallel connection with the client. This is often an active connection, established by connecting back to an ephemeral port opened by the client at the client's IP address. For a description of an alternative method of mapping policy for these special cases, see [“Secondary connection application model” on page 1174](#).

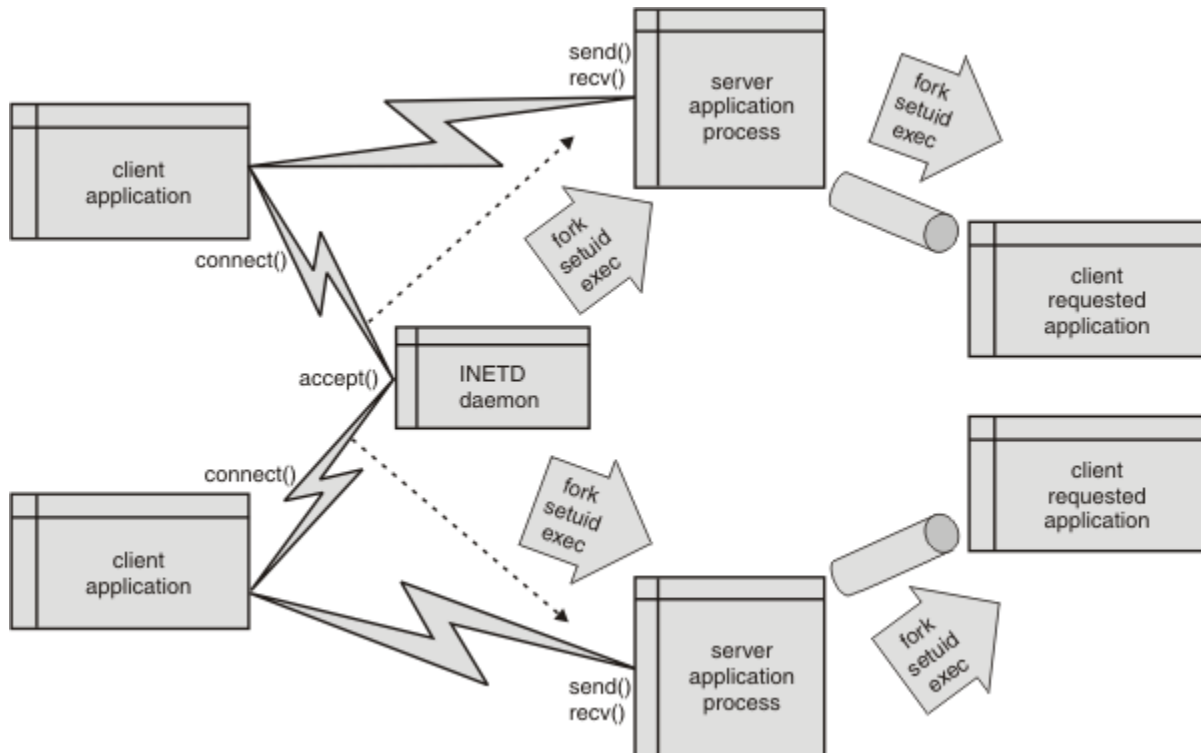

Figure 148. Forked server application model

Many server applications allow the client to log in with a user ID on the server system. Some server applications change the security environment of the server process to the client-specified identity prior to accessing resources on behalf of the client. Other server applications set up another communications path (pseudo terminal, named pipe, UNIX domain socket, and so on) and then fork an additional client process. The server changes the security environment in this client process to the client-specified identity, and then execs a client-specified program or login shell.

The initial child connection transferred by the daemon to the server process, and any additional connections established by the server process, perform TLS handshaking as the server, optionally requiring client authentication. Each forked server process runs under the same user ID. All of the server processes forked to handle child connections of the same parent connection should be able to share the session ID or session ticket cache in the SSL environment. The server processes can use a shared key ring with a site certificate and private key, or a private key ring with the server's personal certificates and associated private keys. The key ring used must also contain the chain of signing (Certificate Authority) certificates needed to validate the site or server certificates it presents to its client. If the server requires client authentication, its key ring must also have any other root certificates necessary to validate client certificates presented during TLS handshakes.

Any client process forked by the server process is treated as a new application by AT-TLS. New connections established will not share an SSL environment with the server process that created them.

CICS transaction model

TCP/IP CICS socket support provides a CICS resource manager that invokes z/OS UNIX socket services. It also provides a CICS Listener transaction that accepts passive connections from a listening socket. Each listening socket has a configured transaction that is launched to process a single established connection.

For more information on configuring TCP/IP CICS socket support, see [z/OS Communications Server: IP CICS Sockets Guide](#).

Advanced application considerations

Some applications need to be aware of when a secure connection is being used or examine the certificate presented by the partner. Other applications need to control if and when the TLS handshake occurs. These applications typically support both TLS and non-TLS connections over the same port. They define an application protocol for negotiating whether to use TLS and when to begin. In both cases, these applications need to be aware that TLS is being used on the connection. However, you might not want to, or might not be able to, use any SSL toolkits in the application. AT-TLS support provides the SIOCTTLSSL_IOCTL commands that can be used in these situations.

Some applications establish a second connection using ephemeral ports or after the server has changed to a client supplied identity. These secondary connections need to be associated with the policy and security environment used on the primary connection. AT-TLS provides special support for these applications.

AT-TLS aware application considerations

Applications that need to examine the partner's certificate can issue the SIOCTTLSSL_IOCTL with request type TTLS_RETURN_CERTIFICATE to get the certificate at any time during a secure connection. Applications that are running under a policy with the HandshakeRole parameter set to CLIENT receive the server's certificate. Applications that are running under a policy with the HandshakeRole parameter set to ServerWithClientAuth receive the client's certificate if provided.

Applications configured as HandshakeRole ServerWithClientAuth that need to examine or use the user ID associated with the certificate in SAF can issue the SIOCTTLSSL_IOCTL with request type TTLS_QUERY_ONLY or TTLS_RETURN_CERTIFICATE. If a partner certificate is available on the secure connection, AT-TLS uses a RACF service to extract the associated user ID. If no client certificate is available, or no user ID has been associated, the ioctl returns zero as the associated user ID length.

AT-TLS controlling application considerations

Applications that need to control AT-TLS behavior, using the SIOCTTLSSL_IOCTL with the TTLS_INIT_CONNECTION, TTLS_RESET_SESSION, TTLS_RESET_CIPHER, TTLS_RESET_WRITE_CIPHER, or TTLS_SEND_SESSION_TICKET request flags, must have the ApplicationControlled parameter set to ON in their TTLSEnvironmentAdvancedParms or TTLSConnectionAdvancedParms statement. This causes AT-TLS to postpone the TLS handshake. After the connection is established, the application can issue the SIOCTTLSSL_IOCTL to get the current AT-TLS connection status and determine whether or not AT-TLS support is available on this connection. When the application is ready for AT-TLS to perform the TLS handshake, it issues the SIOCTTLSSL_IOCTL with request type TTLS_INIT_CONNECTION. The SIOCTTLSSL_IOCTL initiates an AT-TLS policy lookup, if one has not yet been done, and assigns a rule and actions to the connection if a match is found. For more IOCTL information, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Some application protocols provide a way for the client and server programs to negotiate whether to use the TLS or SSL protocol to protect data on the connection. This cleartext negotiation typically occurs very early in the connection. When both partners agree to use TLS, they initiate the handshake. These applications can take advantage of AT-TLS. The policy must indicate ApplicationControlled ON. After the connection is established, the application can use the SIOCTTLSSL_IOCTL to determine whether AT-TLS support is configured, policy covers the connection, and the policy specifies ApplicationControlled ON. The application can then send and receive cleartext data to negotiate the use of TLS. When both partners agree, they each must initiate a secure connection. The AT-TLS application can use the SIOCTTLSSL_IOCTL

with `TTLS_INIT_CONNECTION` to initialize the secure connection. AT-TLS performs the initial handshake and provides encryption and decryption services for the application. The application can simply send and receive cleartext over the socket as it would if it were not a secure connection.

The application can also use the `SIOCTTLSSLCTL` IOCTL to reset the cipher or the session. Resetting the session clears any cached session IDs or session tickets preventing session resumption with this session's credentials. Resetting the cipher causes the encryption key to be updated.

- For TLSv1.2 and earlier versions, it causes AT-TLS to initiate another handshake. If the session is reset first, the subsequent handshake is a full handshake. If the session has not been reset, a short handshake is attempted for the subsequent handshake. The partner application must agree to the short handshake.
- For TLSv1.3, there are two types of reset requests that can be specified on the `SIOCTTLSSLCTL` IOCTL – `TTLS_RESET_CIPHER` and `TTLS_RESET_WRITE_CIPHER`. `TTLS_RESET_CIPHER` causes the encryption key to be updated and a Key Update message to be sent to the session partner, requesting that the session partner also update its encryption key. The `TTLS_RESET_WRITE_CIPHER` causes the encryption key to be updated and a Key Update message to be sent to the session partner but there is no request that the session partner update its encryption key.

For TLSv1.3, the application can also use the `SIOCTTLSSLCTL` IOCTL to request that a session ticket be sent from the server to the client. The `TTLS_SEND_SESSION_TICKET` request can be used when the server is configured to enable session tickets but the count of session tickets automatically sent when the initial handshake completes is 0 (`GSK_SESSION_TICKET_SERVER_ENABLE` and `GSK_SESSION_TICKET_SERVER_COUNT` on the `TTLSSGskAdvancedParms` statement). The session ticket is cached and used for session resumption.

Secondary connection application model

Some applications create two connections between the client and server programs. These applications typically have a single primary connection that is bound to a well-known port on the server side. After exchanging some information, a second connection is established. This second connection often uses dynamically assigned ports on both ends. Examples of this behavior include the `stderr` connection in the `rsh`, `rexec`, and `rlogin` family of applications, as well as the firewall-friendly FTP data connection. It is often not possible to define a set of policy rule conditions to correctly map these secondary connections on the client side or when the server forks a new process, with a dynamic job name, for each connected client.

In other cases, this second connection is established after the server has changed to a client-supplied identity. Mapping this second connection to AT-TLS policy as a new and independent connection would force the use of a different System SSL environment. The client-supplied identity would need to have access to the certificate private keys. Normal FTP data connections are an example of this behavior.

AT-TLS provides an alternate method of mapping policy for these secondary connections. This alternate method causes the secondary connection to share the System SSL environment and security environment of the associated primary connection.

To activate the alternate policy mapping method, define a policy rule using conditions that will map the primary connection. In this policy, specify the `SecondaryMap` parameter with a value of `ON`. When this policy is mapped to a primary connection, an entry is made in an internal table. Future connections do a normal policy lookup, and then look in the internal table for an entry with the same process ID and pair of IP addresses. If a matching entry is found and the new connection has no mapped policy, or has a mapped policy with a lower priority than the matching entry, the new connection is marked as a secondary connection and uses the same policy and user ID as the primary connection.

You should use this alternate policy mapping method only for client applications and server applications that have a single primary connection. Careful consideration should be given before using it for non-forking server applications that accept multiple primary connections, such as `MVRSHD` (TCP/IP's combined `rsh` and `rexec` server for the TSO environment). The alternative method of policy mapping always associates secondary connections with the most recent primary connection mapped by this process. When the process establishes multiple primary connections, the alternate mapping method is not able to reliably associate secondary connections with the correct primary connection. You should not use this alternate policy mapping method when the primary connections can map to different policies

based on client IP address or multiple server listening port numbers. You should use normal policy mapping with a job name condition for the secondary connections of non-forking servers.

Chapter 21. z/OS Load Balancing Advisor

The z/OS Load Balancing Advisor communicates with external load balancers and one or more Load Balancing Agents. The main function of the Load Balancing Advisor is to provide external TCP/IP load balancing solutions, such as the Cisco Content Switching Module (CSM), with recommendations on which TCP/IP applications and target z/OS systems within a z/OS sysplex are best equipped to handle new TCP/IP workload requests. These recommendations can then be used by the load balancer to determine how to route new requests to the target applications and systems (that is, how many requests should be routed to each target). The recommendations provided by the Advisor are dynamic, and can change as the conditions of the target systems and applications change. The recommendations include several key components:

- State of the target application and system

This includes an indication of whether the target application and target system is active. This enables the load balancer to exclude systems that are not active or do not have the wanted application running.

- z/OS Workload Management (WLM) system-wide recommendations

WLM recommendations provide a relative measure of a target system's ability to handle new workload, as compared to other target systems in the sysplex. The WLM recommendations are derived using several measures, including each system's available general CPU capacity, which is used for both system members and application members. For application members, the amount of available System z Application Assist Processor (zAAP) capacity and System z Integrated Information Processor (zIIP) capacity can also be considered.

If systems are 100% used, a WLM recommendation is a measurement of available displaceable capacity (capacity that can be displaced by higher importance workloads). The latter is important for scenarios where systems might be 100% used, but some might be running a larger portion of lower importance work (as defined by the WLM policy) that can therefore be displaced by higher importance workloads.

- z/OS WLM server-specific recommendations

These recommendations are similar to the WLM system-wide recommendations, but are more specific as they are based on the following factors:

- How individual server applications are doing compared to the WLM policy goals that are specified for that workload.
- The amount of displaceable capacity of the general, zAAP, and zIIP processor work on each system, which is based on the following factors:
 - The workload's importance (as defined by the WLM policy).
 - The proportion of each processor type that is being consumed by the application's workload.

These recommendations can help the load balancers avoid selecting application servers that are experiencing performance problems (that is, not meeting the specified WLM policy goals).

- Application server health from a TCP/IP perspective

TCP/IP statistics for target applications are monitored to determine whether specific server applications are encountering problems keeping up with the current workload. For example, is a target TCP server application keeping up with TCP connection requests? Or are requests being rejected because the backlog queue is full? In scenarios where this occurs, the recommendations passed back to the load balancers are adjusted appropriately, so that the load balancer can direct fewer connections to any application that is experiencing these problems. These recommendations are provided for both UDP and TCP server applications. These recommendations are referred to as Communication Server weights in this information.

Figure 149 on page 1178 illustrates the relationship between the load balancer, a z/OS Load Balancing Advisor, and Load Balancing Agents.

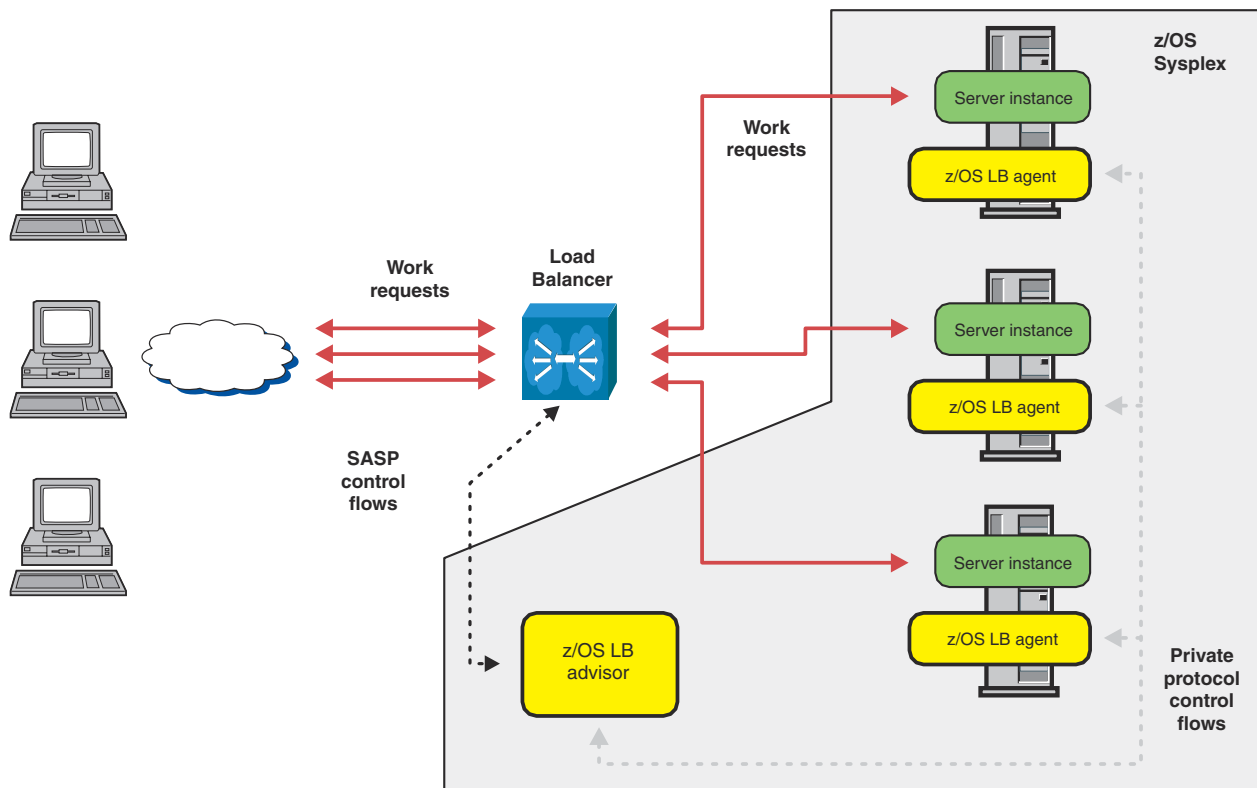

Figure 149. z/OS Load Balancing Advisor

The load balancer is configured with a list of systems and applications that it will balance. The load balancer tells the Load Balancing Advisor about the applications by specifying an IP address, port, and protocol, or about the systems by specifying an IP address. The Advisor is configured with a poll interval at which the Agents update the Advisor's data. You can configure the Advisor with a list of authorized load balancers and a list of authorized Load Balancing Agents with which it can gather data, or you can use AT-TLS support to provide the authorization for the load balancers and Load Balancing Agents. Each Agent gathers data on its own z/OS system about the TCP/IP stacks and applications running on that system.

The Agent is configured with the information it needs to contact the Advisor. The Advisor consolidates the data from all its Agents, and returns the data to the load balancer to advise the load balancer about the status of the systems and applications.

Before using the z/OS Load Balancing Advisor, you need to consider the characteristics of your environment, such as whether you need to use TLS/SSL (using AT-TLS on z/OS), what TCP/IP workloads you want to load balance, what load balancing solution you will use, and so on, as described in [“Steps for preparing to use the z/OS Load Balancing Advisor”](#) on page 1178.

Steps for preparing to use the z/OS Load Balancing Advisor

This topic describes the preparation needed to use the z/OS Load Balancing Advisor, such as selecting a load balancing solution and considering who has authority to start the Advisor and Agents.

Before you begin

You must meet the following requirements:

- You must have at least one external load balancer that supports the Server/Application State Protocol (SASP). This load balancer must have IP connectivity to each z/OS system in the sysplex that is to participate in load balancing. If you are using TLS/SSL (through AT-TLS on z/OS) for incoming connections to the Load Balancing Advisor, the load balancer must also be capable of using TLS/SSL on its SASP communication flows.

- Read [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149 and [Chapter 14, “Policy-based networking,”](#) on page 813 to decide how you want the Advisor and Agents to use AT-TLS policies. To use AT-TLS, AT-TLS must be enabled and the Policy Agent must be configured and activated for each TCP/IP stack where the Load Balancing Advisors and Load Balancing Agents might run.

Procedure

Perform the following steps to prepare to use the z/OS Load Balancing Advisor:

1. Consider whether you need to use TLS/SSL (using AT-TLS on z/OS).
See [“Step 1: Consider whether to use TLS/SSL \(using AT-TLS on z/OS\)”](#) on page 1179.
2. Evaluate TCP/IP workloads to be load balanced and select a load balancing solution. (optional)
See [“Step 2: Evaluate TCP/IP workloads to be load balanced and select a load balancing solution \(optional\)”](#) on page 1180.
3. Decide who will have authority to start the Advisor. (optional)
See [“Step 3: Decide who will have authority to start the Advisor \(optional\)”](#) on page 1180.
4. Decide who will have authority to start the Agents. (optional)
See [“Step 4: Decide who will have authority to start the Agents \(optional\)”](#) on page 1181.
5. Authorize the Agents to use WLM services.
See [“Step 5: Authorize the Agents to use WLM services”](#) on page 1181.
6. Determine how the Advisor and agent are to interact in a subplexing environment (optional)
See [“Step 6: Determine how the Advisor and agent are to interact in a subplexing environment \(optional\)”](#) on page 1182.

Step 1: Consider whether to use TLS/SSL (using AT-TLS on z/OS)

As you plan to use the z/OS Load Balancing Advisor, consider whether you need to use TLS/SSL (using AT-TLS on z/OS). The z/OS Load Balancing Advisor acts as a TCP server application, listening on two distinct ports that allow both Load Balancing Agents and external load balancers [or automated domain name registration (ADNR)] to connect to it. You need to restrict the ability to establish a connection to either of these ports, because sensitive interfaces can be exploited after a connection is accepted by the Load Balancing Advisor. For the agent listening port, you need to ensure that only authorized agents are allowed to connect, because these agents are responsible for providing sensitive information that indicates server application availability, health, and performance. For the external load balancer Server/Application State Protocol (SASP) port, you need to ensure that only authorized load balancers and ADNR are allowed to connect, because this interface can be used to obtain sensitive information regarding TCP/IP applications in a sysplex, CPU usage information for each system, and so on. You can use AT-TLS to encrypt data between the external load balancer and the Advisor's TCP/IP stack, and between the Agent's TCP/IP stack and the Advisor's TCP/IP stack.

You can use one or both of the following methods to authorize connections to the z/OS Load Balancing Advisor:

- You can explicitly configure the following lists:
 - The list of IP addresses of all the external load balancers (including ADNR) that are allowed to connect to the Load Balancing Advisor
 - The list of source IP addresses and source ports that each of the Load Balancing Agents use to connect to the Load Balancing Advisor
- You can establish policies using the z/OS Policy Agent so that the Agents, ADNR, or both are required to use TLS/SSL through AT-TLS, and load balancers are required to use TLS/SSL.

Although the configuration parameters might be sufficient in certain environments in which the Load Balancing Advisor, Agents, and external load balancers all are inside a secure network (that is, isolated by a firewall and so on), they might not be sufficient in environments in which the network is not considered to be as secure or in which the need to protect against IP address spoofing attacks is important.

With AT-TLS, the z/OS Load Balancing Advisor provides you with a more secure way to authorize access to critical Load Balancing Advisor resources using industry-standard network security standards like TLS/SSL. The AT-TLS approach also provides some additional benefits:

- Ease of use
 - Reduces the number of IP address and port lists that need to be maintained in the Load Balancing Advisor and coordinated with the external load balancers and Load Balancing Agents.
 - Eliminates the need for defining a source IP address and port for each Load Balancing Agent. This includes the Agent configuration file, the TCP ports that need to be reserved in the TCP/IP profile, and the DVIPAs that are recommended for the source IP address that is used for Agent connections.
- Outage avoidance

If you do not use AT-TLS, adding an Agent instance into the sysplex requires updates to the Load Balancing Advisor configuration, which in turn requires a recycle of the Load Balancing Advisor so that it can process the configuration changes. With AT-TLS, you can add an Agent instance into the sysplex without recycling the Advisor.

For more information about using AT-TLS, see [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149.](#)

Step 2: Evaluate TCP/IP workloads to be load balanced and select a load balancing solution (optional)

The first steps involve identifying the TCP/IP applications that you want to load balance, the systems that these applications will be running on, and ensuring that these applications can exploit load balancing. When this is done, evaluate the load balancing techniques that best meet your requirements. You might want to use a combination of workload balancing solutions.

There are various technology choices for performing IP load balancing in a sysplex environment. For a discussion of some of these choices, see [“Workload balancing” on page 496.](#)

Step 3: Decide who will have authority to start the Advisor (optional)

Explicit authority should be granted to all users that can start the Advisor, to prevent unauthorized users from starting it. If you do not grant explicit authority, any user able to issue the START command can start the Advisor.

Tip: You might want to combine this step with the next two steps, [“Step 4: Decide who will have authority to start the Agents \(optional\)” on page 1181,](#) and [“Step 5: Authorize the Agents to use WLM services” on page 1181,](#) because these steps use similar commands.

Steps for granting authority to start the Advisor

Follow these steps after you decide who you want to be able to start the Advisor.

Procedure

Perform the following steps to grant authority to start the Advisor:

1. Ensure that the OPERCMDS class is active and RACLISTed, and RACLIST processing is enabled:

```
SETROPTS CLASSACT(OPERCMDS)
SETROPTS RACLIST (OPERCMDS)
```

2. Define the following OPERCMDS class profile using a security product like RACF:

```
RDEFINE OPERCMDS (MVS.SERVGR.LBADV) UACC(NONE)
```

3. Grant the Advisor access to the OPERCMDS class:

```
PERMIT    MVS.SERVGR.LBADV CLASS(OPERCMD) ACCESS(CONTROL) -
          ID(userid)
```

4. Refresh the OPERCMD class:

```
SETROPTS RACLIST(OPERCMD) REFRESH
```

5. See the EZARACF sample in SEZAINST for specific instructions.

All commands that you can issue against the Advisor are MODIFY commands, with the exception of the STOP command used to stop the Advisor. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

Step 4: Decide who will have authority to start the Agents (optional)

Explicit authority should be granted to all users that can start the Agents, to prevent unauthorized users from starting them. If you do not grant explicit authority, any user able to issue the START command can start the Agents.

Steps for granting authority to start the Agents

Follow these steps after you decide who you want to be able to start the Agents.

Procedure

Perform the following steps to grant authority to start the Agents:

1. Ensure that the OPERCMD class is active and RACLISTed, and RACLIST processing is enabled.

If you have already done this for the Advisor, you can skip this step.

```
SETROPTS CLASSACT(OPERCMD)
SETROPTS RACLIST (OPERCMD)
```

2. Define the following OPERCMD class profile using a security product like RACF:

```
RDEFINE  OPERCMD (MVS.SERVGR.LBAGENT) UACC(NONE)
```

3. Grant the Agents access to the OPERCMD class:

```
PERMIT    MVS.SERVGR.LBAGENT CLASS(OPERCMD) ACCESS(CONTROL) -
          ID(userid)
```

4. Refresh the OPERCMD class:

```
SETROPTS RACLIST(OPERCMD) REFRESH
```

5. See the EZARACF sample in SEZAINST for specific instructions.

All commands that you can issue against the Agents are MODIFY commands, with the exception of the STOP command used to stop the Agents. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

Step 5: Authorize the Agents to use WLM services

You might want or need to define the BPX.WLMSEVER resource profile to your security product and grant the Agents access to it. If you are using RACF and already have the resource profile defined and the FACILITY class is enabled, permit the Agents to the resource profile. If you are using a security product other than RACF that by default denies access to the resource profile, grant the Agents access to the resource profile. If you do not already have the resource profile defined and you are using RACF, consult the documentation of other programs and products that require WLM services and coordinate any potential changes with these programs and products.

Steps for defining the resource profile with RACF

You can define the BPX.WLMSEVER resource profile to RACF, and grant the Agents access to it.

Procedure

Perform the following steps for RACF if you choose to define the resource profile:

1. Ensure that the FACILITY class is active and RACLISTed, and RACLIST processing is enabled:

```
SETROPTS CLASSACT(FACILITY)
SETROPTS RACLIST (FACILITY)
```

2. Define the following FACILITY class profile:

```
RDEFINE FACILITY (BPX.WLMSEVER) UACC(NONE)
```

3. Grant the Agent access to the FACILITY class:

```
PERMIT BPX.WLMSEVER CLASS(FACILITY) ACCESS(READ) -
ID(userid)
```

4. Refresh the FACILITY class:

```
SETROPTS RACLIST(FACILITY) REFRESH
```

Results

For more information, see the EZARACF sample in SEZAINST.

Step 6: Determine how the Advisor and agent are to interact in a subplexing environment (optional)

If you are configuring the z/OS Load Balancing Advisor in a subplexing environment, you need to decide how you want the Advisor and Agents to interact:

- You need to determine what set of subplexes will exist in your sysplex, both how many VTAM subplexes and how many TCP/IP subplexes within a VTAM subplex.
- You need to decide which subplexes will need Load Balancing Agents and a Load Balancing Advisor.

For information about subplexing environments, see [“Sysplex subplexing”](#) on page 464.

In addition, if you are also using Automated Domain Name Registration (ADNR), see [Chapter 22, “Automated domain name registration,”](#) on page 1225 for some additional considerations for configuring ADNR in a subplexing environment.

Steps for configuring the z/OS Load Balancing Advisor

The z/OS Load Balancing Advisor provides external TCP/IP load balancing solutions with recommendations on which TCP/IP applications and target z/OS systems within a z/OS sysplex are best equipped to handle new TCP/IP workload requests.

Before you begin

You need to review [“Steps for preparing to use the z/OS Load Balancing Advisor”](#) on page 1178.

Procedure

Perform the following steps to configure the z/OS Load Balancing Advisor and one or more Load Balancing Agents.

1. Configure the Advisor and Agents to automatically restart in case of application or system failure. (optional)

See [“Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure \(optional\)”](#) on page 1183.

2. Configure and start syslogd.

See [“Step 2: Configure and start syslogd”](#) on page 1185.

3. Configure one Advisor per sysplex.

See [“Step 3: Configure one Advisor per sysplex”](#) on page 1186.

4. Configure one Agent per z/OS system in the sysplex.

See [“Step 4: Configure one Agent per z/OS system in the sysplex”](#) on page 1191.

5. Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run. (optional)

See [“Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run \(optional\)”](#) on page 1193.

6. Customize WLM policies for the Advisor and Agents. (optional)

See [“Step 6: Customize WLM policies for the Advisor and Agents \(optional\)”](#) on page 1198.

7. Configure the external load balancers.

See [“Step 7: Configure the external load balancers”](#) on page 1198.

Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure (optional)

Although this step is optional, performing it will provide high availability to your target applications. In the event that an Agent fails, the Advisor would indicate that it has no information for any applications running on that system. As a result, target applications on the failing system would cease to receive new workload requests, in most cases, until the Agent is restarted. Automatically restarting the Agent on the same system would minimize this perceived outage. This can be accomplished using automation software or by defining an automatic restart manager (ARM) policy. For more information on [defining ARM policies](#), see [z/OS MVS Setting Up a Sysplex](#). In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see [“Considerations for automatic restart in a subplexing environment”](#) on page 1185.

The Agent registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP  
ELEMNAME=EZBsyscloneLBAGENT  
TERMTYPE=ELEMTERM
```

where *sysclone* is a 1- or 2-character shorthand notation for the name of the MVS system. For example, if the *sysclone* value is 02, the resulting ELEMNAME value is EZB02LBAGENT. For a complete description of the SYSCclone static system symbol, see [z/OS MVS Initialization and Tuning Reference](#).

This indicates that if the Agent fails on this system, it should be restarted on this system only.

If the Advisor or its underlying system were to fail, the load balancer might continue to distribute workload requests according to the last set of information received from the Advisor, it might resort to preconfigured weights, or it might even stop distributing new work requests to the cluster. (The behavior depends upon the load balancer implementation; consult the load balancer documentation for details.) Therefore, it is important that the Advisor be restarted as soon as possible when a failure occurs, so that it can begin communicating with the load balancer and workload request distribution can resume normally. This restart capability should cover scenarios where the Advisor itself fails, and where the system that the Advisor is running on fails. The Advisor can run on any system in the sysplex and thus can be restarted on any system in the sysplex, as long as it is configured to use dynamic VIPAs and dynamic routing is in effect. The Advisor registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP  
ELEMNAME=EZBLBADV  
TERMTYPE=ALLTERM
```

This indicates that the Advisor should be restarted only on the same system in cases where the Advisor itself fails, and also restarted on a different system if the system fails. Using an ARM policy, you can indicate which systems are eligible for running the Advisor in the case of system failures. You also need to ensure that the specified backup systems have all the necessary configuration in place to enable the Advisor to be restarted there.

Some special considerations exist for scenarios where ARM is used and the TCP/IP stack address space terminates, as the result of a failure or of a planned operation. When the TCP/IP stack becomes unavailable, the Advisor also terminates, as it can no longer establish any TCP/IP communications. An ARM restart of the Advisor will likely fail, as the TCP/IP protocol stack will not be available when the restarts occur. You can handle these scenarios in the following ways:

- Planned outages of the TCP/IP stack

Manually start the Advisor on another system, as soon as the Advisor terminates on the system where TCP/IP is stopped.

- Unplanned outages of the TCP/IP stack

Ensure that an ARM policy (or other automation) is in place to quickly restart the TCP/IP stack on the same system. The Advisor also needs to be quickly restarted on the same system. This can be done by using an automation software package, or by using the TCP/IP profile AUTOLOG statement.

The AUTOLOG statement also has some important considerations:

- You should place the Advisor in the AUTOLOG statement list to ensure that it is started when TCP/IP is started on that system. However, you should specify the NOAUTOLOG parameter on the PORT reservation statements for the Advisor ports in the TCP/IP profile. This prevents TCP/IP from monitoring and attempting to restart the Advisor, as that could interfere with your automation logic or the ARM policy that you have put in place.
- The AUTOLOG function works best on systems where a single TCP/IP stack is active (INET environment). For CINET considerations, see [“Considerations for automatic restart in a CINET environment” on page 1184](#).

Guideline: Establish an ARM policy with TCP/IP at a lower level than the Advisor and Agent, so that TCP/IP is restarted before the Advisor and Agent are restarted. For more information, see [z/OS MVS Setting Up a Sysplex](#).

Requirement: The Load Balancing Advisor and Agent do not run using a system key. Therefore, if you are using ARM registration, the started task IDs need to be permitted with UPDATE authority to the associated IXCARM.SYSTCPIP.EZBLBADV and IXCARM.SYSTCPIP.EZBLBAGENT profiles in the FACILITY class within the SAF product on your system. To enable the Advisor and Agent to register with ARM, use the following RACF commands to define the profiles and grant update access to the user IDs that are assigned to start the Advisor and Agent:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBLBADV UACC(NONE)
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBLBAGENT UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBLBADV CLASS(FACILITY) ID(LBADV) ACCESS(UPDATE)
PERMIT IXCARM.SYSTCPIP.EZBLBAGENT CLASS(FACILITY) ID(LBAGENT) ACCESS(UPDATE)
SETROPTS RACLIST(FACILITY) REFRESH
```

Restrictions:

- If using AUTOLOG for the Agent, code the NOAUTOLOG parameter on the PORT reservation statement for the Agent port in the TCP/IP profile. This prevents the Agent from automatically being cancelled and restarted because the Agent does not listen on the port.
- If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6-enabled TCP/IP stacks.

Considerations for automatic restart in a CINET environment

If you are considering using the AUTOLOG statement to restart the Advisor in a CINET environment, and you placed the Advisor in the AUTOLOG statement list of each TCP/IP stack, each stack attempts to start

the Advisor during initialization. Only the first one will succeed, as only a single instance can be active at any time within a system or within a sysplex.

Considerations for automatic restart in a subplexing environment

When running the Load Balancing Advisor in a subplexing environment, there is one Load Balancing Advisor for each subplex that participates in load balancing. The subplex is determined by both the VTAM and TCP/IP subplex group IDs, which are denoted by *vv* for VTAM and *tt* for TCP/IP. These subplex group IDs are reflected in the TCP/IP sysplex group name, which is of the format EZBT*vvtt*. Each Load Balancing Advisor registers with ARM with the following parameters:

```
ELEMTYPE=SYSTCPIP  
ELEMNAME=EZBTvvttLBADV  
TERMTYPE=ALLTERM
```

You must define an ARM policy. For the EZBT*vvtt*LBADV element name, you must specify the TARGET_SYSTEM keyword to indicate the systems on which the Advisor can be restarted. This ensures that the Load Balancing Advisor for a subplex is restarted only on a system that is in the same subplex. That is, it is restarted on a system that has a VTAM that was started with the same XCFGRPID (*vv*) and that has an available TCP/IP stack with the same XCFGRPID (*tt*).

In a subplexing environment, there must be one Load Balancing Agent per subplex that participates in load balancing on each z/OS system. Each Load Balancing Agent registers with ARM with the following parameters:

```
ELEMTYPE=SYSTCPIP  
ELEMNAME=EZBsysclonevvttLBAGENT  
TERMTYPE=ELEMTERM
```

where:

- *sysclone* is a 1- or 2-character shorthand notation for the name of the MVS system. For a complete description of the SYSCONE static system symbol, see *z/OS MVS Initialization and Tuning Reference*.
- *vvtt* is the last 4 characters of the *sysplex_group_name* parameter in the Agent configuration file. If this parameter is not specified, *vvtt* is omitted.

For example, if the *sysclone* value is 02 and the *sysplex_group_name* is EZBTCPCS, the resulting ELEMNAME value is EZB02CPCSLBAGENT.

Requirement: When ARM registration is used, the started task IDs for each Agent and each Advisor must be permitted with UPDATE authority to the IXCARM.SYSTCPIP.*elemname* profiles in the FACILITY class in the SAF-compliant security product on your system. The *elemname* value is the EZBT*vvtt*LBADV value or the EZB*sysclonevvtt*LBAGENT value previously described. You can use the following RACF commands to define the profiles and grant update access to the user IDs that are assigned to the Advisors and Agents. For each Advisor:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBTvvttLBADV UACC(NONE)  
PERMIT IXCARM.SYSTCPIP.EZBTvvttLBADV CLASS(FACILITY) ID(advisor_userid) ACCESS(UPDATE)  
SETROPTS CLASSACT(FACILITY)
```

For each Agent:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBsysclonevvttLBAGENT UACC(NONE)  
PERMIT IXCARM.SYSTCPIP.EZBsysclonevvttLBAGENT CLASS(FACILITY) ID(agent_userid) ACCESS(UPDATE)  
SETROPTS CLASSACT(FACILITY)
```

Step 2: Configure and start syslogd

The Advisor and Agent write most log messages and trace data to the syslog daemon (syslogd). A limited number of messages are written to the MVS console, but these are unaffected by syslogd configuration. For the Advisor and Agent to be able to write their log messages and trace data to syslogd, syslogd must be properly configured and started before the Advisor and Agent are started.

Because it is likely that you will be running an Agent on the same system as the Advisor, for better readability, you might want to configure syslogd to place Advisor and Agent log output in separate files. For further information, see [“Configuring the syslog daemon” on page 235](#). In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see [“Syslogd considerations in a subplexing environment” on page 1186](#).

Tip: As more data is logged by the Advisor and Agent, performance of the Advisor and Agent can be adversely affected. The amount of data that is logged by the Advisor and Agent is determined by the debug_level statement. Backing the syslogd output file with a z/OS File System instead of an HFS file system can minimize performance impacts caused by logging.

Syslogd considerations in a subplexing environment

When you are using subplexing, if you will be starting more than one instance of an Advisor or Agent on the same system, you can configure the syslog daemon (syslogd) to place the output from the different instances of the Advisor and Agent into separate files based on job name, or you can use the syslogd -u start option to cause the user ID and job name to be displayed on each line of the syslog. For more information, see [“Configuring the syslog daemon” on page 235](#).

Step 3: Configure one Advisor per sysplex

There can be only one Advisor active in the sysplex at any given time, unless you are using sysplex subplexing. In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see [“Configuring Advisors in a subplexing environment” on page 1190](#).

The Advisor reads configuration data from one file, which might exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. If you plan on allowing the Advisor to move within the sysplex in the case of failure, you probably want the Advisor configuration file or data set to exist on shared DASD, to make it accessible to all systems in the sysplex if necessary. The Advisor configuration file is specified on the CONFIG DD statement in the Advisor start procedure. A sample start procedure is provided in EZBLBADV in SEZAINST.

The Advisor configuration file serves three basic purposes:

- Defines the listening sockets for the load balancers and Agents
- Provides an access control list for specifying which load balancers and Agents can connect to the Advisor
- Customizes some optional parameters

A sample Advisor configuration file is provided in EZBLBADC in SEZAINST.

Define listening sockets/ports (required)

The Advisor maintains at least two, and up to three, listening sockets/ports, one for Agents to connect to and up to two for load balancers to connect to. There are separate IPv4 and IPv6 listening sockets for load balancers. If your TCP/IP stack is not IPv6 enabled, you will not be able to use the IPv6 listening socket.

The Advisor and Agent statements define addresses and ports on the local system and on remote systems. At times, it can be difficult to remember which statements refer to local sockets and which statements refer to remote addresses and ports.

Tip: Any statement containing the word connection refers to a local socket, and any statement containing the word id refers to a remote address and possibly a port.

Specify the local IPv4 address and port that the Advisor listens on for IPv4 load balancer connections with the lb_connection_v4 configuration statement. The default port for communications with load balancers is 3860.

The lb_connection_v6 statement does the equivalent for IPv6 that lb_connection_v4 does for IPv4. You can specify either or both of these statements. For CINET considerations regarding stack termination, see [“Configuring one Advisor per sysplex in a CINET environment” on page 1190](#).

Guideline: To enable movement of the Advisor to another system in the sysplex or to another TCP/IP stack on the same system in the event of failure of the Advisor or its underlying system, use a dynamic VIPA (DVIPA) for the address specified on the `lb_connection_v4` and `lb_connection_v6` statements. Furthermore, make this DVIPA a unique application-instance DVIPA (defined through `VIPARANGE`) rather than a multiple application-instance DVIPA (defined through `VIPADefine`), to enable movement of the Advisor if the Advisor itself failed. For CINET considerations with DVIPAs, see [“Configuring one Advisor per sysplex in a CINET environment”](#) on page 1190.

Restriction: If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6-enabled TCP/IP stacks.

Specify the local port that the Advisor listens on for Agent connections with the `agent_connection_port` statement. If the Advisor's TCP/IP stack is IPv6 enabled, the Advisor opens a listening socket for Agents on the IPv6 unspecified address (::) on the port specified by this statement. This enables Agents to connect to the Advisor using either IPv4 or IPv6, and by using any address on the Advisor's system. If the TCP/IP stack is not IPv6 enabled, the Advisor opens a listening socket on the IPv4 unspecified address, 0.0.0.0. This enables Agents to connect to the Advisor using any IPv4 address on the Advisor's system.

Guideline: The port number used on the `agent_connection_port` statement should not be the same as the port used on the `lb_connection_v4` statement or the `lb_connection_v6` statement.

Rules:

- The port number specified on the `agent_connection_port` statement must match the port number specified on the Agents' `advisor_id` statement.
- If at least one IPv4 address is specified in the `lb_id_list` statement, the `lb_connection_v4` statement must be specified. Similarly, if at least one IPv6 address is specified in the `lb_id_list` statement, the `lb_connection_v6` statement must be specified.

Define the access control list

You can use one or both of the following methods for z/OS Load Balancing Advisor security:

- Access control list configuration statements

The Advisor can control which load balancers and which Agents are allowed to connect to it by maintaining an access control list. The access control list specifies the remote IP address of the connecting load balancers and the remote IP address and port of the Agents that are allowed to connect.

Specify the list of load balancers that are allowed to connect to the Advisor in the `lb_id_list` statement. Specify the list of Agents that are allowed to connect in the `agent_id_list` statement.

Rules:

- Specify only complete IP addresses in access control lists; subnetworks, IP prefixes, or other types of wildcards are not allowed.
- The addresses in the `agent_id_list` statement must match the addresses in the `host_connection` statement of the Agents. For the purposes of high availability, the addresses specified in the `agent_id_list` statement of the Advisor and the `host_connection` statement of the Agents should be static or dynamic VIPAs, to tolerate individual link outages on the hosts.

Restriction: There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

- Policies

You can establish policies using the z/OS Policy Agent so that the Agents, ADNR, or both are required to use TLS/SSL through AT-TLS for connections to the Advisor, and load balancers are required to use TLS/SSL.

When you are using AT-TLS for all connections to the Advisor, the Advisor's `lb_id_list` and `agent_id_list` statements and the Agents' `host_connection` statements are optional. If you use these statements, the rules for access control list configuration statements still apply. AT-TLS is an alternative to using these

statements, but you can still specify the statements. If you specify these statements and you are using AT-TLS, the statements are not required to match on the Advisor. For example, if an Agent connects using AT-TLS, the Advisor allows the connection to succeed even if the `agent_id_list` statement does not list that Agent.

Customizing optional statements

Customize the optional statements in the Advisor's configuration file.

The `update_interval` statement controls how often each Agent updates the Advisor with data, and depending upon load balancer implementation and configuration, can control how often load balancers are updated with information from the Advisor. The default value is 60 seconds. At each update interval, each Agent refreshes the Advisor with the status of each registered member for which the Agent is responsible. This information includes the status of the target application (active or not), whether it is an application member, the operator quiesce state of the member, and various weights that measure the target system and application's ability to handle additional workload requests. The lower the update interval, the more up-to-date the load balancer's data will be with respect to the target's availability and capability to handle additional workload requests. Of course, the lower the update interval, the higher the network traffic and CPU overhead is.

Depending upon load balancer implementation and configuration, the `update_interval` statement might also determine how often the load balancer is updated with data from the Advisor. If the load balancer supports the SASP push flag, and it has been specified in the load balancer, the Advisor sends data to the load balancer at least every update interval. Regardless of what the update interval is set to, if this push flag is supported and configured in the load balancer, certain events might cause the Advisor to update the load balancer with information before the update interval timer expires. These events include the starting or stopping of a target application, or the addition or deletion of a member's IP address on the Agent host.

Therefore, the update interval is a key factor in determining the latency period between when changes occur on the target application system, and when the load balancer is informed of them. Each Agent updates the Advisor with new information every update interval. The Advisor, in turn, updates the load balancer with changes in weights every update interval, if the load balancer supports the push flag. In addition, if the push flag is supported and configured by the load balancer, the Advisor updates the load balancer with any change in the target's availability status as soon as it discovers such a change from the Agent, instead of waiting for the update interval to expire. Therefore, when the load balancer supports and configures the push flag, the maximum amount of latency expected between a change in a member's weight and when the load balancer is informed of it is twice the update interval (that is, one update interval for the Agent to report it to the Advisor and one update interval for the Advisor to report it to the load balancer). However, on the average, it should take one update interval for a change in the target application weight to reach the load balancer.

Use the optional `wlm` statement to specify the default type of WLM recommendation to be used for all groups. There are two choices for this, the `basewlm` and `serverwlm` values. If you do not specify this statement, the default is `basewlm`. If you want a specific group of applications to use a type of WLM recommendation other than the default, you can override the default WLM recommendation type for that group on a port number basis using the `port_list` statement. The WLM recommendation is a key component used in determining the net weight assigned to a member.

The type of WLM recommendation represented by the `basewlm` value indicates the overall displaceable capacity (general, zAAP, and zIIP) of the system where the application represented by the member is, relative to the other systems in the sysplex. This is referred to as a WLM system weight recommendation. Use the optional `proctype` parameter with `basewlm` to specify the proportion of general, zAAP, and zIIP CPU that is consumed by an application's workload.

The `serverwlm` value represents a different type of WLM recommendation, in that it reflects how well an individual server application is performing from a WLM perspective (based on the WLM policy). This type of recommendation is a server-specific recommendation and is referred to as a server-specific WLM recommendation. Server-specific WLM recommendations are composed of two key elements:

- The amount of displaceable capacity (general, zAAP, and zIIP) available on the target system based on the importance level of the application, and the proportion of general, zAAP, and zIIP CPU that is currently being consumed by the application's workload. For example, if the application is using only general and zAAP CPU, the displaceable zIIP capacity is not considered.
- How well the application is performing compared to the WLM goals for that application workload.

In addition, WLM provides an interface that enables applications to report the following additional information:

- Abnormal transaction completion rate, or the rate of abnormal completions per 1000 total transactions
- Application health, a value in the range 0–100% (100% being optimal), representing the overall health of the application

Using this additional information, WLM might reduce the server-specific recommendation. For more information, see [“Sysplex distributor”](#) on page 503.

Evaluate whether you can use WLM server-specific distribution as an alternative to WLM system weight distribution for an application. In addition to the above reasons, server-specific distribution has the added advantage that processor proportions are automatically determined and dynamically updated by WLM, based on the actual CPU usage by the application. If you need to use system weight distribution, to determine the processor proportions to configure, study the workload usage of assist processors by analyzing SMF records, using performance monitors reports such as RMF, and so on.

System members (port and protocol are zero) always use WLM system weight recommendations and cannot be configured to consider zAAP and zIIP CPU, because the type of workload is unknown. This is true even if proctype is coded on the wlm statement.

Application members can use either type.

It is important that you choose the type of WLM recommendation that is best suited to each group of applications. Some types of applications are better suited to using WLM system weight recommendations rather than server-specific WLM recommendations. For most applications, server-specific WLM recommendations provide a more accurate way to distribute workload to their servers. However, when a server acts as an access point to applications that run in other address spaces (and therefore in a different service class), WLM system weight recommendations might be the preferred distribution method; if expected usage of general, zAAP, and zIIP processors is known, this recommendation can be further refined by using the proctype parameter. The sysplex distributor function can also use server-specific WLM recommendations or WLM system weight recommendations. For examples of some applications that might be better represented by WLM system weight recommendations, see [“Sysplex distributor”](#) on page 503.

The optional port_list statement enables you to override or specify parameters for members on a port number basis. The wlm parameter of the port_list statement enables you to override the value defined (or specified by default) on the wlm statement, for all members that use the port number specified. The actual WLM recommendation type used is still dependent upon the value specified and the z/OS level of the Agents owning the members of the group.

When selecting the type of WLM recommendation to use for a given group, it is important to consider the following requirements:

- All members in a group must specify the same type of WLM recommendation (using the wlm or port_list statement).
- To use server-specific recommendations, no Agent reporting on behalf of a member of a group can be at a release level prior to z/OS V1R7.

For any groups where these requirements are not met, the Advisor uses WLM system weight recommendations, and a warning message is written to syslogd. The main rationale behind this is that WLM system weight recommendations and server-specific WLM recommendations cannot be directly compared to one another.

The Advisor can detect dynamically whether these requirements are being met. For example, if all owning Agents of a group, except one, support server-specific WLM recommendations, and the application on that one system is brought down, the WLM recommendation type would change dynamically from

WLM system weight recommendations to server-specific WLM recommendations, provided the Advisor was configured to request server-specific WLM recommendations for that group. Similarly, if that same application is started back up, the WLM recommendation type would dynamically switch back to WLM system weight recommendations. A similar circumstance would arise if the member owned by the Agent that does not support server-specific WLM recommendations was quiesced by the z/OS operator or the load balancer administrator.

The optional `debug_level` statement determines how much trace data is captured in the Advisor's log file.

Restriction: In most cases, you should not customize the `debug_level` statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default might make diagnosing a problem more difficult.

For more details on the [Load Balancing Advisor configuration file statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

Configuring one Advisor per sysplex in a CINET environment

You must define listening sockets and ports, as described in [“Define listening sockets/ports \(required\)”](#) on page 1186.

Rule: If you use a unique application-instance DVIPA for the Advisor in a CINET environment, all TCP/IP stacks on that system must code the VIPARANGE statement for that DVIPA. Alternatively, and less desirably, you can establish stack affinity to one of the TCP/IP stacks that are coded with the VIPARANGE statement for that DVIPA, if you do not have VIPARANGE coded for that DVIPA on all of the TCP/IP stacks on that system. This alternative, of course, does not enable the Advisor to be moved to another TCP/IP stack in the event of failure, unless you are able to restart the Advisor with a different start procedure that can establish stack affinity to another TCP/IP stack that has the DVIPA defined in a VIPARANGE statement. For information on the use of the `_BPXK_SETIBMOPT_TRANSPORT` environment variable that can be used to establish stack affinity, see [“Generic server versus server with affinity for a specific transport provider”](#) on page 46.

The `lb_connection_v6` statement does for IPv6 what the `lb_connection_v4` statement does for IPv4. You can specify either or both of these statements. If you run the Advisor on a CINET system, be aware that the address or addresses you choose for these statements tie the Advisor to the stack owning those addresses. Consequently, termination of that stack results in termination of the Advisor.

Configuring Advisors in a subplexing environment

When you are using subplexing, there can be more than one Advisor active in the sysplex at any given time. In fact, there should be one Advisor active for each subplex in the sysplex that you want to participate in load balancing through the Load Balancing Advisor. Each Advisor reads configuration data from a file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. In the configuration file for each Advisor, the `sysplex_group_name` statement specifies the TCP/IP sysplex group name, in the form `EZBTvvtt`, where `vv` is the VTAM subplex group ID specified on the VTAM XCFGRPID start option, and `tt` is the TCP/IP subplex group ID specified by the XCFGRPID parameter on the GLOBALCONFIG statement in the TCP/IP profile. If no VTAM subplex ID is specified when VTAM is started, then `vv` is CP. If no TCP/IP subplex ID is specified in the TCP/IP profile, then `tt` is CS. If you have a default subplex in your sysplex (that is, a subplex in which both the VTAM and TCP/IP subplex IDs are not specified), configure the Load Balancing Advisor for that subplex with a sysplex group name of `EZBTCPCS`.

Requirement: In a subplexing environment, the IP address of the Advisor's listening socket must exist on a TCP/IP stack belonging to the subplex that corresponds to the TCP/IP sysplex group name specified in the Advisor's configuration file. If there is more than one TCP/IP stack in a subplex, the IP address must be a DVIPA defined within a VIPARANGE statement on each of the stacks in the subplex. This enables the Advisor to connect regardless of the order that the TCP/IP stacks in the subplex are started.

Tip: In a subplexing environment, if you will have more than one Advisor started on the same z/OS system (in different subplexes), create unique start procedures for them or ensure that they have unique job names when they are started (for example, `S LBADV.ADV0105` or `S LBADV.JOBNAME=ADV0105`).

Step 4: Configure one Agent per z/OS system in the sysplex

There can be only one Agent active per z/OS system in the sysplex at any point in time, unless sysplex subplexing is used. When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see [“Configuring Agents in a subplexing environment”](#) on page 1193.

The Agent reads configuration data from one file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. The Agent configuration file is specified on the CONFIG DD statement in the Agent start procedure. A sample start procedure is provided in EZBLBAGE in SEZAINST.

The Agent configuration file serves three basic purposes:

- Defines the IP address and port that the Agent binds to for communication with the Advisor
- Identifies the location (IP address and port) of the Advisor
- Customizes optional parameters

A sample Agent configuration file is provided in EZBLBAGC in SEZAINST.

The Advisor and Agent statements define addresses and ports on the local system and on remote systems. At times, it can be difficult to remember which statements refer to local sockets and which statements refer to remote addresses and ports.

Tip: Any statement containing the word `connection` refers to a local socket, and any statement containing the word `id` refers to a remote address and possibly port.

Defining the IP address and port to bind to for communications with the Advisor

Specify the local IP address and port that the Agent binds to for communications with the Advisor on the `host_connection` statement. This is used as part of the Advisor's access control enforcement.

Rules:

- The IP address on the `host_connection` statement can be an IPv6 address, if the Agent's system is running an IPv6-enabled TCP/IP stack and the Advisor has an IPv6-enabled TCP/IP stack available.
- If an IPv4 address is specified on the `host_connection` statement, an IPv4 address must be specified on the `advisor_id` statement. Similarly, if an IPv6 address is specified on the `host_connection` statement, an IPv6 address must be specified on the `advisor_id` statement.

Guidelines:

- For simplicity and consistency, you might want to specify the same port on the `host_connection` statement for each Agent, and reserve the same port for the Agent on each TCP/IP stack that an Agent will run on. For more information about port reservation, see [“Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run \(optional\)”](#) on page 1193.
- The address in the `host_connection` statement (and therefore, also in the Advisor's `agent_id_list` statement) should be a static VIPA. For CINET considerations regarding the `host_connection` statement, see [“Configuring one Agent per z/OS system in the sysplex in a CINET environment”](#) on page 1192.

The Agent `host_connection` statement and the Advisor `agent_id_list` statement are optional if AT-TLS is used for all Agent-Advisor connections. If you specify these statements, the rules and guidelines previously stated still apply. AT-TLS is an alternative to using these statements, but you can still specify the statements. If you specify these statements and you are using AT-TLS, the statements are not required to match on the Advisor. For example, if an Agent connects using AT-TLS, the Advisor allows the connection to succeed even if the `agent_id_list` statement does not list that Agent.

Also see [“Configuring one Advisor per sysplex in a CINET environment”](#) on page 1190 for CINET considerations regarding unique application-instance DVIPAs and stack affinity.

Restriction: If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6-enabled TCP/IP stacks.

Identifying the location of the Advisor (required)

Specify the location of the Advisor on the `advisor_id` statement. This statement contains an IP address and port that the Advisor uses to listen for connections from Agents in the sysplex.

Guideline: Use a dynamic VIPA for this address, to enable the Advisor to be moved within the sysplex in the event of a failure of the Advisor or the Advisor's underlying system.

Rules:

- The port specified on the `advisor_id` statement must match the port specified on the Advisor's `agent_connection_port` statement.
- If an IPv4 address is specified on the `advisor_id` statement, an IPv4 address must be specified on the `host_connection` statement. Similarly, if an IPv6 address is specified on the `advisor_id` statement, an IPv6 address must be specified on the `host_connection` statement.

Customizing optional statements

Similar to the Advisor, the optional `debug_level` statement determines how much trace data is captured in the Agent's log file.

Restriction: In most cases, you should not customize this statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default might make diagnosing a problem more difficult.

For more details on the [Agent configuration file statements](#), see [z/OS Communications Server: IP Configuration Reference](#).

Configuring one Agent per z/OS system in the sysplex in a CINET environment

If the system where the Agent is running is a CINET system, the address in the `host_connection` statement (and therefore, also in the Advisor's `agent_id_list` statement) should be a dynamic VIPA (DVIPA) to facilitate movement of the Agent to another TCP/IP stack on that system.

Rule: If you use a unique application-instance DVIPA (coded with `VIPARANGE`) for the Agent in a CINET environment, all TCP/IP stacks on that system must code the `VIPARANGE` statement for that DVIPA. When configured in this manner, if the TCP/IP stack that currently owns the DVIPA fails, the Agent remains up and automatically attempts to bind again to the DVIPA. The next available default TCP/IP stack becomes the new owner of the DVIPA. (If this is a sysplex subplexing environment, all TCP/IP stacks on that system that are within the same subplex as the Agent must code the same `VIPARANGE` statement for that DVIPA. This allows the Agent to reestablish connectivity with the Advisor through another stack in the same subplex on that system.) Alternatively, and less desirably (see following restriction), you can establish stack affinity to one of the TCP/IP stacks that are coded with the `VIPARANGE` statement for that DVIPA, if you do not have `VIPARANGE` coded for that DVIPA on all of the TCP/IP stacks on that system. Of course, this does not enable the Agent to be automatically moved to another TCP/IP stack in the event of failure. To recover the Agent in this type of configuration, manual intervention (or automation) is required. Because the Agent remains active if its TCP/IP stack fails, you must manually terminate the Agent. Then you must restart the Agent with a different start procedure that can establish stack affinity to another available TCP/IP stack. For information on the use of the `_BPXK_SETIBMOPT_TRANSPORT` environment variable that can be used to establish stack affinity, see [“Generic server versus server with affinity for a specific transport provider” on page 46](#).

Restriction: When running in a CINET environment, establishing stack affinity between the Agent and one of the TCP/IP stacks on that system enables only resources on that TCP/IP stack to participate in workload balancing. The Agent running on that system is not aware of resources on the other TCP/IP stacks on that system. If you want to enable resources on all TCP/IP stacks in a CINET environment to participate in workload balancing, do not establish stack affinity with the Agent.

Configuring Agents in a subplexing environment

When you are using subplexing, there can be more than one Agent per z/OS system in the sysplex. In fact, there should be one Agent active for each subplex with a TCP/IP stack on a system that you want to participate in load balancing through the Load Balancing Advisor. Each Agent reads configuration data from a file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. In the configuration file for each Agent, the `sysplex_group_name` statement specifies the TCP/IP sysplex group name, in the form `EZBTvvtt`, where `vv` is the VTAM subplex group ID specified with the VTAM `XCFGRPID` start option, and `tt` is the TCP/IP subplex group ID specified with the `XCFGRPID` parameter on the `GLOBALCONFIG` statement in the TCP/IP profile. If no VTAM subplex ID is specified when VTAM is started, then `vv` is `CP`. If no TCP/IP subplex ID is specified in the TCP/IP profile, then `tt` is `CS`. If you have a default subplex in your system (that is, a subplex in which both the VTAM and TCP/IP subplex IDs are not specified), configure the Load Balancing Agent for that subplex with a sysplex group name of `EZBTCPCS`.

Tip: In a subplexing environment, if you will have more than one Agent started on the same z/OS system (in different subplexes), create unique start procedures for them or ensure that they have unique job names when they are started (for example, `S LBAGENT.AGE0105` or `S LBAGENT,JOBNAME=AGE0105`).

Requirements:

- In a subplexing environment, the IP address used by the Agent to connect to the Advisor must exist on a TCP/IP stack belonging to the subplex that corresponds to the TCP/IP sysplex group name specified in the Agent's configuration file. If there is more than one TCP/IP stack in a subplex, the IP address must be a DVIPA defined within a `VIPARANGE` statement on each of the stacks in the subplex. This enables the Agent to connect regardless of the order that the TCP/IP stacks in the subplex are started.
- If you have more than one stack on a system, those stacks are not all in the same subplex, and you will be starting Load Balancing Agents on that system, the system must not be at a level prior to V1R10.

Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run (optional)

When operating in a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see [“Customizing TCP/IP profiles in a subplexing environment”](#) on page 1198.

There are several things to do to customize the TCP/IP profile to accommodate the Advisor and Agents.

- In the appropriate TCP/IP profiles that they will use, including the TCP/IP stacks that they could potentially move to, reserve the ports that the Advisor and Agents will use. All ports for the Advisor and Agent use the TCP protocol, and thus should be reserved for TCP. The Advisor has at least two ports, and potentially three ports, to reserve, including the ports specified on the following statements:

- `lb_connection_v4`
- `lb_connection_v6`
- `agent_connection_port`

For CINET considerations regarding the `lb_connection_v4` and `lb_connection_v6` statements, see [“Customizing TCP/IP profiles in a CINET environment”](#) on page 1198.

- If you use dynamic VIPAs for the Advisor as recommended, you need to configure the appropriate TCP/IP profiles in the sysplex for the DVIPA definition and usage. The preferred definitions would include `VIPADefine` with `MOVEABLE IMMEDIATE`, or `VIPARANGE` with `MOVEABLE NONDISRUPTIVE`. For more specific information, see [“Using dynamic VIPAs”](#) on page 397.

Restriction: Do not mix sysplex distributor functions with these DVIPAs.

- If you are currently using the `SHAREPORT` or `SHAREPORTWLM` parameters on the TCP/IP profile `PORT` statement to enable multiple TCP applications to share the same port, some additional considerations might apply to your configuration. For example, if the TCP applications sharing the same port are also members of groups that are being reported to external load balancers with `SASP`, it is important to ensure that consistent criteria are used by the various load balancing components.

When using the z/OS Load Balancing Advisor, all instances of a TCP application sharing the same port on a target system are reported to external load balancers using a single member entry, and therefore, a single recommendation. This recommendation reflects the average net weight calculated for all the servers sharing the same port on a target system, and is based on the type of WLM recommendation configured on the Advisor. When the TCP connection requests reach a target TCP/IP stack and multiple applications are sharing the same port, the connections are then load balanced by TCP/IP across the multiple application server instances. How this load balancing is performed depends on whether the SHAREPORT or SHAREPORTWLM parameter is specified on the PORT statement. For more details on the [PORT statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Guideline: If server-specific WLM recommendations are configured within the Advisor for a given group that contains servers that share the same port on a given system or TCP/IP stack, the SHAREPORTWLM parameter should also be specified on the PORT statement in the TCP/IP profile for these servers. This enables both the external load balancers and the internal TCP/IP load balancer to operate with the same type of recommendations when load balancing work requests to these servers. Similarly, if WLM system weight recommendations were configured in the Advisor for a group, the SHAREPORT parameter would probably be more appropriate.

Enabling TLS/SSL for z/OS Load Balancing Advisor (optional)

For AT-TLS, the following customization tasks are required before starting the TCP/IP stacks and the Advisor and Agent applications:

- Enable AT-TLS in the TCP/IP stack.

Specify the TTLS parameter on the TCPCONFIG statement in the TCP/IP profile. For additional information about AT-TLS, see [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149. For information about the [TCPCONFIG](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

- Set up authorization for the **pasearch** command, if the command will not be issued from a superuser.

Create a SERVAUTH profile of EZB.PAGENT.*sysname.image.ptype*, where the *ptype* value is set to TTLS or to a wildcard value. For more information, see [“Steps for configuring the Policy Agent”](#) on page 834 and [z/OS Security Server RACF Security Administrator's Guide](#).

- Enable AT-TLS configuration for the Policy Agent.

Specify the CommonTTLSConfig and TTLSConfig statements in the Policy Agent configuration file for each stack. On the TTLSConfig statement, specify the path of the stack-specific AT-TLS policy file to be installed for the server. For additional information about the [CommonTTLSConfig](#) and [TTLSConfig](#) statements, see [z/OS Communications Server: IP Configuration Reference](#).

- Define AT-TLS policies in new or existing Policy Agent configuration files.

Specify the AT-TLS policies in the configuration files that are identified with the CommonTTLSConfig and TTLSConfig statements. Ensure that the Load Balancing Advisor policy definitions are defined on all systems in the sysplex on which the Advisor can run.

The Load Balancing Advisor is a server application. For general information about setting up AT-TLS for a server, see [Table 59](#) on page 1154.

The following example shows the TTLSConfig policy file statements in the path file for the load balancer connections to the Advisor. Port 3860 is the default port.

```

TTLSRule                                LBAdvisorLBRule
{
  LocalPortRange                        3860
  Direction                            Inbound
  TTLSGroupActionRef                    LBAdvisorLBGroup
  TTLSEnvironmentActionRef              LBAdvisorLBEnvironment
}
TTLSGroupAction                         LBAdvisorLBGroup
{
  TTLSEnabled                           On
}
TTLSEnvironmentAction                  LBAdvisorLBEnvironment
{

```

```

TTLSTLSKeyRingParms
{
    Keyring                LBADV/server_key_ring
}
TTLSEnvironmentAdvancedParms
{
    # TLS will verify a user ID is associated with certificate
    ClientAuthType          SAFCheck
    ApplicationControlled    On
}
HandshakeRole              ServerWithClientAuth
TTLSCipherParmsRef         RequireEncryption
Trace                      7
}

```

In this example, all external load balancers must use TLS/SSL and supply a client certificate that will be validated in the key ring and must be associated with a user ID on the SAF-compliant security product on the local z/OS system. This type of policy allows additional finer-grain SAF checks using optional SERVAUTH profiles. You can use other, less restrictive, policies; however, if you use less restrictive policies, the Advisor, Agent, and ADNR require that you specify the configuration parameters for those connections (lb_id_list or agent_id_list statements in the Advisor configuration file, host_connection statement in the Agent configuration file, and host_connection_addr statement in the ADNR configuration file).

The following example shows the TTLSTLSConfig policy file statements in the path file for the Agent connections to the Advisor. Port 8100 is the port that is used in the sample Advisor configuration file:

```

TTLSTLSRule                LBAdvisorAgentRule
{
    LocalPortRange          8100
    Direction               Inbound
    TTLSTLSGroupActionRef    LBAdvisorAgentGroup
    TTLSEnvironmentActionRef LBAdvisorAgentEnvironment
}
TTLSTLSGroupAction          LBAdvisorAgentGroup
{
    TTLSEnabled             On
}
TTLSTLSEnvironmentAction    LBAdvisorAgentEnvironment
{
    TTLSTLSKeyRingParms
    {
        Keyring                LBADV/server_key_ring
    }
    TTLSEnvironmentAdvancedParms
    {
        # TLS will verify a user ID is associated with certificate
        ClientAuthType          SAFCheck
        ApplicationControlled    On
    }
    HandshakeRole              ServerWithClientAuth
    TTLSTLSCipherParmsRef      RequireEncryption
    Trace                      7
}

# Set of TLS Ciphers with Encryption
TTLSTLSCipherParms RequireEncryption
{
    V3CipherSuites            TLS_RSA_WITH_RC4_128_MD5
    V3CipherSuites            TLS_RSA_WITH_RC4_128_SHA
    V3CipherSuites            TLS_RSA_WITH_DES_CBC_SHA
    V3CipherSuites            TLS_RSA_WITH_3DES_EDE_CBC_SHA
}

```

The Load Balancing Agent is a client application. For general information about setting up AT-TLS for a client, see [Table 60 on page 1156](#).

You must configure the policy on the TCP/IP stack where the Agents will run with the same SSL protocol, key ring, and cipher suite (if encrypting data) for which the Advisor is configured.

The following example shows the TTLSTLSConfig policy file statements for a Load Balancing Agent. On the TTLSTLSConfig statement, specify the path of the stack-specific AT-TLS policy file to be installed for

the client. For more information about the [TTLSConfig](#) statement, see [z/OS Communications Server: IP Configuration Reference](#). Port 8100 is the port that is used in the sample Agent configuration file.

```

TTLSRule
{
  RemotePortRange      8100
  Direction            Outbound
  TTLSGroupActionRef   LBAGroup
  TTLSEnvironmentActionRef LBAgentEnvironment
}
TTLSGroupAction        LBAGroup
{
  TTLSEnabled          On
}
TTLSEnvironmentAction  LBAgentEnvironment
{
  TTLSKeyRingParms
  {
    Keyring            LBAGENT/client_key_ring
  }
  HandshakeRole        CLIENT
  TTLSCipherParmsRef   RequireEncryption
  Trace                7
}

# Set of TLS Ciphers with Encryption
TTLSCipherParms RequireEncryption
{
  V3CipherSuites       TLS_RSA_WITH_RC4_128_MD5
  V3CipherSuites       TLS_RSA_WITH_RC4_128_SHA
  V3CipherSuites       TLS_RSA_WITH_DES_CBC_SHA
  V3CipherSuites       TLS_RSA_WITH_3DES_EDE_CBC_SHA
}

```

For additional information, see:

- [Chapter 14, “Policy-based networking,”](#) on page 813.
- [Chapter 20, “Application Transparent Transport Layer Security data protection,”](#) on page 1149. [Table 59](#) on page 1154 is for the Advisor, and [Table 60](#) on page 1156 is for the Agent and for load balancers.
- [AT-TLS policy statements](#) in [z/OS Communications Server: IP Configuration Reference](#)
- [CommonTTLSConfig](#) and [TTLSConfig](#) statements in [z/OS Communications Server: IP Configuration Reference](#).
- Online help for the IBM Configuration Assistant for z/OS Communications Server
- Create z/OS server (Advisor) and client (Agent, ADNR, external load balancer) key rings and necessary certificate authority certificates.

The server key ring needs to contain a server certificate, and any certificates that are used to sign it. The server needs access to the private keys of the server certificate. The client key ring needs the root certificate that is used to sign the server certificates.

For a TLS/SSL primer and some step-by step examples, see [Appendix B, “TLS/SSL security,”](#) on page 1359. For more information about managing key rings and certificates with RACF and the RACDCERT command, see [z/OS Security Server RACF Security Administrator's Guide](#). For detailed information about managing key rings and certificates with gskkyman, see [z/OS Cryptographic Services System SSL Programming](#).

- Send the external load balancer's certificate to the z/OS host.
- Associate each user ID (for the Advisor, Agents, ADNRs, and external load balancers) with a certificate.

Use the RACDCERT ADDRING command to define a key ring in RACF and to associate it with your application's user ID. Use the RACDCERT CONNECT command to connect certificates to the key ring. For detailed information about [setting up your certificate environment](#), see [z/OS Security Server RACF Security Administrator's Guide](#).

- Create client side certificates for the external load balancers. See the load balancer documentation for instructions.

- Define client user IDs on the TCP/IP stacks on which the Advisor will run by issuing security product commands to establish authorization for the user IDs.

You can configure the Advisor's clients (Agents, ADNR, and external load balancers) to present security credentials, including a user ID. If you configure this, you must set up the security manager on the Advisor system to accept these credentials.

Using a security product like RACF, perform the following steps to control access to the Load Balancing Advisor, Agents, and ADNR.

1. Use the following commands to ensure that the SERVAUTH class is active and RACLISTed, and that RACLIST processing is enabled:

```
SETROPTS CLASSACT(SERVAUTH)
SETROPTS RACLIST (SERVAUTH)
```

2. Use the following commands to define the following SERVAUTH class profiles on each system on which the Advisor might run.

```
RDEFINE SERVAUTH EZB.LBA.LBACCESS.sysname.tcpsysplexgroupname UACC(NONE)
RDEFINE SERVAUTH EZB.LBA.AGENTACCESS.sysname.tcpsysplexgroupname UACC(NONE)
```

where *sysname* is the MVS system name or a wildcard (*) and *tcpsysplexgroupname* is the TCP/IP sysplex group name. If you are not using subplexing, use the default subplex identifier EZBTCPCS or a wildcard (*). For example, on system MVSSYS using the default subplex, the profile name is EZB.LBA.LBACCESS.MVSSYS.EZBTCPCS.

3. Use the following commands to grant access to the SERVAUTH class for the user IDs associated with the Agents, ADNR, and the external load balancers on each system on which the Advisor might run:

```
PERMIT EZB.LBA.LBACCESS.sysname.tcpsysplexgroupname -
CLASS(SERVAUTH) ACCESS(READ) ID(userid)
PERMIT EZB.LBA.AGENTACCESS.sysname.tcpsysplexgroupname -
CLASS(SERVAUTH) ACCESS(READ) ID(userid)
```

4. Use the following command to refresh the SERVAUTH class:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

For specific instructions, see the EZARACF sample in SEZAINST.

Requirements:

- The AT-TLS policies and SERVAUTH profiles must be coordinated to provide the appropriate level of security. For example:
 - If a connection is presented to the Advisor and the AT-TLS check indicates that this is not a secure connection, then no subsequent SAF check is performed but an IP address ACL check (using the statements in the Load Balancer Advisor configuration files) is performed. If the IP address ACL check is successful, the connection is accepted.
 - If you always want a SAF level check to be performed, then ensure that the AT-TLS policy requires client certificates that are associated with user IDs defined on the local SAF-compliant security product. Also ensure that the SAF profile is defined and the correct user IDs are permitted READ access to the profile. If a secure connection is presented to the Advisor, and the SAF profile exists but the user ID is not authorized to the profile, then the connection will fail and no ACL check will be performed.
 - If the SERVAUTH profile is not defined, then the Load Balancer Advisor performs the IP Address (and port where appropriate) access control list checks before permitting a connection to the Load Balancer Advisor.
- If the Advisor might run on more than one system, perform set up on all those systems or use a wildcard (*).

For additional information, see [z/OS Security Server RACF Security Administrator's Guide](#).

Customizing TCP/IP profiles in a CINET environment

The Advisor can use multiple TCP/IP stacks in a CINET environment. The addresses specified in the `lb_connection_v4` and `lb_connection_v6` statements can belong to different TCP/IP stacks. Moreover, because the socket that listens for Agent connections uses the IPv4 or IPv6 unspecified address, the TCP/IP stack or stacks that incoming Agent connections use depends upon the IP addresses specified in the Agents' `agent_id_list` statements. To simplify your configuration and to make Advisor outages that are the result of a TCP/IP stack failure or termination more predictable and recoverable, all incoming connections to the Advisor should use a single TCP/IP stack. Therefore, the addresses you specify in the `lb_connection_v4` and `lb_connection_v6` statements should belong to the same TCP/IP stack, and you should configure all load balancers and Agents to use these same IP addresses when connecting to the Advisor. The addresses you specify should be dynamic VIPAs to enable the movement of the Advisor in case of failure. This implies that these dynamic VIPAs should be defined in the TCP/IP profiles of all the stacks using a `VIPARANGE` statement. If the Advisor is restarted as a result of failure in a given TCP/IP stack, the dynamic VIPAs are then activated on another TCP/IP stack in that system. If you decide to use the IPv4 or IPv6 unspecified addresses for the `lb_connection_v4` and `lb_connection_v6` statements, you should use the `BIND` parameter on the `PORT` reservation statement to bind these sockets to the dynamic VIPA on the one TCP/IP stack you have decided to use.

Customizing TCP/IP profiles in a subplexing environment

In a subplexing environment, each Advisor and Agent must use a TCP/IP stack that is in its associated subplex. That stack should specify the TCP/IP subplex group ID that corresponds to the TCP/IP part (`tt`) of the `sysplex_group_name` (`EZBTvvtt`) for which the Advisor or Agent has been configured. The DVIPA for the Advisor must be defined in all the stacks that are associated with the subplex, where a restart of the Advisor can occur.

Step 6: Customize WLM policies for the Advisor and Agents (optional)

It is important that the Advisor and Agents receive an adequate amount of system resources to properly balance workloads. Part of this task involves making the Advisor and Agent run non-swappable. In addition, WLM can control the amount of system resources allocated to the Advisor and Agents.

Guideline: The Advisor and Agents should be assigned to the WLM `SYSSTC` service class to receive the appropriate dispatching priority. For more information about [Defining classification rules](#), see [z/OS MVS Planning: Workload Management](#).

Step 7: Configure the external load balancers

Configure the load balancers with the location (IP address and port) of the Advisor. For maximum availability, this address should be defined as a DVIPA.

In a sysplex subplexing environment, this step requires additional actions. For information about the changes to this step, see [“Configuring the external load balancers in a subplexing environment” on page 1200](#).

If you are using TLS/SSL, the load balancers are client applications in a z/OS Load Balancing Advisor environment. You must configure the load balancers with the same TLS/SSL protocol and cipher suite (if encrypting data) with which the Advisor is configured. Client certificates should be configured on the load balancer, and also defined in the z/OS SAF-compliant security product if that level of authentication is required. See the load balancer documentation for instructions.

Restrictions:

- If the Advisor is using IPv6 for the load balancer connections, or if any Agents are using IPv6 to connect to the Advisor, movement of the Advisor is limited to IPv6-enabled TCP/IP stacks.
- There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

You might be able to customize features of the load balancer's communication with the Advisor. The SASP protocol defines two features that the load balancer implementation might or might not allow to be configured. One determines whether the load balancer polls the Advisor for updated data, or whether

updated data is pushed to the load balancer. The other determines whether only members that have updated data should be sent to the load balancer, or whether all members should be sent to the load balancer regardless of whether their data has changed or not. To determine whether these features can be customized, and how to perform the customization if available, consult your load balancer's documentation. If the load balancer is capable and configured to request that the Advisor push updated information to the load balancer, the Advisor will update the load balancer at least every update interval. If the load balancer is capable and configured to poll the Advisor for updated information, the Advisor will recommend to the load balancer that it poll every update interval. However, the load balancer can choose to disregard this guideline. Consult the load balancer documentation for the expected behavior in these circumstances.

You might want to consider having redundant load balancers configured alike for availability reasons. If so, you need to be aware of the load balancer's unique load balancer identifier (LB UID), sometimes referred to as the UID or UUID, which uniquely identifies a load balancer. Duplicate LB UIDs are not allowed and connection attempts to the Advisor from a load balancer using the same LB UID as an existing connection will force the existing connection to be broken and replaced by the new connection. Redundantly configured load balancers either need to have unique LB UIDs, if you want them to serve as hot standbys that are connected simultaneously along with the load balancer they are backing up, or if they are configured with the same LB UID, they must remain unconnected from the Advisor until the original load balancer fails.

Some load balancers might be capable of using either dispatch or directed mode when forwarding packets to their destinations. External load balancers typically use a cluster IP address to represent the set of applications being load balanced. Client applications use this cluster IP address as the destination IP address for their requests. When a load balancer uses dispatch mode, the destination IP addresses for incoming IP packets is not changed. Instead, the load balancer forwards the packet to a target z/OS system by using the MAC address of a network adapter on that system. The receiving z/OS system inspects the destination IP address of the packet, and if it matches one of the IP addresses in its HOME list, accepts the packet. As a result, with dispatch mode, all target z/OS systems must have the load balancer's cluster IP address defined in their HOME list. However, it is important that these addresses are not advertised externally through dynamic routing protocols. One way to accomplish this is by defining these IP addresses as loopback addresses on z/OS.

With directed mode, the load balancer converts the destination IP address (that is, the cluster IP address) to an IP address owned by the target z/OS system, using technologies such as network address translation (NAT). When IP packets for these connections are sent back to clients, the load balancer converts the source IP address (that is, the target z/OS system's IP address) back to the cluster IP address that the application had used on its request.

While dispatch mode eliminates the need for performing NAT, it does have some special considerations. For example, in [Figure 154 on page 1218](#), both SYSA and SYSB have the same server, FTPD, bound to the same port number using INADDR_ANY. The packet will have the cluster IP address (both SYSA and SYSB are in the same cluster), so the load balancer will use the MAC address to decide to send the packet to SYSA or SYSB, and TCP/IP will then route the packet to the server.

Restrictions: When using dispatch mode, for the load balancer to function correctly, there are the following limitations:

- An OSA can be shared among LPARs only if Virtual MAC (VMAC) addressing is configured for each TCP/IP target stack sharing the OSA.
- All target applications must bind to the IP address specified by INADDR_ANY or in6addr_any, and the cluster IP address must be defined to the stack; however, this must be done so that the address is not advertised (as in a loopback address).

If these restrictions are not met, load balancing will not be optimal because some servers will not get work routed to them.

With directed mode, either the destination IP address (server NAT) is modified in the packet itself, or both the destination and source IP addresses (server NAT and client NAT) are modified in the packet. The packet must return through the same load balancer that will recognize the changes and do the reverse mapping, so a packet can flow from the original destination to the original source.

Configure each load balancer with the members that represent the individual target application instances, or system members that generically represent a system in the sysplex, or both. Members that can share the same type of workload are defined under the same group. For example, TN3270E Telnet servers are defined under one group, and HTTP servers in another. Application members are defined by specifying an IP address, a nonzero port, and a nonzero protocol. System members are defined by specifying an IP address, and specifying the port and protocol to be zero. Members that have only a port of zero or only a protocol of zero (that is, one but not both are zero) are not considered valid members and will not receive any data from the Advisor. The IP addresses of the members must represent valid, reachable addresses within the sysplex that are unique to a specific sysplex system. This excludes such addresses as the loopback addresses, and other non-advertised addresses.

Tip: The Advisor does not check for improperly configured members. After the entire z/OS Load Balancing Advisor system is operational, display all members registered by each load balancer and verify each member you expect to be available is flagged as available. Screen any unavailable members for coding errors in the member, such as incorrect IP addresses, ports, or protocols.

Guideline: For availability reasons, the IP addresses configured for each member should be VIPA addresses (static or dynamic). If the IP address of a physical interface fails and a member specifies that IP address, the Advisor still indicates that the member is available, as alternate routing paths to that member might exist. However, if no alternate routing paths exist, workload requests cannot be delivered to the target system. By using static or dynamic VIPAs in members, the chance of an alternate route being available when a physical interface fails is greatly increased, as long as at least one physical interface is still available.

Restrictions:

- All IP addresses configured in members belonging to the same group must exist within the same sysplex.
- All members belonging to the same group must be of the same type. That is, all members must be application members or all must be system members.
- Certain classes of IP addresses must not be coded for members in the load balancer. This includes the following classes of addresses:
 - Distributed DVIPAs (the address specified on a VIPADISTRIBUTE statement). Defining members with these addresses would combine two load balancing methodologies for the same workload, wasting system resources.
 - Deprecated IPv6 addresses. These are flagged as such in a NETSTAT HOME display. It is probably safest to not code any autoconfigured IPv6 addresses within members.
 - Addresses that are not unique within the sysplex.
 - Addresses that are not reachable from the load balancer, including:
 - Loopback addresses.
 - Unavailable IPv6 addresses. These might be marked as unavailable if duplicate address detection is in progress, has failed, or the interface ID is unknown. These addresses are displayed in a NETSTAT HOME display, including the reason they are marked unavailable.

Configuring the external load balancers in a subplexing environment

You might configure separate load balancers for each subplex, if the subplexes represent connectivity to networks with different security domains. When configuring a load balancer with the IP address of a Load Balancing Advisor, ensure that you have connectivity from the load balancer to the subplex that the Load Balancing Advisor is handling. In addition, groups and target applications that the external load balancer requests information on should belong to the same subplex that the Load Balancing Advisor is handling.

Steps for starting the z/OS Load Balancing Advisor

Follow these steps to start the TCP/IP stacks that the Advisor and Agents are to use, the target applications, the Agents, the Advisor, and the load balancers.

Procedure

Perform the following steps to start the z/OS Load Balancing Advisor:

1. Start the TCP/IP stacks that the Advisor and the Agents will use.
See [“Step 1: Start the TCP/IP stacks that the Advisor and the Agents will use” on page 1201.](#)
2. Start the target applications that will be the targets of load balancing.
See [“Step 2: Start the target applications that will be the targets of load balancing” on page 1201.](#)
3. Start one Agent on each sysplex system that you want to participate in this method of workload balancing.
See [“Step 3: Start one Agent on each sysplex system you want to participate in this method of workload balancing” on page 1201.](#)
4. Start the one instance of the Advisor in the sysplex.
See [“Step 4: Start the one instance of the Advisor in the sysplex” on page 1202.](#)
5. Start the load balancers.
See [“Step 5: Start the load balancers” on page 1202.](#)

Step 1: Start the TCP/IP stacks that the Advisor and the Agents will use

The TCP/IP stacks that the Advisor will use must be started prior to starting the Advisor. An Agent can be started before the TCP/IP stack it uses is started. If the TCP/IP stack that an Agent uses terminates, the Agent remains active and reestablishes communication with the TCP/IP stack after it becomes active again. For CINET considerations regarding Agent recovery after stack failure, see [“Starting the TCP/IP stacks in a CINET environment” on page 1201.](#)

Starting the TCP/IP stacks in a CINET environment

In a CINET environment, certain configurations might necessitate manual intervention for recovery if the Agent's TCP/IP stack fails. For more information, see the rule in [“Configuring one Agent per z/OS system in the sysplex in a CINET environment” on page 1192.](#)

Step 2: Start the target applications that will be the targets of load balancing

No modifications are necessary to these applications, their configurations, or start procedures, unless the load balancer is using dispatch mode for packet forwarding. For more information on dispatch mode, see [“Step 7: Configure the external load balancers” on page 1198.](#)

Step 3: Start one Agent on each sysplex system you want to participate in this method of workload balancing

It does not matter whether the Agents are started before the Advisor, or whether the Advisor is started before the Agents. If the Advisor is started after the Agents are started, the Agent periodically attempts to connect to the Advisor. Only one Agent can be started per z/OS system. Agents must be started from a start procedure as a started program (EXEC PGM=). They cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make the Agents run non-swappable. You should not override this entry to make the Agents run swappable.

Starting Agents in a subplexing environment

You can start more than one Agent on a z/OS system, if there are TCP/IP stacks for more than one subplex on that system.

Step 4: Start the one instance of the Advisor in the sysplex

As Agents connect to the Advisor, MVS console messages appear on the Advisor's MVS console and on the Agents' MVS consoles. Verify that each Agent you expect to connect to the Advisor has connected. You can also use the NETSTAT,CONN command on the Advisor's TCP/IP stack to see which Agents are currently connected. The Advisor must be started from a start procedure as a started program (EXEC PGM=). It cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make the Advisor run non-swappable. You should not override this entry to make the Advisor run swappable.

Starting Advisors in a subplexing environment

You can start more than one Advisor in the sysplex, one for each subplex in the sysplex.

Step 5: Start the load balancers

When a load balancer has connected, messages appear on the Advisor's MVS console. You can also use the Advisor's MODIFY *procname*,DISPLAY,LB command to see which load balancers are connected to the Advisor. For details on the Advisor's MODIFY command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Restriction: There is a maximum limit of 100 load balancers that can be connected to an Advisor at any given time.

Verifying that the Advisor system is functioning correctly (optional)

View the MVS console of the Advisor and Agent systems after they are started to verify that the applications started correctly and are still running. If there are any failure messages, see the appropriate message description for the appropriate corrective action. View the syslogd files of the Advisor and Agent systems to see whether any error or warning messages were issued.

Use the following commands to verify that the Advisor system is functioning correctly:

- Verify that the Advisor is started and connected to the expected load balancers by issuing the Advisor's MODIFY *procname*,DISPLAY,LB command. Verify that each load balancer is displayed. Take note of the LB INDEX displayed for each load balancer. This identifier is needed to display details of the load balancer, including its registered groups and members.

Tip: Individual load balancers are identified in displays by their load balancer index (LB Index), which is generated by the Advisor when the load balancer first connects. To display the details of a particular load balancer, first obtain the LB Index by displaying the list of all load balancers using the Advisor's MODIFY *procname*,DISPLAY,LB command. When you have the LB Index, display the details of a particular load balancer using the appropriate LB Index on the INDEX parameter as follows:

```
MODIFY procname,DISPLAY,LB,INDEX=lb_index
```

- Verify that each load balancer configured and registered the appropriate groups and members with the Advisor by issuing the following command:

```
MODIFY procname,DISPLAY,LB,INDEX=assigned_lb_index
```

This display should show all groups and members defined to the load balancer.

- Verify that each Agent has started properly and is communicating with the Advisor. On each Agent, issue the following command:

```
MODIFY procname,DISPLAY,MEMBERS
```

Each member that has an IP address owned by this Agent should appear in the display.

- Verify that the target applications that you want to load balance to are actually available for load balancing. On the Advisor, for each load balancer connected to the Advisor, issue the following command:

```
MODIFY procname,DISPLAY,LB,INDEX=assigned_lb_index
```

Check for the AVAIL flag for each member in the display. The flag is either YES, meaning the member is available for load balancing, or NO, meaning it is not available for load balancing. To be available for load balancing, all of the following conditions must be true:

- The Agent owning the member's IP address must be active and communicating with the Advisor.
- The application must be active, if the member represents an application member, and must be on a TCP/IP stack that has not had eventual action message EZD1973E issued by sysplex problem detection and recovery. For more information, see [“Problem detection” on page 481](#).
- The member must not be quiesced by the Agent operator or the load balancer. The z/OS Agent operator is able to quiesce any member that is owned by that Agent. Also, depending upon load balancer implementation, it might be possible for the load balancer administrator to quiesce individual members.

If one of the above conditions is false, correct the situation and repeat the display command until you are satisfied that all members that you intend to have available for load balancing are displayed as being available.

- Verify that the Advisor system is functioning correctly when using AT-TLS:
 - Use the **pasearch** command from the z/OS UNIX shell to query information from the Policy Agent. For example, **pasearch -t -r** displays active AT-TLS rule details. For more information about displaying policy based networking information, see [z/OS Communications Server: IP System Administrator's Commands](#).
 - Use the Netstat TTLS/-x command to display z/OS Load Balancing Advisor, Agent, and ADNR AT-TLS policies. For more information about the [Netstat TTLS/-x report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Operating the z/OS Load Balancing Advisor

When the Advisor and Agent are operational, you can monitor and customize processing:

- Change the logging level of the Advisor and Agents to suit your needs (optional)
- Interpret Agent and Advisor display information
- Stop distributing new workload requests (QUIESCE) to particular members or resume distribution (ENABLE) to those members (optional)

Changing the logging level of the Advisor and Agents

Optionally, you can change the logging level of the Advisor and Agents to suit your needs. The amount of information that is logged by the Advisor and Agents can be modified dynamically using the following command:

```
MODIFY procname,DEBUG,LEVEL=debug_level
```

However, modifying the logging level is not a step that should be taken lightly. The IBM default of 7 should not be changed unless instructed to do so by an IBM Service representative. For things to consider before modifying this value, see [“Customizing optional statements” on page 1188](#).

Interpreting Agent and Advisor display information

Successfully interpreting the various flags and indicators that appear in Advisor and Agent displays can help you identify configuration problems, or might help explain why workloads are not being distributed as expected. For information on each field in the [Advisor's MODIFY command](#) and [Agent's MODIFY](#)

procname,QUIESCE command displays, see *z/OS Communications Server: IP System Administrator's Commands*. Some portions of the displays are described in more depth in [Table 62 on page 1204](#), [Table 63 on page 1207](#), and the subtopics that follow.

Table 62. Summary of selected Advisor display output fields and flags		
Flag or field name	Location	Description
ABNORM	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	The rate of abnormal transaction completions per 1000 total transaction completions for this application. This value is optionally provided to WLM by the application. WLM provides this value along with the server-specific recommendation on the system where the member is. For 1000 total transactions completed, it displays the number of those transactions that could not successfully complete. If the value is nonzero, WLM uses it to reduce the server-specific recommendation (WLM weight).
AVAIL	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	Indicates whether the member is available for workload balancing requests.
BASEWLM	GROUP FLAGS field of the group area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	WLM system weight recommendations were configured or specified by default for the members of this group, and are being used as a component of the net weight.
BASEWLM*	GROUP FLAGS field of the group area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	Server-specific WLM recommendations were configured or specified by default for the members of this group. However, WLM system weight recommendations are actually being used as a component of the net weight.
CP	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	When shown on the next line after ProcType, indicates the proportion that is applied against the CP weight. When shown on the line starting with RAW, indicates the raw CP weight that was returned by WLM. When shown on the line starting with Proportional, indicates the proportionally adjusted raw CP weight that was used to determine the BASEWLM or SERVERWLM composite weight.
CS WEIGHT	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	Communications Server weight. A value calculated by the Agent that owns the member, representing the health of the application with respect to its ability to process the work that has recently been received.

Table 62. Summary of selected Advisor display output fields and flags (continued)

Flag or field name	Location	Description
HEALTH	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	The general health of the application. This value is optionally provided to WLM by the application. WLM provides this value along with the server-specific recommendation on the system where the member is. If the value is less than 100, WLM uses it to reduce the server-specific recommendation (WLM weight).
LB INDEX	For the MODIFY <i>procname</i> ,DISPLAY,LB and MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> commands, an output field of the load balancer area	A unique identifier assigned to a load balancer for the purpose of referencing the load balancer in subsequent operator commands
LBQ	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	The load balancer has quiesced the member.
NET WEIGHT	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	The weight the Advisor passes to the load balancer, representing the desirability of the member to receive additional workload requests relative to the other members of the same group. The net weight is calculated using the WLM weight and Communications Server weight.
NOCHANGE	For the MODIFY <i>procname</i> ,DISPLAY,LB and MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output, the FLAGS field of the load balancer area	The load balancer has requested that it be sent only information about members that have changed their status or weights since the last time the load balancer received information on its members.
NODATA	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	A transient flag indicating that the responsible Agent has not had enough time to calculate a Communications Server weight.
NOTARGETAPP	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	The target application of this application member is not active.
NOTARGETIP	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	This is an unusable system member.
NOTARGETSYS	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	The Advisor is not aware of the system that owns the IP address of the member.
OPQ	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	The z/OS operator has quiesced the member.

Table 62. Summary of selected Advisor display output fields and flags (continued)

Flag or field name	Location	Description
ProcType	A field of the group area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	Indicates that CP, zAAP, and zIIP proportions were configured. These proportions are applied against the processor weights to determine the composite BASEWLM weight.
PUSH	For the MODIFY <i>procname</i> ,DISPLAY,LB and MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output, the FLAGS field of the load balancer area	The load balancer has requested to receive information from the Advisor on a scheduled basis, rather than having to poll the Advisor for the information.
SERVERWLM	GROUP FLAGS field of the group area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	Server-specific WLM recommendations are being used for the members of this group as a component of the net weight.
TRUST	For the MODIFY <i>procname</i> ,DISPLAY,LB and MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output, the FLAGS field of the load balancer area	The load balancer will allow other system components besides itself to register members with the load balancer. The z/OS Load Balancing Advisor does not currently exploit this feature.
WLM WEIGHT	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	WorkLoad Manager weight. The value received from WLM on the system where the member is, representing the displaceable capacity of that system relative to other systems in the sysplex (system weight), or the value received from WLM representing how well the server is performing relative to its WLM policies (server-specific weight). This weight is a composite weight determined from the displayed CP, zAAP, and zIIP weights.
zAAP	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	<p>When shown on the next line after ProcType, indicates the proportion that is applied against the zAAP weight.</p> <p>When shown on the line starting with RAW, indicates the raw zAAP weight that was returned by WLM.</p> <p>When shown on the line starting with Proportional, indicates the proportionally adjusted raw zAAP weight that was used to determine the BASEWLM or SERVERWLM composite weight.</p>

Table 62. Summary of selected Advisor display output fields and flags (continued)		
Flag or field name	Location	Description
zIIP	A field of the member area of the MODIFY <i>procname</i> ,DISPLAY,LB,INDEX= <i>nn</i> command output	<p>When shown on the next line after ProcType, indicates the proportion that is applied against the zIIP weight.</p> <p>When shown on the line starting with RAW, indicates the raw zIIP weight that was returned by WLM.</p> <p>When shown on the line starting with Proportional, indicates the proportionally adjusted raw zIIP weight that was used to determine the BASEWLM or SERVERWLM composite weight.</p>

Table 63. Summary of selected Agent display output flags		
Flag or field name	Location	Description
ANY	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,MEMBERS command output	The target application is bound to the unspecified address, 0.0.0.0 for IPv4 or :: for IPv6.
V6	FLAGS field of the member area of the MODIFY <i>procname</i> ,DISPLAY,MEMBERS command output	The target application was bound using the IPV6_V6ONLY socket option.

MODIFY *procname*,DISPLAY,LB

This command displays all load balancers that are currently connected to the Advisor. In [Figure 150 on page 1207](#), the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure.

```

1  MODIFY LBADV,DISPLAY,LB

```

Figure 150. Sample output for the MODIFY *procname*,DISPLAY,LB command

LB INDEX

The LB index is generated by the Advisor to uniquely identify a load balancer, and is used in other MODIFY commands to display details of a particular load balancer. The LB index that is assigned to the next load balancer that connects can be difficult to predict at times, in case your automation attempts to predict them. Each time a load balancer connects, it is assigned a different LB index. At first, the numbers are assigned in order from 0 to 99, and then the numbers are reused. The next number assigned after 99 is based on a least-recently-used algorithm. Thus, of the load balancer connections that used the numbers 0-99, the index of the load balancer connection that ended first would be the next number assigned as the next LB index. This is done to prevent the confusion that could result if new load balancer connections obtained the lowest available index. If that were the case, it might be difficult to ascertain whether different load balancer displays referred to the same or different load balancer connection instances. If the Advisor is brought down and back up, the indexes start from zero again. Lines 3 and 6 in [Figure 150 on page 1207](#) show two LB indexes. For more information about the Advisor's MODIFY command field, see [z/OS Communications Server: IP System Administrator's Commands](#).

NOCHANGE, PUSH, TRUST

All of these flags are set only by the load balancer. Whether they appear or not depends upon whether the particular load balancer implementation supports them, and if they are configured in the load balancer. The z/OS administrator has no control over the settings of these flags.

The NOCHANGE flag can affect the amount of data transferred between the load balancer and the Advisor. If this flag is set, only data that has changed since the last time data was sent to the load balancer is included. Consult the load balancer documentation to determine whether this setting is supported.

The PUSH flag can have an effect on how soon the load balancer is informed of certain events. If the PUSH flag is not on, the load balancer must poll the Advisor periodically for updates. If this flag is on, certain events can be communicated to the load balancer earlier than would be possible if polling were in effect. Those events include quicker notification of a target application being taken out of service, and quicker notification of when the member's IP address has been moved to another system in the sysplex (VIPA takeover) or removed entirely. When the PUSH flag is on, the Advisor also sends the load balancer updated information about weights and status at least every update interval, if new information is available. Consult the load balancer documentation to determine whether this setting is supported.

The TRUST flag indicates that the load balancer allows other system components besides itself to register members with the load balancer. The z/OS Load Balancing Advisor does not currently exploit this feature.

Line 5 of [Figure 150 on page 1207](#) shows all of these flags. For more information on the [Advisor's MODIFY command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

MODIFY procname,DISPLAY,LB,INDEX=lbindex

This command displays details about a particular load balancer, including its registered groups and members. In [Figure 151 on page 1209](#), the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure.

```

1  MODIFY LBADV,DISP,LB,INDEX=0

Figure 152. Sample output for the MODIFY procname,DISPLAY,LB,INDEX=lbindex command, part 2 of 2

Group flags - BASEWLM, BASEWLM*, and SERVERWLM

The BASEWLM flag indicates that WLM system weight recommendations were configured or specified by default for this group, and are being used to calculate the net weight. The BASEWLM* flag indicates that server-specific WLM recommendations were configured for this group, but WLM system weight recommendations are being used instead. This occurs when at least one of the Agents owning members within the group does not support server-specific WLM recommendations. The SERVERWLM flag indicates that server-specific WLM recommendations are being used to calculate the net weight for each member in the group. Line 7 in Figure 151 on page 1209 shows the BASEWLM flag, line 39 shows the BASEWLM* flag, and line 25 shows the SERVERWLM flag. For more information on the Advisor's MODIFY command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Member flags - LBQ and OPQ

The LBQ flag indicates that the load balancer has quiesced the member. For details on what this entails, see [“Stopping or resuming workload distribution to particular members \(QUIESCE and ENABLE\)” on page 1216](#). Do not confuse this with the OPQ flag, which indicates that the z/OS operator has quiesced the member at the z/OS Agent. In both cases, the member is ineligible for future workloads through the external load balancer. Line 43 in Figure 151 on page 1209 shows the LBQ flag and the OPQ flag.

For more information on the [Advisor's MODIFY command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Member flags - NOTARGETSYS, NOTARGETIP, and NOTARGETAPP

These flags indicate that the Advisor will advise the load balancer that the member should not currently receive new workload requests because a resource is unavailable. If the IP address in the member is not present on any TCP/IP stack within the sysplex or subplex, NOTARGETSYS is displayed for that member. This flag can also appear if the Agent owning the IP address in the member has lost contact with the Advisor or has yet to be started. There might be rare instances where the load balancer might decide to go ahead and route workload requests to members that have the NOTARGETSYS flag displayed, if it has no better candidates within the group to route workload requests to. If the member represents an application member and the application is not active, NOTARGETAPP is displayed for that member. If the member is a system member and the IP address is unusable, NOTARGETIP is displayed. This includes distributed VIPAs (DVIPAs), deprecated IPv6 addresses, and unavailable IPv6 addresses. If you ever see the NOTARGETIP flag, you should update the IP address in the member at the load balancer. If application members are coded with any of these addresses, you will always see NOTARGETAPP displayed for these members. Line 19 in [Figure 151 on page 1209](#) shows the NOTARGETSYS flag, line 23 shows the NOTARGETIP flag, and line 47 shows the NOTARGETAPP flag. For more information on the [Advisor's MODIFY command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Member flag - NODATA

This flag is transient and indicates that not enough time has elapsed for the reporting Agent to calculate a Communications Server weight for the member. Therefore, only the WLM weight is used to calculate the net weight, until such time that the Agent can report a Communications Server weight. Until that time, the CS WEIGHT is displayed as 100. When a Communications Server weight has been calculated and transmitted to the Advisor, the NODATA flag is turned off. This flag appears when new members are registered by the load balancer, when the target application that the member represents first becomes active, or shortly after a target application has been moved within the sysplex or subplex. Line 51 in [Figure 151 on page 1209](#) shows the NODATA flag. For more information on the [Advisor's MODIFY command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Member field - AVAIL

This field is always displayed for each registered member, and has a value of YES or NO. YES indicates that the member is available for workload request distribution. NO indicates that the member is not available for workload request distribution. For the member to be available for workload request distribution, the target application must be active (if the member represents an application member) on a TCP/IP stack that has not had eventual action message ESD1973E issued by sysplex problem detection and recovery, an Agent must be active on the target system and connected to the Advisor, and the member must not be quiesced by the z/OS operator or by the load balancer. Line 9 in [Figure 151 on page 1209](#) shows an example of the AVAIL field set to YES, and line 17 shows an example of the AVAIL field set to NO. For more information on the [Advisor's MODIFY command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Member field - NET WEIGHT

This field is always present for each registered member, and is the only weight that the load balancer actually receives. It is calculated by applying the Communications Server weight as a percentage of the WLM weight, and then the weight is normalized within its group. Normalization involves reducing the weight values while largely preserving the ratios between the weights. Normalization is performed within a group only if there is more than one available member within the group. Net weights can be in the range 0 – 64. A higher net weight means that member is capable of receiving more work than a member within the same group that has a lower weight. There are certain situations where the net weight can be 0 when neither the WLM weight or the Communications Server weight is 0. This can happen if the member has been quiesced by the z/OS operator or the load balancer. Conversely, there is one case where the WLM weight or the Communications Server weight can be zero, but the net weight is nonzero. This can happen if the net weight of every member in the group calculates to zero, and at least one member of the group is available. In this case, the net weights of all of the available members in the group are changed to 1 to force round-robin distribution among the members in the group, rather than to stop sending new workloads to the group entirely. Line 10 in [Figure 151 on page 1209](#) shows an example of the NET WEIGHT field set to a nonzero value, while line 18 shows an example of the field set to zero. For more information about the [Advisor's MODIFY command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Member field - WLM WEIGHT

This field is always present for each registered member, and represents the desirability of the system owning the member, relative to the other systems in the sysplex or subplex (system weight), or a measure of how well the individual application is meeting its WLM policies (server-specific weight). Like the Communications Server weight and net weight, a higher value means it is more desirable. WLM weights can be in the range 0 – 64. The WLM weight is used as a key component of the net weight. The WLM weight is the composite weight, and is the sum of the modified CP, zAAP, and zIIP weights displayed on the next line. Line 10 in Figure 151 on page 1209 is one of many lines that contain the WLM WEIGHT field, and Lines 10a and 10b are some of the many lines that contain the modified CP, zAAP, and zIIP weights described in Table 64 on page 1213.

Table 64. WLM WEIGHT - CP, zAAP, and zIIP fields		
Processor	DISTMETHOD BASEWLM	DISTMETHOD SERVERWLM
CP	<p>The first value is the WLM system general CP weight recommendation. It is based on the amount of displaceable general CPU capacity on this system, as compared to the other target systems.</p> <p>The second value is the first value modified by the expected general CP usage proportion configured on the PORTLIST and WLM statement for this application.</p>	<p>The first value is the WLM server-specific general CP recommendation. This is the amount of displaceable general CPU capacity, based on the application workload's importance (as defined by the WLM policy) as compared to the other target systems.</p> <p>The second value is the first value modified by the proportion of general CP capacity that is currently being consumed by the application's workload, as compared to the other processors (zAAP and zIIP).</p>
zAAP	<p>The first value is the WLM system zAAP weight recommendation. It is based on the amount of displaceable zAAP capacity on this system, as compared to the other target systems.</p> <p>The second value is the first value modified by the expected zAAP usage proportion configured on the PORTLIST and WLM statement for this application.</p>	<p>The first value is the WLM server-specific zAAP recommendation. This is the amount of displaceable zAAP capacity, based on the importance (as defined by the WLM policy) of the application's workload, as compared to the other target systems.</p> <p>The second value is the first value modified by the proportion of zAAP capacity that is currently being consumed by the application's workload, as compared to the other processors (general CPU and zIIP).</p>
zIIP	<p>The first value is the WLM system zIIP weight recommendation. It is based on the amount of displaceable zIIP capacity on this system, as compared to the other target systems.</p> <p>The second value is the first value modified by the expected zIIP usage proportion configured on the PORTLIST and WLM statement for this application.</p>	<p>The first value is the WLM server-specific zIIP recommendation. This is the amount of displaceable zIIP capacity, based on the importance (as defined by the WLM policy) of the application's workload, as compared to the other target systems.</p> <p>The second value is the first value modified by the proportion of zIIP capacity that is currently being consumed by the application's workload, as compared to the other processors (general CPU and zAAP).</p>
Restriction: This information is available to be displayed only if no systems in the sysplex are prior to z/OS V1R9. If any systems in the sysplex are not at this release level, only CP weights are considered when determining a composite weight recommendation.		

For more information about the Advisor's MODIFY command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Member field - CS WEIGHT

This CS WEIGHT field is always present for each registered member, and represents the health of the server with respect to its ability to satisfy recent requests. As with the WLM weight and the net weight, the higher the value the better the health. The Communications Server weight can range from 0 to 100, and is used as a component of the net weight. Line 10 in Figure 151 on page 1209 is one of many lines that contains the CS WEIGHT field. For more information on the Advisor's MODIFY command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Member field - ABNORM

This field is displayed if the GROUP FLAGS field indicates that server-specific (SERVERWLM) WLM recommendations are being used. The ABNORM value is a nonzero value if the server application is experiencing conditions in which transactions are completing abnormally, and represents a rate of abnormal transaction completions per 1000 total transaction completions. It is applicable only for target applications that act as Subsystem Work Managers, reporting transaction status using Workload Management Services, such as IWMRPT. For example, the value of 200 in this example (see Line 28c in Figure 151 on page 1209) indicates that 20% of all transactions processed by the server application are completing abnormally. Under normal conditions or if the server is not providing this information to WLM, this value is 0.

A nonzero value indicates that the server application has reported abnormal transaction completions to WLM and that WLM has reduced the server-specific recommendation for this server instance. The higher the value of this field, the greater the reduction in the recommendation provided by WLM. For more information regarding the conditions leading to abnormal transaction completions for a given server application, see the documentation provided by the server application.

Restriction: Although WLM uses the abnormal transaction completion rate provided by the application to reduce the server-specific recommendation, this information is available for display on an Advisor only if the Load Balancing Agents and the Advisor are running on a z/OS V1R8 system. A z/OS V1R7 Load Balancing Agent does not provide this information to the Load Balancing Advisor. In this situation, a z/OS V1R8 Advisor shows a normal abnormal transaction completion rate of 0, even if WLM is reducing the server-specific recommendation because of a nonzero abnormal transaction completion rate reported from the application.

Member field - HEALTH

This field is displayed if the GROUP FLAGS field indicates that server-specific (SERVERWLM) WLM recommendations are being used. This health indicator is available only for applications that provide this information to WLM using the IWM4HLTH or IWMSRSG services, and it indicates the general health for an application or subsystem. Under normal circumstances, or if the server is not providing this information to WLM, the value of this field is 100, meaning the server is 100% healthy.

Any value less than 100 indicates that the server is experiencing problem conditions that are preventing it from processing new work requests successfully, which causes WLM to reduce the server-specific recommendation for this server instance. The lower the value of this field, the greater the reduction in the recommendation provided by WLM.

Restriction: Although WLM uses the health indicator provided by the application to reduce the server-specific recommendation, this information is available for display on an Advisor only if the Load Balancing Agents and the Advisor are running on a z/OS V1R8 system. A z/OS V1R7 Load Balancing Agent does not provide this information to the Load Balancing Advisor. In this situation, a z/OS V1R8 Advisor shows a normal health indicator of 100, even if WLM is reducing the server-specific recommendation because of an abnormal health indication from the application.

Member field - ProcType

Indicates that CP, zAAP, and zIIP proportions were configured. These proportions are applied against the processor weights to determine the composite BASEWLM weight. For a description of the CP, zAAP, and zIIP fields for ProcType, see [Table 62 on page 1204](#). Lines 54 and 54a in [Figure 151 on page 1209](#) contain these fields.

MODIFY procname,DISPLAY,MEMBERS,DETAIL

This command displays details about members that are owned by the Agent. In [Figure 153 on page 1215](#), the line numbers appearing in the left margin are for reference purposes only, and are used in the subtopics following the figure. For information about every field displayed by the Agent's MODIFY procname,QUIESCE command command, see [z/OS Communications Server: IP System Administrator's Commands](#).

Figure 153. Sample output for the MODIFY procname,DISPLAY,MEMBERS,DETAIL command

Member flag - ANY

The ANY flag means that the application represented by the port in the member is bound to INADDR_ANY or the IPv6 unspecified address (in6addr_any). This means that in an INET (one TCP/IP stack) environment, any externally available IP address owned by that TCP/IP stack might be used to reach the target application, not just the IP address coded in this member. Therefore, there is the potential that multiple members might exist in the load balancer or other load balancers that actually represent the same application, if members were coded with the same port, protocol, and an IP address owned by the same TCP/IP stack. You need to be aware of this if you want to issue operator commands to quiesce that application. If this were the case, quiescing the application at the port level, but specifying the individual IP address of the member, might not quiesce all new workload requests to that application. Quiescing the application at the port level without specifying an IP address would be required to accomplish that task. If the application is running in a CINET (multiple TCP/IP stack) environment, any externally available IP address on the z/OS system can be used to reach the target application, unless the application has stack affinity. If the application has stack affinity, the Advisor indicates the member is available only if the IP address coded in the member belongs to the TCP/IP stack that the application has affinity to. Line 18 in [Figure 153 on page 1215](#) shows an example of this flag. For more information on the V6 flag, see [z/OS Communications Server: IP System Administrator's Commands](#).

Member flag - V6

The V6 flag indicates that the application that the member refers to has set the IPV6_V6ONLY socket option. This socket option disallows connections to the server application using an IPv4 address as the destination IP address when the server application has bound to the IPv6 unspecified address

(in6addr_any). If a member is coded with an IPv4 address and intends to represent an application that has the IPV6_V6ONLY socket option set, the member will not be available for workload balancing and the V6 flag is displayed for this member. Conversely, for any member that represents this target application and is coded with an IPv6 address that can be used to reach the target application, the member will be available for workload balancing and the V6 flag is displayed. Line 22 in [Figure 153 on page 1215](#) shows an example of this flag. For more information on the V6 flag, see [z/OS Communications Server: IP System Administrator's Commands](#).

Stopping or resuming workload distribution to particular members (QUIESCE and ENABLE)

At least one and possibly two methods exist to stop sending new workload requests to particular members, referred to as quiescing. Quiescing does not disrupt existing connections with the target applications, but does prevent new workload requests from being distributed to those members from load balancers. Requests sent directly to applications that do not go through the load balancer are unaffected by quiescing. Quiescing certain members can be useful for a planned outage of a particular system in the sysplex, a particular TCP/IP stack, a particular application, or a homogeneous group of applications, such as all HTTP servers. The first method of quiescing is done using the `MODIFY procname,QUIESCE` operator command available at each Agent. The second potential method is through the load balancer administrator, if the load balancer implementation supports this function. Only the `MODIFY procname,QUIESCE` command is described in detail in this topic.

The `MODIFY procname,QUIESCE` command is available only on the Agents, because they own the IP addresses that belong to TCP/IP stacks on that z/OS system. Therefore, the scope of the quiesce operation cannot affect members that are not owned by the Agent that is issuing the command.

There are three major scopes or target options for the `MODIFY procname,QUIESCE` command:

- **SYSTEM**

Every member owned on that z/OS system can be quiesced

- **TCPNAME=tcpname**

Every member on one of the Agent's TCP/IP stacks can be quiesced

- **PORT=portnum**

All members using a particular port can be quiesced

The last target option, quiescing by port, enables you to refine the quiesce to an individual member instead of quiescing all members using the port. For more information on how to specify individual members using the Agent's `MODIFY procname,QUIESCE` command, see [z/OS Communications Server: IP System Administrator's Commands](#).

When ready for new workloads, use the `MODIFY procname,ENABLE` command to make the quiesced members available again. Like the quiesce command, this command is only an Agent command, and also has the same target options as the quiesce command.

The quiesce and enable commands are hierarchical. The system level (SYSTEM target option) is at the top of the hierarchy, the stack level (TCPNAME=tcpname target option) is the next highest, and the member level (PORT=portnum target option) is the lowest.

Rules:

- In the quiesce and enable hierarchy, a member quiesced at one level of the hierarchy cannot be enabled at a lower or higher level of the hierarchy. For example, if the `MODIFY procname,QUIESCE,TCPNAME=tcpname` command has been issued, a `MODIFY procname,ENABLE,SYSTEM` command or a `MODIFY procname,ENABLE,PORT=portnum` command will not be accepted.
- An enable command must be issued at the same level of the hierarchy as the last quiesce command that affected the member.

- When a member has been quiesced at one level of the hierarchy, it can be quiesced at a higher level of the hierarchy. This promotes the quiesce level of the member from the lower hierarchy level to the higher hierarchy level, and any history of it being quiesced at the lower level of the hierarchy is erased. When subsequently issuing an enable command in these circumstances, the enable command must be issued at the higher, promoted level of the hierarchy. For example, if member A was quiesced at the port level, a subsequent command to quiesce all members of the TCP/IP stack would be accepted. Furthermore, only a subsequent enable command at the TCP/IP stack level would be accepted to re-enable the member.

Table 65 on page 1217 shows which quiesce and enable commands are valid for a member after a previous quiesce command has affected that same member. A dot at the intersection of the prior command column and the current command row indicates that the current command would be valid for that member. Absence of a dot indicates that the current command would not be valid after the prior command had affected that member.

Table 65. Allowed quiesce and enable command sequences for members				
		Prior command		
		QUIESCE,SYSTEM	QUIESCE,TCPNAME=	QUIESCE,PORT=
Current command	QUIESCE,SYSTEM		●	●
	QUIESCE,TCPNAME=			●
	QUIESCE,PORT=			
	ENABLE,SYSTEM	●		
	ENABLE,TCPNAME=		●	
	ENABLE,PORT=			●

Rules:

- A quiesce command is rejected if any member it applies to has already been quiesced by a command at a higher level of the hierarchy. For example, if you are running in a CINET configuration and you quiesce all members under stack A, which includes a member on stack A that used port 80, you cannot subsequently issue a quiesce command at the port level hoping to quiesce members using port 80 on stacks B and C, because the member on stack A that used that port was already quiesced at the stack level. Because the command would fail for one member, the entire command fails for all members.
- Quiesce commands at the system and stack level apply to currently registered members and also members that are registered in the future, provided that the IP addresses of those future members are owned by the Agent that issued the command. For quiesce commands issued at the stack level, the specified stack must exist at the time the command is issued.
- Quiesce commands at the port level can apply to members registered in the future, if a member currently exists at that port number. For example, if a member is registered by one load balancer at port 80 and the Agent operator quiesces all members at port 80, and then another load balancer registers that same member (same IP address, port, and protocol), the newly registered member would inherit the quiesce performed at the port level.

When a member represents a shareport group (that is, multiple server application instances sharing the same TCP port on the same TCP/IP stack), members cannot be defined to distinguish between the individual server application instances. That is, the combination of the IP address, port, and protocol represents all of the applications sharing the port. Therefore, you cannot selectively quiesce workload requests to only some of the applications sharing the port. Consequently, if you quiesce a member that represents a shareport group, all of the application instances in the group are quiesced.

If an Agent is stopped or fails and is restarted, the quiesce states of any members it might have previously owned are lost. If this occurs, reenter the appropriate quiesce commands to regain the quiesce states that existed during the previous instance of the Agent.

If you plan to take a sysplex system out of service, simply stopping the Agent running on that system is not always a wise alternative to issuing a system-level quiesce command on that system's Agent. If an Agent is simply shut down, there are rare cases where a load balancer might choose to continue routing new workload requests to the applications on that system.

z/OS Load Balancing Advisor configuration example

This topic includes a specific configuration example of the z/OS Load Balancing Advisor, two Load Balancing Agents, and some customization of PROFILE.TCPIP considerations.

In this example, as shown in [Figure 154 on page 1218](#), load balancer LB1 distributes workload requests to two z/OS systems in a sysplex, SYSA and SYSB. SYSA is a CINET configuration with two TCP/IP stacks. SYSB is an INET configuration with one TCP/IP stack. The load balancer is connected to a LAN that also connects to each target TCP/IP stack in the sysplex, including the TCP/IP stack where the Advisor is running. All addresses in this example are IPv4, but the Advisor and Agents are enabled for IPv6.

This example configuration does not use subplexing or AT-TLS.

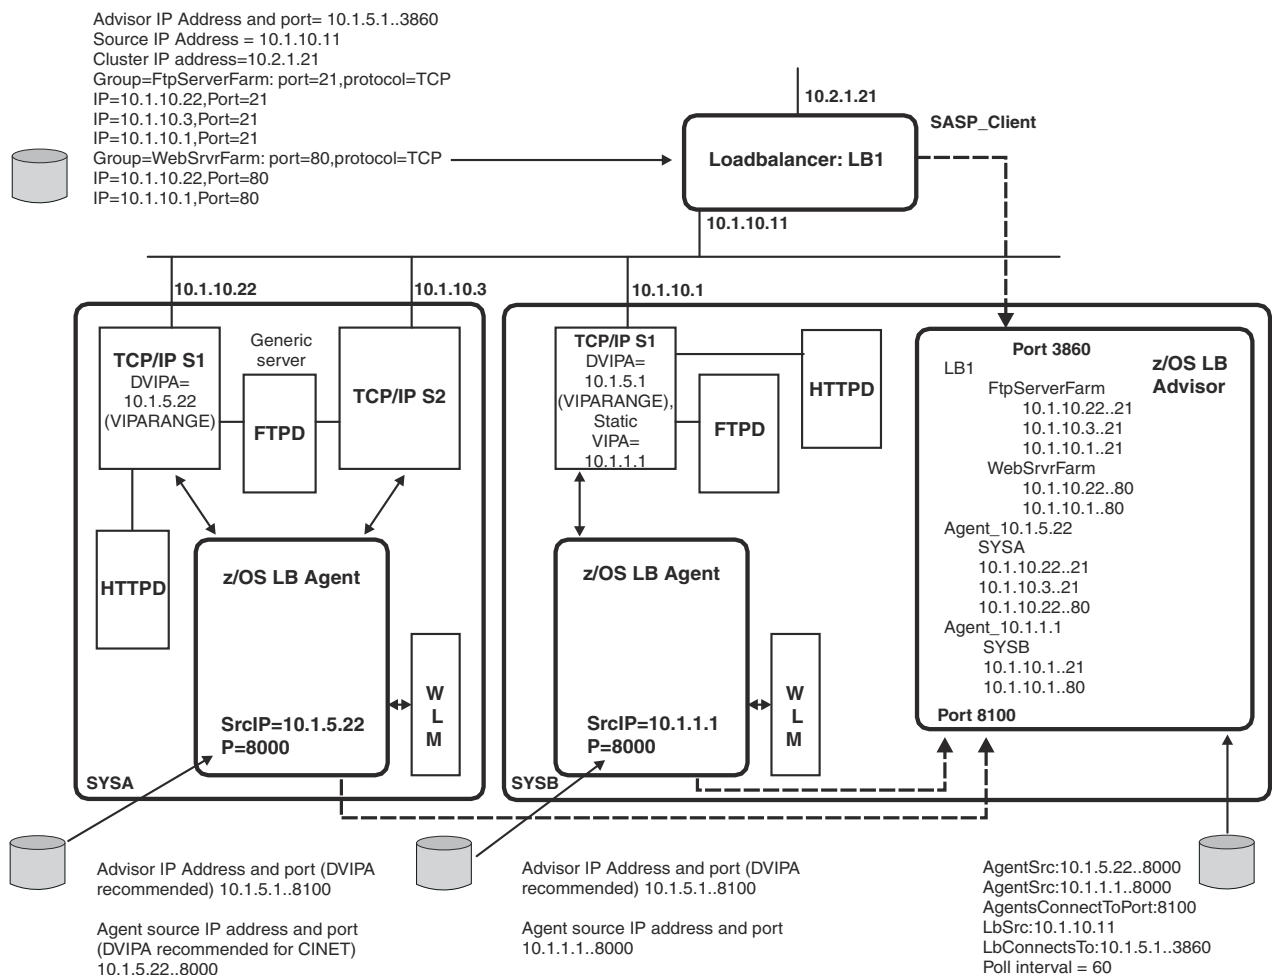

Figure 154. z/OS Load Balancing Advisor configuration example

Load balancer configuration details

The load balancer distributes two types of workload requests in this example, FTP and HTTP traffic, both of which use the TCP protocol. (Keep in mind that UDP workload requests can also be distributed if wanted.) On SYSA, one FTP server is running, which is shared as a generic server between the two TCP/IP stacks. Also, on SYSA, an HTTP server is bound to stack S1. On SYSB, an FTP and HTTP server are running.

The load balancer must be configured with the IP address and port of the Advisor's load balancing connection socket. In this example, the TCP/IP stack on SYSB has defined 10.1.5.1 as a dynamic VIPA. In addition, this same address and port is defined to the Advisor on the `lb_connection_v4` statement in the Advisor's configuration file. The load balancer also uses one of its interfaces to communicate with the Advisor. The IP address assigned to this interface must be coded in the Advisor's `lb_id_list` statement. In this example, the load balancer uses the interface assigned to the address 10.1.10.11. For information on how to determine which interface the load balancer will use to communicate with the Advisor, consult the specific load balancer documentation.

The load balancer advertises its cluster IP address, 10.2.1.21, so that clients that want to connect to specific applications in the sysplex will connect to this cluster IP address as a proxy. After the connection reaches the load balancer, to determine the actual target of the request, the load balancer consults the information that the Advisor has provided as well as possibly examining the content of the packet. The load balancer might substitute the target IP address in the packet header with the IP address of the member that is best suited to receive the new workload requests, or forward the packet as is using the appropriate MAC address. For example, if a connection request came to the load balancer (10.2.1.21) for port 21 using protocol TCP, the load balancer would forward the packet to either 10.1.10.22, 10.1.10.3, or 10.1.10.1, depending upon which member is the better candidate at that point in time.

To distribute FTP workload requests to the sysplex, a group called `FtpServerFarm` is defined to the load balancer. The load balancer maps the cluster IP address, 10.2.1.21, port 21, and protocol TCP to this group. In other words, if the load balancer receives a TCP connection with destination 10.2.1.21, port 21, it consults this group to find a member to which it can forward the connection. Within this group are three members that can handle FTP connections, representing target applications within the sysplex. One target can be reached at 10.1.10.22 on port 21, the second at 10.1.10.3 on port 21, and the third at 10.1.10.1 on port 21. The target applications represented by these members do not necessarily all have to be available at all times. The load balancer avoids trying to forward connections to target applications that are not currently available. Therefore, the list of target applications represented by the members in the group should be the entire set of possible members that could handle this workload, now or in the foreseeable future.

To distribute HTTP workload requests to the sysplex, a group called `WebSrvrFarm` is defined to the load balancer. The load balancer maps the cluster IP address, 10.2.1.21, port 80, and protocol TCP to this group. In other words, if the load balancer receives a TCP connection with destination 10.2.1.21, port 80, it consults this group to find a member to which it can forward the connection. Within this group are two members that can handle HTTP connections, representing target applications within the sysplex. One target can be reached at 10.1.10.22 on port 80, and the second can be reached at 10.1.10.1 on port 80.

Advisor configuration details

There are two aspects of Advisor configuration, the Advisor configuration file itself, and the underlying PROFILE.TCPIP changes that go along with the remainder of the z/OS Load Balancing Advisor system configuration.

The following example is the Advisor configuration file:

```
debug_level 7                # Error, Warning, Events-- the default
update_interval 60           # Agents update every minute-- the default
wlm serverwlm                # Request server-specific WLM weights
port_list
{
    21      wlm basewlm       # Use system WLM weights for FTP
```

```

}
lb_connection_v4 10.1.5.1..3860    # DVIPA load balancer connects to
lb_id_list
{
    10.1.10.11                    # Load balancer's SASP client interface
}
agent_connection_port 8100        # Port Agents connect to
agent_id_list
{
    10.1.1.1..8000                # This system's Agent source
    10.1.5.22..8000              # SYSA's Agent source
}

```

In this example Advisor configuration file, the debug level is set to 7 in the optional `debug_level` statement. The value of 7 is the default value, so this statement is redundant but is shown for completeness. At the default level of 7, messages are written to the log if they are at error, warning, or event level. Messages at other debug levels, such as info or debug, are not written to the log file.

The optional `update_interval` statement is set to 60 seconds, which is also the default. This means that each Agent updates the Advisor with new information every minute. For some load balancer implementations, depending upon load balancer configuration, it might also determine how often the load balancer is updated with new information from the Advisor.

The `wlm` statement specifies the default WLM recommendation type to be used for all groups when calculating the net weights. The value of `serverwlm` indicates that server-specific WLM recommendations will be requested of each Agent, unless overridden by the `port_list` statement (see next paragraph). Although server-specific WLM is the WLM recommendation type to be used for all groups except FTP in this example, there is still a possibility that WLM system weights might have to be used for some or all groups. For further details on the `serverwlm` value on the `wlm` statement, see [z/OS Communications Server: IP Configuration Reference](#).

The `port_list` statement contains one port number, 21. The `wlm` keyword indicates that the WLM recommendation type will be overridden for all members using port 21 (FTP), to use WLM system weights rather than server-specific WLM weights when calculating the net weight. Multiple port numbers can appear in the `port_list` statement on separate lines, if you want to use WLM system weights for other groups of members.

The `lb_connection_v4` statement includes DVIPA 10.1.5.1 and port 3860 (the default) as the address and port that load balancers use to connect to the Advisor. The load balancer specifies this address and port when defining the location of the Advisor.

The `lb_id_list` statement contains the address 10.1.10.11, which is the source IP address of the load balancer when the load balancer connects to the Advisor as a SASP client. If more than one load balancer is used to distribute workload requests to the sysplex, each load balancer needs to be represented in this statement list.

The `agent_connection_port` statement specifies that port 8100 is used to listen for connections from Agents in the sysplex. This same port appears on each Agent's `advisor_id` statement. This port is reserved on the TCP/IP stack that the Advisor runs on, and on any TCP/IP stacks that the Advisor could be moved to in the event of failure. Using this port, the Advisor opens a listening socket on the IPv4 or IPv6 unspecified address (0.0.0.0 or ::, respectively), depending upon the TCP/IP stack's IPv6 capability.

The `agent_id_list` statement contains the source IP address and port of each Agent in the sysplex. The 10.1.1.1 address and the associated port of 8000 represent the source IP address and port that the Agent on SYSB uses to communicate with the Advisor. This same address and port combination appears on the `agent_connection` statement in the Agent's configuration file on SYSB. The 10.1.5.22 address and the associated port of 8000 represent the source IP address and port that the Agent on SYSA uses to communicate with the Advisor. This same address and port combination appears on the `agent_connection` statement in the Agent's configuration file on SYSA.

Agent configuration file on SYSB

The following example is the Agent configuration file on SYSB:

```
debug_level 7                # Error, Warning, Events
advisor_id 10.1.5.1..8100    # DVIPA of Advisor Agent connects to
host_connection 10.1.1.1..8000 # Source address and port this Agent
                                # uses to connect to the Advisor
```

In this example Agent configuration file for SYSB, the debug level is set to 7 in the optional debug_level statement. The debug_level statement for an Agent functions similarly to the way it functions for the Advisor.

The advisor_id statement is configured with the address 10.1.5.1 and port 8100. This tells the Agent which address and port the Advisor is using for connections from Agents. The address 10.1.5.1 is configured as a DVIPA on the Advisor's TCP/IP stack. The port of 8100 also appears on the agent_connection_port statement in the Advisor's configuration file, and is also reserved on the Advisor's TCP/IP stack.

The host_connection statement is configured with the address 10.1.1.1 and port 8000. This is the source IP address and port that this Agent uses when connecting to the Advisor. The address is defined as a static VIPA on the TCP/IP stack that the Agent will run on. This address and port must also be specified in the agent_id_list statement in the Advisor's configuration file. The port, 8000, is also reserved in PROFILE.TCPIP of stack S1 on system SYSB.

Agent configuration file on SYSA

The following example is the Agent configuration file on SYSA:

```
debug_level 7                # Error, Warning, Events
advisor_id 10.1.5.1..8100    # DVIPA of Advisor Agent connects to
host_connection 10.1.5.22..8000 # Source DVIPA and port this Agent
                                # uses to connect to the Advisor
```

This Agent configuration file is for the Agent running on SYSA. The debug_level and advisor_id statements are identical to the Agent configuration file on SYSB. The host_connection statement is configured with the address 10.1.5.22 and port 8000. This is the source IP address and port that this Agent uses when connecting to the Advisor. This address and port must also be specified on the agent_id_list statement in the Advisor's configuration file. The port, 8000, is also reserved in PROFILE.TCPIP of stack S1 and S2 on system SYSA. This address is defined as a dynamic VIPA on both TCP/IP stacks on SYSA, in the event that one of the TCP/IP stacks fails.

Customization of PROFILE.TCPIP

Each TCP/IP profile in the sysplex must be updated to accommodate the z/OS Load Balancing Advisor.

The updated portion of PROFILE.TCPIP for stack S1 on system SYSB follows:

```
VIPADYNAMIC
;Address LB & Agents use to reach Advisor fall into this subnet
VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

DEVICE VIPA41 VIRTUAL 0      ; Static VIPA for Agent's source address
LINK LVIPA41 VIRTUAL 0 VIPA41
HOME 10.1.1.1 LVIPA41

PORT
3860 TCP LBADV              ; SASP Workload Advisor (LB connections)
8100 TCP LBADV              ; SASP Workload Advisor (Agent connections)
8000 TCP LBAGENT            ; SASP Workload Agent (Advisor connection)
```

In this example, the address 10.1.5.1 would be within the subnetwork that has been reserved for dynamic VIPAs in the VIPARANGE statement. The load balancer and the Agents use this address to reach the Advisor. Using a dynamic VIPA (DVIPA) facilitates the movement of the Advisor to another TCP/IP stack in the event of failure. This address is defined in the lb_connection_v4 statement in the Advisor's configuration file, in the load balancer as the location of the Advisor [known generically as the SASP Global Workload Manager (GWM)], and on the advisor_id statement in each of the Agent's configuration files.

The address 10.1.1.1 is a static VIPA. The Agent on this system uses this address as its source IP address. Because SYSB is a single stack system (INET), a static VIPA is sufficient. If this were a CINET system like SYSA, a DVIPA would be best. This address appears on the agent_id_list statement in the Advisor's configuration file, as well as on the agent_connection statement in the Agent's configuration file on SYSB.

The ports used for the Advisor and Agent are reserved, as advised. Port 3860 is reserved for the Advisor and is used to communicate with load balancers. This port appears on the lb_connection_v4 statement in the Advisor's configuration file. Port 8100 is also reserved for the Advisor, and is the port that the Agents use to connect to the Advisor. This port appears on the agent_connection_port statement in the Advisor's configuration file, as well as on the advisor_id statement in each of the Agents' configuration files. Port 8000 is reserved for the Agent on this system and is used as the source port for the connection with the Advisor. This port appears on the agent_id_list statement in the Advisor's configuration file, as well as on the agent_connection statement in the Agent's configuration file on this system.

The updated portion of PROFILE.TCPIP for stack S1 on system SYSA follows:

```
VIPADYNAMIC
;Address Agent uses as source will fall into this subnet
VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

PORT
3860 TCP LBADV          ; SASP Workload Advisor LB connections,
                        ; in case Advisor is moved to this stack
8100 TCP LBADV          ; SASP Workload Advisor Agent connections,
                        ; in case Advisor is moved to this stack
8000 TCP LBAGENT        ; SASP Workload Agent Advisor connection
```

In Figure 154 on page 1218, the DVIPA that the Agent uses as a source IP address on this system is shown belonging to stack S1. It could just as easily belong to stack S2, but for the purposes of this example the DVIPA belongs to stack S1.

In this updated portion of PROFILE.TCPIP, the address that the Agent uses as a source address when connecting to the Advisor, 10.1.5.22, is within the subnetwork that has been reserved for dynamic VIPAs on the VIPARANGE statement. Using a dynamic VIPA (DVIPA) facilitates the movement of the Agent to another TCP/IP stack on the same system in the event of failure. This address is defined on the host_connection statement in this Agent's configuration file, and in the agent_id_list statement in the Advisor's configuration file. The DVIPA that the Advisor would use, should the Advisor be moved to this stack, would also fall within this subnetwork.

The port that is used for the Agent is reserved, as advised. Additionally, ports that the Advisor would use if it were to be moved to this TCP/IP stack are also reserved.

The updated portion of PROFILE.TCPIP for stack S2 on system SYSA follows:

```
VIPADYNAMIC
;Address Agent uses as source will fall into this subnet
VIPARANGE DEFINE 255.255.255.0 10.1.5.0
ENDVIPADYNAMIC

PORT
3860 TCP LBADV          ; SASP Workload Advisor LB connections,
                        ; in case Advisor is moved to this stack
8100 TCP LBADV          ; SASP Workload Advisor Agent connections,
                        ; in case Advisor is moved to this stack
8000 TCP LBAGENT        ; SASP Workload Agent Advisor connection
```

This updated portion of the TCP/IP profile is identical to that of stack S1 on SYSA. This TCP/IP stack is capable of supporting the Advisor and the Agent running on this z/OS system, should it be necessary to move either to this TCP/IP stack.

Chapter 22. Automated domain name registration

The automated domain name registration (ADNR) application is a function that dynamically updates name servers with information about sysplex resources in near real time. As resources in the sysplex become available, Domain Name System (DNS) resource records are added to one or more name servers. As those resources become unavailable, the corresponding DNS resource records are removed from the name server. Clients that connect to sysplex resources using DNS names have a greater likelihood of connecting to an available resource in the sysplex. ADNR also removes the administrative burden of manually configuring and updating a name server to represent sysplex resources.

The DNS names managed by ADNR can be application-specific names. All instances of the same application within the sysplex can be represented by the same DNS name. Clients can therefore use one DNS name to connect to any available application instance within the sysplex. ADNR can also manage DNS names that map to specific application instances. These names are used when a client wants affinity to one particular application instance.

In addition to application-specific names, ADNR can also manage DNS names that generically represent the entire sysplex, as well as names that represent individual systems within the sysplex.

How connections are distributed within the sysplex is determined by name server and ADNR configuration. Typically, connections are fairly evenly distributed among the available application instances over time. Connections are not load balanced within the sysplex, as they are with load balancing solutions such as sysplex distributor and the z/OS Load Balancing Advisor.

ADNR supports both IPv4 and IPv6 addresses.

System overview

Figure 155 on page 1225 shows a z/OS sysplex containing four systems, a name server external to the sysplex, a name server in the sysplex, and several clients in the network. The z/OS Load Balancing Advisor and ADNR are running on one of the systems in the sysplex. An instance of the z/OS Load Balancing Agent is active on three of the sysplex systems. Three instances of a server application are active within the sysplex.

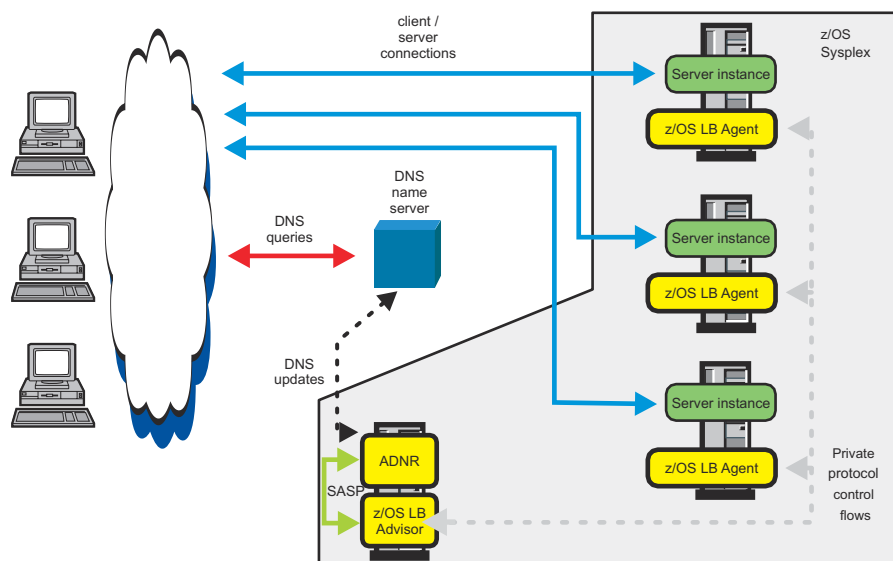

Figure 155. System overview

ADNR is configured with information about sysplex resources to which you want to assign DNS names. These resources are configured on a group basis. For example, to have ADNR manage DNS names in a name server for a sysplex containing several instances of a CICS listener application, all potential

CICS listener instances for a given port in the sysplex are defined under the same group in the ADNR configuration file.

ADNR registers its configured information about sysplex resources with a z/OS Load Balancing Advisor application. The Advisor application disseminates this information to the z/OS Load Balancing Agents (Agents), which report back to the Advisor about the availability of the resources registered by ADNR. The Advisor then reports back to ADNR about which of its registered resources are active and which are not. The Advisor subsequently reports to ADNR any changes in the availability of those resources.

For each group of resources that the Advisor reports as available, ADNR adds a DNS name to the name server that represents the entire group of resources in that group, and maps that name to the IP addresses of the available resources in that group. Continuing with the CICS listener example, the IP address of each active CICS listener application is mapped to the name representing the entire group of CICS listener applications. The IP address of each inactive CICS application is not mapped to that DNS name. Clients then connect to their application using the name that ADNR added to the name server. The address or addresses returned to the client's resolver reflect only active application instances. Thus, the client can use one DNS name to connect to any active instance of an application. As application instances become unavailable, the addresses of those unavailable application instances are disassociated from that DNS name in the name server. If all application instances in that group become unavailable, the DNS name representing that group of applications is removed from the name server.

You can also configure ADNR to update the name server with the names of individual server instances, which map to IP addresses that can be used to reach those server instances as those server instances become available. Thus, if a client needs to connect to a specific server instance, that name can be used to make the connection. As each individual server instance becomes unavailable, the DNS name representing the unavailable server instance is removed from the name server.

The name servers that ADNR manages must support RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. For information about accessing RFCs, see [Appendix G, “Related protocol specifications,” on page 1439](#).

For administrative purposes, it is advantageous to run ADNR within the same sysplex as the resources it manages. Run ADNR in a sysplex so that it can be moved to provide optimal availability. You can reduce network traffic between ADNR and the Advisor by running ADNR on the same system where the Advisor is running. In addition, the possibility of network outages disrupting communication between ADNR and the Advisor is eliminated by this configuration.

Interaction with name servers

The name servers that ADNR manages require a one-time setup. These name servers must be configured as the primary master name servers for the zones managed by ADNR. The name servers must support RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. For information about accessing RFCs, see [Appendix G, “Related protocol specifications,” on page 1439](#).

For more background information about DNS, see [“DNS overview” on page 753](#).

For more information about name server configuration considerations, see [“Name server configuration considerations” on page 1240](#).

Interaction with the z/OS Load Balancing Advisor

The ADNR function is provided by the ADNR application, which uses the z/OS Load Balancing Advisor function.

Requirement: You must configure and deploy the z/OS Load Balancing Advisor and Agent to use ADNR.

An external load balancer is not required.

The ADNR application communicates with the Advisor using the Server/Application State Protocol (SASP). In SASP protocol terms, the Advisor is known as a Global Workload Manager (GWM). The terms Advisor and GWM are used interchangeably. From the GWM's perspective, the ADNR application appears as a load balancer. Despite its appearance as a load balancer to the GWM, ADNR does not perform load balancing. The z/OS Load Balancing Advisor supplies sysplex resource availability and weight information to what

it views as load balancers, including ADNR. ADNR uses the availability information but does not use the weight information.

For more information about this function, see [Chapter 21, “z/OS Load Balancing Advisor,” on page 1177](#).

For more information about z/OS Load Balancing Advisor configuration considerations, see [“z/OS Load Balancing Advisor configuration considerations” on page 1238](#).

Enabling TLS/SSL for ADNR

Consider whether to use AT-TLS for security between ADNR and the z/OS Load Balancing Advisor. AT-TLS provides the ability to authenticate a client, check authorizations, and encrypt data. You must restrict the ability to establish a connection to the Advisor, because sensitive interfaces can be exploited after a connection is accepted by the Load Balancing Advisor. Because ADNR acts as a client to the Load Balancing Advisor SASP port, it must be explicitly authorized to establish its connection to the Load Balancing Advisor.

You can use one or both of the following methods to authorize connection to the z/OS Load Balancing Advisor:

- You can explicitly configure the `host_connection_addr` keyword on the `gwm` statement in the ADNR configuration file, and the corresponding `lb_id_list` statement in the Advisor's configuration file.
- You can establish policies using the z/OS Policy Agent so that ADNR is required to use AT-TLS.

Although the configuration parameters might be sufficient in certain environments where the Load Balancing Advisor and ADNR are inside a secure network (that is, isolated by a firewall and so on), they might not be sufficient in environments in which the network is not considered to be as secure or in which the need to protect against IP address spoofing attacks is important. For more information about using AT-TLS, see [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#). For more information about the Advisor, see [Chapter 21, “z/OS Load Balancing Advisor,” on page 1177](#).

Steps for configuring automated domain name registration

The automated domain name registration (ADNR) application dynamically updates name servers with information about sysplex resources. Detail for each step is provided in the corresponding subtopic.

Procedure

Perform the following steps to configure the automated domain name registration (ADNR) application.

1. Decide which sysplex resources should be managed by ADNR.
2. Decide on one or more domain names to be managed by ADNR.
3. Decide which name server or name servers are to be managed by ADNR.
4. Configure the selected name servers to be the primary master name servers for the domain names that ADNR is to manage.
5. Delegate the domain names to be managed by ADNR to the selected name servers from the parent domain's name server.
6. Configure the z/OS Load Balancing Advisor (LBA) function.
7. Define security server profiles for ADNR.
8. Configure ADNR to automatically restart in case of application or system failure. (optional)
9. Configure and start `syslogd`. (optional, but required to have ADNR write log messages and trace data to `syslogd`)
10. Configure one ADNR application per sysplex.
11. Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run. (optional)
12. Start the TCP/IP stacks on which ADNR and the LBA applications are to run.

13. Start the z/OS Load Balancing Advisor and Agent.
14. Start the target applications that are to be managed by ADNR.
15. Start the ADNR application.
16. Verify that the ADNR system is functioning correctly. (optional)

Results

These steps are described in detail in the following subtopics.

Step 1: Decide which sysplex resources should be managed by ADNR

ADNR can manage two types of sysplex resources, including server applications and the traditional DNS mappings of host names to IP addresses. Server applications are represented in ADNR as server groups using the `server_groups` statement. Traditional DNS host name-to-IP address mappings are represented as host groups using the `host_groups` statement. For more information about server groups and host groups, see [“Identifying the sysplex resources to be managed by ADNR” on page 1234](#).

ADNR can dynamically create application-specific host names in a name server to represent a cluster of equivalent servers in the sysplex. For example, the name `ztelnet.mvsplex.mycorp.com` can represent all TN3270E Telnet server applications in the sysplex. Any TCP or UDP server application in the sysplex can be managed by ADNR and have application-specific host names dynamically added and removed from a name server to represent active instances of those servers. As server applications become available, ADNR dynamically adds resource records representing those instances to the name servers managed by ADNR. As those server applications or their systems become unavailable, ADNR dynamically deletes resource records representing those instances from the name servers it manages. These types of DNS names can be used to connect to any active instance of a particular type of server. ADNR also dynamically creates and removes application-specific host names that represent individual instances of server applications as they become available and unavailable.

Most IP addresses in the home lists of sysplex hosts can be dynamically added to the name server as traditional DNS name-to-IP address mappings. As IP addresses are removed from a home list (for example, by issuing a `VARY TCPIP,,OBEYFILE` command), the DNS resource records representing those IP addresses are dynamically removed from the ADNR-managed name servers. These types of DNS names can be used to connect to any resource in the sysplex, or on a particular sysplex host without regard to which servers are available on that system, such as when using the **ping** or **traceroute** commands.

The IP addresses that are added to DNS by ADNR can be interface addresses, static VIPAs, or dynamic VIPAs (DVIPAs). A small set of addresses cannot be managed by ADNR because of z/OS Load Balancing Advisor restrictions. For more information, see [“Step 7: Configure the external load balancers” on page 1198](#) and the restriction that certain classes of IP addresses must not be coded for members in the load balancer.

You might want to make some sysplex resources visible to some set of clients and not visible to other sets of clients. For example, you might want to add DNS entries to make some sysplex resources visible to intranet clients, but not make the resources visible to Internet clients. There are several ways to accomplish this. Some methods can be accomplished with only name server configuration, others might involve ADNR configuration. For more information, see [“Split DNS \(views\)” on page 1242](#).

Step 2: Decide on one or more domain names to be managed by ADNR

All resource records added to a name server have a domain suffix related to a name server zone. Typically, an enterprise's domain suffix is something like `mycorp.com`. Subdomains can exist under a domain, which have the subdomain name added before the parent's domain suffix, such as `raleigh.mycorp.com` and `austin.mycorp.com`.

Guideline: Because ADNR should be the only entity updating the zones it manages, ADNR should manage one or more unique sub-zones. For example, if your enterprise has a domain name of `mycorp.com`, ADNR can be configured to manage resources in a domain called `mvsplex.mycorp.com`.

The domain suffix of the resource records that ADNR creates is determined by the `domain_suffix` keyword of the zone keyword of the `dns` statement in the ADNR configuration file.

Step 3: Decide which name server or name servers are to be managed by ADNR

ADNR can manage name servers that support RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. For information about accessing RFCs, see [Appendix G, “Related protocol specifications,”](#) on page 1439.

The name servers that ADNR communicates with can be existing name servers, or name servers you set up exclusively for ADNR. Each name server that ADNR is to communicate with is identified on the `dns_id` keyword of the `dns` statement.

You might also want to configure one or more secondary name servers for the ADNR-managed zones. Secondary name servers replicate zone data information from the master name server for those zones. Typically, secondary name servers are configured to avoid a single point of failure if a name server fails, and to reduce network traffic by locating secondary name servers in strategic areas of a network so that name server lookups traverse fewer hops in the network.

ADNR does not communicate directly with secondary name servers. Secondary name servers communicate directly with the master name server by performing zone transfers. Ideally, because of the dynamic nature of the data in the zones that ADNR manages, secondary name servers need to be updated as soon as the master name server is updated by ADNR. Otherwise, the secondary name server contains stale information that does not accurately reflect the current availability of sysplex resources. Some name server implementations can minimize the latency with which secondary name servers are updated from their masters, if they have implemented RFC 1996, *A Mechanism for Prompt Notification of Zone Changes (DNS NOTIFY)*. For information about accessing RFCs, see [Appendix G, “Related protocol specifications,”](#) on page 1439.

Step 4: Configure the selected name servers to be the primary master name servers for the domain names that ADNR is to manage

The name servers that ADNR communicates with must be configured as the primary master name servers of the zones that ADNR will manage. For more information and further references about configuring the zones that ADNR is to manage in the name server, see [“Initial zone configuration”](#) on page 1240.

Step 5: Delegate the domain names to be managed by ADNR to the selected name servers from the parent domain's name server

Typically, the DNS domains that ADNR manages are subdomains of an existing DNS domain. For resolvers to reliably find resource records in the ADNR-managed subdomains, the ADNR-managed subdomain must be delegated by its parent domain. This enables resolvers to find resource records in the ADNR-managed subdomain if those resolvers are not pointing directly to the ADNR-managed name server. DNS queries from resolvers can follow the DNS delegation tree downward from the root domain, if necessary, and find an authoritative name server for the ADNR-managed subdomain.

Delegating a subdomain from a parent involves updating the parent domain's zone data file. In the parent's zone data file, an NS record and an associated A or AAAA glue record is added to represent each authoritative name server for the child domain. For example, to delegate the ADNR-managed `mvspsex.mycorp.com` zone from the `mycorp.com` zone, the following resource records are added to the zone data file for the `mycorp.com` zone:

```
mvspsex 86400      IN      NS      mvspsexnameserver.mvspsex.mycorp.com.
        86400      IN      NS      networknameserver.mvspsex.mycorp.com.
mvspsexnameserver.mvspsex.mycorp.com. 86400      IN      A      10.5.1.1
networknameserver.mvspsex.mycorp.com. 86400      IN      AAAA   2001:0DB8:0:0:8:800:200C:417A
```

The example resource records delegate the mvsplex.mycorp.com zone to two authoritative name servers, one of which must be the master name server and the other a secondary name server.

Step 6: Configure the z/OS Load Balancing Advisor function

Configuring and running the z/OS Load Balancing Advisor (LBA) function is a corequisite to implementing ADNR. The z/OS Load Balancing Advisor application communicates with ADNR and serves as ADNR's Global Workload Manager (GWM). The z/OS Load Balancing Agents communicate with the Advisor application and supply it, and ultimately ADNR, with information about the availability of the resources that ADNR has registered with the Advisor. Therefore, each system in the sysplex that contains resources that you want ADNR to manage must be running an Agent, and one system in the sysplex must be running an Advisor.

The Advisor views ADNR as a load balancer, although ADNR does not perform load balancing. ADNR merely uses the information to update the name servers based on the resource availability that the Advisor provides. Therefore, to enable ADNR to connect to the Advisor, the source IP address that ADNR uses to connect to the Advisor must be configured in the Advisor's `lb_id_list` statement, if AT-TLS is not used. For information about the `lb_id_list` statement, see [z/OS Communications Server: IP Configuration Reference](#).

For complete information about configuring the Advisor and Agents, see “[Steps for configuring the z/OS Load Balancing Advisor](#)” on page 1182. While following those steps, you should skip step 10 to start the TCP/IP stacks that the Advisor and Agents will use until completing the TCP/IP profile customization for those stacks, described in “[Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run \(optional\)](#)” on page 1236. You should also skip steps 13 and 14 in those steps, starting the Agents and Advisor, until you reach “[Step 13: Start the z/OS Load Balancing Advisor and Agent](#)” on page 1237.

Step 7: Define security server profiles for ADNR

Create a USERID profile for ADNR as follows:

```
ADDUSER  ADNR      DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(nn) -  
              HOME('/RDWR_working_directory') PROGRAM('/bin/sh'))
```

ADNR must have read and write access to the directory specified on the HOME keyword. This directory becomes ADNR's working directory. ADNR creates and deletes temporary files in this directory during its operation. The UID value, *nn*, can be zero or nonzero.

ADNR is a multi-threaded application. If you define an unusually large number of name servers or zones to ADNR, you should check to determine whether the maximum number of threads allowed per process, represented by the THREADSMAX value in BPXPRMxx, is going to be exceeded. The number of threads required for ADNR is determined in the following way: (number of dns statements) + (number of zone keywords within all dns statements) + 3. You can customize the maximum number of threads allowed for ADNR by specifying the THREADSMAX keyword on the ADDUSER command.

The program specified on the user ID assigned to run ADNR must be /bin/sh. For more information about specifying a user program and the `ADDUSER` (Add user profile) command, see [z/OS Security Server RACF Command Language Reference](#).

Add ADNR to the STARTED class profile:

```
RDEFINE  STARTED  ADNR.*              STDATA(USER(ADNR))
```

Steps for granting authority to start ADNR

Grant explicit authority to all users that can start ADNR, to prevent unauthorized users from starting it. If you do not grant explicit authority, any user able to issue the START command can start ADNR.

Procedure

Perform the following steps to grant authority to start ADNR.

1. Ensure that the OPERCMDS class is active and RACLISTed, and that RACLIST processing is enabled:

```
SETOPTS CLASSACT(OPERCMDS)
SETOPTS RACLIST (OPERCMDS)
```

2. Define the following OPERCMDS class profile using a security product like RACF:

```
RDEFINE OPERCMDS (MVS.SERVGR.ADNR) UACC(NONE)
```

3. Grant ADNR access to the OPERCMDS class:

```
PERMIT MVS.SERVGR.ADNR CLASS(OPERCMDS) ACCESS(CONTROL) -
      ID(userid)
```

4. Refresh the OPERCMDS class:

```
SETOPTS RACLIST(OPERCMDS) REFRESH
```

5. See the EZARACF sample in SEZAINST for specific instructions.

All commands that you can issue against ADNR are MODIFY commands, with the exception of the STOP command used to stop ADNR. Therefore, you might also want to limit which users are able to issue MODIFY and STOP commands.

Step 8: Configure ADNR to automatically restart in case of application or system failure (optional)

Automatically restarting ADNR minimizes the period of time that name servers do not accurately reflect the status of sysplex resources. This can be accomplished using automation software or by defining an automatic restart manager (ARM) policy. For more information about [defining ARM policies](#), see [z/OS MVS Setting Up a Sysplex](#).

ADNR registers with ARM using the following values:

```
ELEMTYPE=SYSTCPIP
ELEMNAME=EZBADNRelemsuffix
TERMTYPE=ALLTERM
```

The *elemsuffix* value is specified in the arm_element_suffix configuration statement. ADNR registers the element name EZBADNR concatenated with the *elemsuffix* value. If there is no arm_element_suffix statement, the ELEMNAME is EZBADNR. For example, if the following statement is configured:

```
arm_element_suffix SYS1
```

ADNR registers ELEMNAME=EZBADNRSYS1.

When ADNR registers with ARM using these values, then if ADNR fails or the system fails, ADNR can be restarted on any system in the sysplex.

An ARM policy or other automation software should be in place to quickly restart the TCP/IP stack that ADNR is running on if the TCP/IP stack fails. ADNR continues to run after its TCP/IP stack fails, and reconnects to its GWM after the TCP/IP stack recovers.

Although this step is optional, performing it provides high availability to your target applications. In the event that ADNR fails, the name servers it manages are no longer updated with sysplex resource availability information. As a result, client connections might fail because the name server might resolve

their requests to application instances that are not available, or be unable to resolve DNS requests to any application when active application instances might actually exist. When ADNR is restarted, it again accurately reflects the availability of sysplex resources after its convergence period. The *convergence period* is twice the interval at which the Advisor normally updates ADNR with new information. The interval is determined by the `update_interval` statement in the Advisor's configuration file.

Guidelines:

- Each ADNR instance should have a unique ARM element name within a sysplex.
- Establish an ARM policy with TCP/IP at a lower level than ADNR, so that TCP/IP is restarted before ADNR is restarted. For more information, see [z/OS MVS Setting Up a Sysplex](#).
- To enable ADNR to continue operating on another TCP/IP stack in a Common INET (CINET) environment in the case of TCP/IP stack failure, or to restart on another system in case of system failure, configure ADNR with a unique application-instance DVIPA. The unique application-instance DVIPA is coded on the `host_connection_addr` keyword of the `gwm` statement. For more information about unique application-instance DVIPAs, see [“Configuring the unique application-instance scenario”](#) on page 401.

Rule: AUTOLOG can be used to start ADNR when the TCP/IP stack is started, but it cannot be used for ADNR recovery. Using AUTOLOG for recovery requires port reservation, but ADNR does not listen on a port. Therefore, ADNR can appear in the TCP/IP AUTOLOG statement, but it cannot appear on the PORT statement. ADNR uses ephemeral ports when connecting to its GWM.

Requirement: ADNR does not run using a system key. Therefore, if you are using ARM registration, the started task ID needs to be permitted with UPDATE authority to the associated IXCARM.SYSTCPIP.EZBADNR* profile in the FACILITY class within the SAF product on your system. To enable ADNR to register to ARM, use the following RACF commands to define the profile and grant update access to the user ID that is assigned to start ADNR:

```
RDEFINE FACILITY IXCARM.SYSTCPIP.EZBADNR* UACC(NONE)
PERMIT IXCARM.SYSTCPIP.EZBADNR* CLASS(FACILITY) ID(ADNR) ACCESS(UPDATE)
SETROPTS REFRESH RACLIST(FACILITY)
```

Restriction: If ADNR is using IPv6 for the GWM connection, or if ADNR is using IPv6 to connect to a name server, movement of ADNR is limited to those TCP/IP stacks that are enabled and configured for IPv6. For considerations for configuring z/OS for IPv6, see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

Step 9: Configure and start syslogd (optional, but required to have ADNR write log messages and trace data to syslogd)

ADNR writes most log messages and trace data to the syslog daemon (syslogd). A limited number of messages are written to the MVS console, but these are unaffected by syslogd configuration. For ADNR to be able to write log messages and trace data to syslogd, syslogd must be properly configured and started before ADNR is started.

Because you might be running ADNR on the same system as the Advisor, for better readability, you might want to configure syslogd to place Advisor and ADNR log output in separate files. For further information, see [“Configuring the syslog daemon”](#) on page 235.

Step 10: Configure one ADNR application per sysplex

ADNR reads configuration data from one file, which can exist as a z/OS UNIX file, a PDS or PDSE member, or a sequential data set. If you plan to enable ADNR to move within the sysplex in the case of failure, the ADNR configuration file or data set should be on shared DASD, to make it accessible to all systems in the sysplex if necessary. The ADNR configuration file is specified on the CONFIG DD statement in the ADNR start procedure. A sample start procedure is provided in EZBADNRS in SEZAINST.

The ADNR configuration file serves five basic purposes:

- Identifies the name servers to update and the zones to be updated in those name servers
- Identifies the GWM to connect to and IP address to bind to for communications with the GWM

- Identifies the sysplex resources to be managed by ADNR
- Uniquely identifies the ADNR instance
- Customizes optional statements

A sample ADNR configuration file is provided in EZBADNRC in SEZAINST.

Tip: Consistent with the Advisor and Agent configuration terminology, any statement or keyword containing the word *connection* refers to a local socket, and any statement containing the word *id* refers to a remote address and possibly a port.

The ADNR configuration file contains statements or keywords that reference other statements or keywords. All such references are made using labels.

Identifying the name servers to update and the zones to be updated in those name servers

Use the dns statement to identify the location of a name server to be managed by ADNR. This statement has a dns_id keyword that contains the IP address of a name server and optionally a port. You can code multiple dns statements.

Rule: In general, for data integrity reasons, multiple dns statements should not refer to the same name server. However, if you are configuring ADNR to work with a split DNS configuration, this is acceptable. For more information, see [“Split DNS \(views\)” on page 1242](#).

The dns statement also contains one or more zone keywords that identify a zone in the name server to be updated. The domain suffix specified on the domain_suffix parameter must represent a zone previously configured in the name server that is being updated. For more information, see [“Initial zone configuration” on page 1240](#).

The zone keyword contains three optional parameters, update_key, transfer_key, and ttl.

- The update_key parameter and the transfer_key parameter enable the use of digital signatures on requests sent from ADNR to the name server. The digital signatures provide a way for the name server to authenticate ADNR as a client that is authorized to update the name server and to receive zone transfer information. These digital signatures are called transaction signatures (TSIG). Use of TSIGs requires coordination between ADNR configuration and name server configuration. For more information about TSIG security, see [“Authorizing dynamic updates” on page 1240](#) and [“Authorizing zone transfers” on page 1241](#).
- The ttl parameter determines how long resolvers and non-authoritative name servers keep ADNR-managed resource records cached. For more information, see [“Near real-time availability information of sysplex resources” on page 1239](#).

Identifying the GWM to connect to and IP address to bind to for communications with the GWM

Specify the location of the GWM on the gwm_id keyword of the gwm statement. This keyword contains an IP address and optionally a port that the GWM uses to listen for connections from load balancers. From the GWM's point of view, ADNR is considered a load balancer.

Specify the IP address that ADNR will bind to for communications with the GWM on the host_connection_addr keyword of the gwm statement. If you are using AT-TLS, the host_connection_addr keyword is optional.

Rules:

- The IP address specified on the gwm_id keyword of the gwm statement must match the address specified on the lb_connection_v4 statement or the lb_connection_v6 statement in the Advisor configuration file.
- The port specified on the gwm_id keyword of the gwm statement must match the port specified on the Advisor's lb_connection_v4 or lb_connection_v6 statement, depending upon whether you specify an IPv4 or IPv6 address, respectively, on the gwm_id keyword.

- If an IPv4 address is specified on the `gwm_id` keyword of the `gwm` statement, an IPv4 address must be specified on the `host_connection_addr` keyword of the `gwm` statement. Similarly, if an IPv6 address is specified on the `gwm_id` keyword of the `gwm` statement, an IPv6 address must be specified on the `host_connection_addr` keyword of the `gwm` statement.

Guideline: For high availability, use a unique application-instance DVIPA for the address on the `host_connection_addr` keyword. This enables ADNR to be moved to another TCP/IP stack or another system in the event of TCP/IP stack or system failure.

Identifying the sysplex resources to be managed by ADNR

Specify which sysplex resources should be managed by ADNR using the `host_group` and `server_group` statements.

Host groups

The `host_group` statement identifies the set of IP addresses to update in a name server that represents a group of hosts. ADNR updates the name server with the intersection between the IP addresses configured to ADNR in the `host_group` statement and the IP addresses that exist in the home lists of the hosts in the sysplex. The DNS names that are dynamically added to the name server take the form `host_group_name.domain_suffix`, where `host_group_name` is the ADNR administrator-defined name of the group of hosts being registered to the GWM, and `domain_suffix` is the domain suffix name specified in a zone parameter on a `dns` statement. To construct the DNS name, the value of the `host_group_name` keyword of the `host_group` statement is used, followed by the value of the `domain_suffix` keyword of the zone referenced in the `host_group` statement. The intervening dot is supplied by ADNR; do not explicitly code the dot.

ADNR can also update name servers with DNS names representing individual host instances within the sysplex, using the `member` keyword. ADNR updates name servers with the intersection between the IP addresses configured for the member and the set of IP addresses that exist in the home list of a particular host in the sysplex. The DNS names that are dynamically added to the name server take the form `host_name.domain_suffix`, where `host_name` is the ADNR administrator-defined name of the member being registered to the GWM, and `domain_suffix` is the domain suffix name specified in a zone parameter on a `dns` statement. To construct the DNS name, the value of the `host_name` keyword of the `host_group` statement is used, followed by the value of the `domain_suffix` keyword of the zone referenced in the `host_group` statement. The intervening dot is supplied by ADNR; do not explicitly code the dot. If the `host_group` statement contains a `member` keyword containing an optional `host_name` parameter, the name server is updated with these types of DNS names.

A `host_group` statement can have multiple `member` keywords within it. One of the coded `member` keywords does not have to have a `host_name` parameter. The member without a `host_name` parameter is sometimes referred to as the *unnamed member*, while members with a `host_name` parameter are sometimes referred to as *named members*. The IP addresses associated with the unnamed member are ones that can potentially be dynamically added to the name server with the DNS name of the form `host_group_name.domain_suffix`. Configuring an unnamed member is not required. However, a virtual unnamed member is created for you if you do not configure one.

Result: The IP addresses associated with the unnamed member are the union of all IP addresses explicitly configured in the unnamed member (if configured), and all IP addresses configured to all named members in that host group. In contrast, only the IP addresses explicitly configured in a named member are associated with the named member.

Typically, you configure one named member per system in the sysplex. Each named member contains IP addresses that cannot move to other systems in the sysplex.

Guideline: To provide reachability to the sysplex or system in case of interface failure, configure named members of `host_group` statements with static VIPAs. In addition, you can also code an unnamed member, and associate with it IP addresses that could potentially be moved from one system to another (DVIPAs).

Host names added to a name server using ADNR might be useful for situations when you want connectivity to the sysplex or a host in the sysplex, but the presence of a particular server is not required. For this reason, host group names would be useful for utilities such as ping or traceroute.

Server groups

The `server_group` statement identifies the set of IP addresses to update in a name server that represents a cluster of equivalent servers in the sysplex. ADNR updates the name server with the intersection between the IP addresses configured to ADNR in the `server_group` statement and the IP addresses on which each server in the group can be reached in the sysplex. The DNS names dynamically added to the name server take the form `server_group_name.domain_suffix`, where `server_group_name` is the ADNR administrator-defined name of the group of servers being registered to the GWM, and `domain_suffix` is the domain suffix name specified in a zone parameter on a `dns` statement. To construct the DNS name, the value of the `server_group_name` keyword of the `server_group` statement is used, followed by the value of the `domain_suffix` keyword of the zone referenced in the `server_group` statement. The intervening dot is supplied by ADNR; do not explicitly code the dot.

ADNR can also update name servers with DNS names representing individual server instances within the sysplex, using the `member` keyword. ADNR updates name servers with the intersection between the IP addresses configured for the member and the set of IP addresses on which the server can be reached on a particular host in the sysplex. The DNS names dynamically added to the name server take the form `server_name.server_group_name.domain_suffix`, where `server_name` is the ADNR administrator-defined name of the member being registered to the GWM, `server_group_name` is the ADNR administrator-defined name of the group of servers being registered to the GWM, and `domain_suffix` is the domain suffix name specified in a zone parameter on a `dns` statement. To construct the DNS name, the value of the `server_name` parameter of the `server_group` statement is used, followed by the value of the `server_name` keyword of the `server_group` statement, followed by the value of the `domain_suffix` keyword of the zone referenced in the `host_group` statement. The intervening dot is supplied by ADNR; do not explicitly code the dot. If the `server_group` statement contains a `member` keyword containing an optional `server_name` parameter, the name server is updated with these types of DNS names.

A `server_group` statement can have multiple `member` keywords within it. One of the coded member keywords does not have to have a `server_name` parameter. The member without a `server_name` parameter is sometimes referred to as the *unnamed member*, while members with a `server_name` parameter are sometimes referred to as *named members*. The IP addresses associated with the unnamed member are ones that can be dynamically added to the name server with the DNS name of the form `server_group_name.domain_suffix`. Configuring an unnamed member is not required. However, a virtual unnamed member is created for you if one is not configured.

Result: The IP addresses associated with the unnamed member are the union of all IP addresses explicitly configured in the unnamed member (if configured), and all IP addresses configured to all named members in that server group. In contrast, only the IP addresses explicitly configured in a named member are associated with the named member.

Typically, if affinity to a particular server instance is important, you configure one named member per server instance in the sysplex. If affinity to a particular server instance is not important, configuring only an unnamed member suffices.

Guideline: For high availability to the target applications to prevent reachability problems in the event of interface failure, IP addresses in `server_group` statements should either be static or dynamic VIPAs. If the target application is enabled to move from one TCP/IP stack to another, DVIPAs are appropriate for the server group. Otherwise, static VIPAs are appropriate.

Uniquely identifying this ADNR instance

ADNR appears as a load balancer to the GWM that it connects to. Each load balancer must uniquely identify itself to the GWM. Therefore, each ADNR instance must be uniquely identified, to distinguish it from other ADNR instances, as well as external load balancers that connect to a GWM using SASP. Use the `uuid` (universally unique ID) statement of the ADNR configuration file to uniquely identify an ADNR instance.

According to the SASP protocol, each load balancer should be universally unique from all other load balancers. In practical terms, only load balancers that connect to the same GWM must be unique.

Guideline: To prevent possible future uuid conflicts among load balancer and ADNR, the uuid configured for each ADNR instance should be universally unique.

Customizing optional statements

Customize the optional statements in the ADNR configuration file.

The optional `debug_level` statement determines how much log data is captured in the ADNR's log file.

Restriction: In most cases, you should not customize the `debug_level` statement, unless directed to do so by an IBM Service representative. Adding additional types of trace data can cause the amount of data captured to become voluminous. Reducing the amount of trace data from the default value might make diagnosing a problem more difficult.

Technically, the `host_group` and `server_group` statements are optional. They can be omitted to flush a name server of all ADNR-managed resource records. However, if you omit these statements, ADNR will not manage name servers for the sysplex until the ADNR configuration file is updated with `host_group` and `server_group` statements and the `MODIFY REFRESH` command is issued. When no `host_group` or `server_group` statements are configured, the `ipaddrlist` statement is also optional. For more information, see [“Flushing a zone” on page 1244](#).

The `key` statement defines the key file used in creating digital signatures, which is used when specifying transaction signatures (TSIGs) for zone updates and zone transfers. For more information about keys, see [“Authorizing dynamic updates” on page 1240](#) and [“Authorizing zone transfers” on page 1241](#).

Guideline: Key files must have access permissions that allow ADNR to read the file, either as the file's owner or as a member of the associated group.

Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run (optional)

The TCP/IP profiles can optionally be customized to better accommodate ADNR, the Advisor, and Agents. For information about Advisor and Agent TCP/IP profile customization, see [“Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run \(optional\)” on page 1193](#). You might have already performed the steps for customizing the Advisor and Agent TCP/IP profiles in [“Step 6: Configure the z/OS Load Balancing Advisor function” on page 1230](#).

If you use dynamic VIPAs for ADNR, you need to configure the appropriate TCP/IP profiles in the sysplex for the DVIPA definition and usage. The preferred definitions include `VIPARANGE` with `MOVEABLE NONDISRUPTIVE`. For more specific information, see [“Using dynamic VIPAs” on page 397](#).

If you are using AT-TLS, you need to perform several steps to set up the z/OS Policy Agent, enable ADNR's TCP/IP stack for AT-TLS, and so on. For more information, see [“Step 5: Customize the TCP/IP profiles of the TCP/IP stacks on which the Advisor and Agents are to run \(optional\)” on page 1193](#). For ADNR, you need to customize the AT-TLS policies that are identified with the `CommonTTLSSConfig` and `TTLSSConfig` statements.

Tip: Because ADNR and the Agent are both client applications to the Advisor, you can define AT-TLS policy rules similar to the `LBAAdvisorAgentRule` and the `LBAgentRule` for ADNR.

Step 12: Start the TCP/IP stacks on which ADNR and the LBA applications are to run

You can start ADNR before or after you start the TCP/IP stack it uses. If the TCP/IP stack that ADNR uses terminates or is not yet started, ADNR remains active and establishes communication with the TCP/IP stack when it becomes active. For additional information about the Advisor and Agents, see [“Step 1: Start the TCP/IP stacks that the Advisor and the Agents will use” on page 1201](#).

Step 13: Start the z/OS Load Balancing Advisor and Agent

You can start the z/OS Load Balancing Advisor and Agents before or after you start ADNR. If you start ADNR before you start the Advisor, an eventual action message, EZD1272E, is displayed until the Advisor is active and a connection is successful. When a successful connection is established, ADNR issues message EZD1270I, and the Advisor issues message EZD1263I indicating that a load balancer connected. At the same time, the eventual action message is converted to a non-action message (DOMed). If Agents were not active at the time that ADNR and the Advisor established a connection, Agents report on any ADNR-registered resources that the Agent owns when the Agent becomes active. ADNR updates its name servers with that information at that time.

Step 14: Start the target applications that are to be managed by ADNR

ADNR can manage TCP and UDP server applications. No modifications are necessary to these applications, their configurations, or start procedures.

Step 15: Start the ADNR application

As ADNR connects to the Advisor, an MVS console message appears on the MVS console of the system on which ADNR is running. Simultaneously, a message appears on the Advisor's MVS console, indicating that a load balancer connected. If ADNR fails to connect to the Advisor, an eventual action message is displayed on ADNR's MVS console until the connection is successful. ADNR must be started from a job control procedure that is in a procedure library. It cannot be started under BPXBATCH. The IBM-supplied program properties table has entries to make ADNR run non-swappable. You should not override this entry to make ADNR run swappable.

Step 16: Verify that the ADNR system is functioning correctly (optional)

View the MVS console of the ADNR system after you have started it to verify that the application started correctly and is still running. If there are any failure messages, see the appropriate message description for the appropriate corrective action. View the syslogd file of the ADNR system to see whether any error or warning messages were issued.

Use the following commands to verify that ADNR is functioning correctly:

- If connectivity cannot be established, ADNR issues the eventual action message EZD1272E, ADNR CONNECTION ATTEMPT TO GWM *gwmipaddress* FAILED. If this message is issued and the GWM is active, verify that routing exists between the IP addresses used by the GWM and ADNR.
- Verify that ADNR is started and connected to the expected Advisor by issuing ADNR's MODIFY *procname*,DISPLAY,GWM,DETAIL command. Verify that the GWM IP address and port is the expected IP address and port of the Advisor to which you intended to connect.
- From the Advisor, issue the MODIFY *procname*,DISPLAY,LB command to list the LB indexes known to the Advisor. Identify the LB index representing ADNR, and then issue the Advisor MODIFY *procname*,LB,INDEX=*lb-index* command. Verify that each member you have registered that you expect to be available in the sysplex displays as available in the AVAIL field. If there is a discrepancy in the availability status, check the FLAGS field for possible reasons why a member is not available. For more information about the flags in the FLAGS field for the Advisor's MODIFY command, see [z/OS Communications Server: IP System Administrator's Commands](#).
- Verify that server and host groups have been properly registered to the GWM by issuing ADNR's MODIFY *procname*,DISPLAY,GWM,GROUPS,DETAIL command. Verify that each member you have registered that you expect to be available in the sysplex displays as available in the AVAIL field. If there is a discrepancy in the availability status, check the FLAGS field for possible reasons why a member is not available. For more information about the flags in the FLAGS field for MODIFY command for ADNR, see [z/OS Communications Server: IP System Administrator's Commands](#).
- Verify that Agents are aware of members that they own by issuing the MODIFY *procname*,DISPLAY,MEMBERS Agent command. Any ADNR-registered IP addresses owned by the system where the Agent is running should appear in the display.

- Verify that ADNR is able to communicate properly with the name servers it manages by issuing ADNR's `MODIFY procname,DISPLAY,DNS,ZONES,SUMMARY` command. Verify that the `ZONE STATUS` field is or changes to `SYNCHRONIZED` after the convergence period expires. For the definition of the convergence period, see [“Step 8: Configure ADNR to automatically restart in case of application or system failure \(optional\)” on page 1231](#). If any zone status begins with the value `NOT_RESPONSIVE`, there is either a connectivity problem between ADNR and the name server, or there is a configuration mismatch between ADNR and the name server. For more information about [diagnosing unresponsive zones](#), see [z/OS Communications Server: IP Diagnosis Guide](#). If ADNR is unable to properly communicate with a name server, ADNR issues eventual action message `EZD1278E`, which remains until the problem is resolved.
- Verify that name servers reflect the availability status of the sysplex resources that you have configured with ADNR. Issue ADNR's `MODIFY procname,DISPLAY,ZONES,ZONEID=zone_label,DETAIL` command for each zone configured to ADNR, or issue the `MODIFY procname,DISPLAY,ZONES,DETAIL` to view all zones. Verify that the `DNS RR STATUS` field for each resource record display is `PRESENT` for each resource that is available in the sysplex.
- Use the z/OS UNIX **dig** command to perform a zone transfer of the ADNR-managed zones, and verify that the zone contents match the expected content, based on the members configured to ADNR and the availability status of those members in the sysplex. The **dig** command to use has the following form:

```
dig @name_server_address domain_name axfr
```

Tip: If zone transfers were restricted by name server configuration to clients from specific IP addresses or from clients that have digitally signed their requests (TSIG), you might have to issue the **dig** command with the `-b` option or the `-k` option to, respectively, force the request to originate from a specific IP address or be digitally signed with the appropriate signature. For more information about the **dig** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

- Verify that ADNR is functioning correctly when using AT-TLS:
 - Use the **pasearch** command from the z/OS UNIX shell to query information from the Policy Agent. For more information about [displaying policy based networking information](#), see [z/OS Communications Server: IP System Administrator's Commands](#).
 - Use the `Netstat TTLS/-x` command to display z/OS Load Balancing Advisor and ADNR AT-TLS policies. For more information about the [Netstat TTLS/-x report](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

z/OS Load Balancing Advisor configuration considerations

The z/OS Load Balancing Advisor solution consists of a z/OS Load Balancing Advisor application, and one or more z/OS Load Balancing Agents, per sysplex. For more information about the z/OS Load Balancing Advisor solution, see [Chapter 21, “z/OS Load Balancing Advisor,” on page 1177](#).

Connectivity considerations

ADNR connects to the Advisor. The Advisor can use an access control list (ACL) to determine which load balancers are permitted to connect to it. From the Advisor's perspective, ADNR is considered to be a load balancer.

Rules:

- If you are not using AT-TLS, the Advisor's `lb_id_list` statement must include the IP address coded on the `host_connection_addr` keyword of the ADNR `gwm` statement. If you are using AT-TLS for all ADNR-Advisor connections, the `lb_id_list` statement and `host_connection_addr` keyword are ignored. If you are defining external load balancers that are not using TLS/SSL, the `lb_id_list` statement is required.
- The IP address and port coded on the Advisor's `lb_connection_v4` or `lb_connection_v6` statement must match the IP address and port coded on the `gwm_id` keyword of the ADNR `gwm` statement, depending on the address family used.

Guideline: For availability reasons, the IP address coded on the gwm_id keyword of the ADNR gwm statement should be a unique application-instance DVIPA.

Near real-time availability information of sysplex resources

To take advantage of the near real-time availability information that ADNR can provide regarding sysplex resources, clients must query the ADNR-managed name servers relatively frequently rather than use cached information from a previous name server query. The length of time that name server information is cached is typically controlled by the Time To Live (TTL) value received from the name server. A TTL is associated with each resource record in a name server, and the TTL information is part of the information that the resolver receives when the name server successfully responds to a query. ADNR provides a mechanism to define the TTL for name server resources it manages.

ADNR permits the TTL to be defined to a specific value per zone, or it can be set to a value determined by the GWM, which is the default. When the TTL value is the default value determined by the GWM, it takes on the update_interval value in the Advisor's configuration file.

Guideline: Allowing the GWM to set the TTL for an ADNR zone by using the default TTL value enables clients to obtain the most accurate, near real-time sysplex resource availability information, without wasting network resources with unnecessary DNS queries.

Because ADNR can be configured to use a GWM-defined interval to set the TTL value, the GWM can dynamically change this interval. The z/OS Load Balancing Advisor does not support dynamically changing this interval, but a future Advisor implementation or other future GWM implementations might. If this occurs, ADNR has the capability to find out about the new GWM interval only when the connection to the GWM is re-established.

z/OS Load Balancing Advisor and Agent operational considerations

Several operational characteristics of the z/OS Load Balancing Advisor and Agent can affect ADNR.

Advisor operational considerations

For ADNR to accurately maintain the resource records that represent available sysplex resources in its managed name servers, the Advisor and all Agents in the sysplex need to be active. If the Advisor stops, ADNR can no longer receive information about the current availability of sysplex resources, and consequently, the resource records in the name servers that ADNR manages eventually become stale. That is, resource records are left in the name server representing sysplex resources that are no longer available, or resource records are not added to the name server to represent sysplex resources that have become available. Because of the ramifications of the Advisor becoming unavailable, you should perform the necessary configuration for optimal availability of the Advisor. For more information, see [“Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure \(optional\)” on page 1183.](#)

Agent operational considerations

If an Agent in the sysplex stops, all resource records in the ADNR-managed name servers that represent sysplex resources managed by that Agent are removed from the name server. This makes it appear as though the resources are unavailable when they actually might be available. For this reason, it is important to perform the necessary configuration for optimal availability of each Agent. For more information, see [“Step 1: Configure the Advisor and Agents to automatically restart in case of application or system failure \(optional\)” on page 1183.](#)

The Agent is also capable of making resources appear unavailable to ADNR by quiescing them with the Agent's MODIFY QUIESCE command. All resource records in a name server associated with a quiesced member are removed and are not added back until the member is enabled with the Agent's MODIFY ENABLE command, or if the Agent is stopped and restarted.

Name server configuration considerations

The name servers that ADNR manages must support RFC 2136, *Dynamic Updates in the Domain Name System (DNS UPDATE)*. For information about accessing RFCs, see [Appendix G, “Related protocol specifications,”](#) on page 1439.

Many of the subjects discussed in this topic are applicable to other name server implementations. For BIND 9 name servers, specific instructions are provided for how to accomplish configuration objectives. For other name server implementations, consult the appropriate product documentation.

Initial zone configuration

ADNR cannot create a zone in a name server. It can only add and delete resource records from an existing zone. The zones that ADNR manages must initially be configured to the appropriate name servers. This involves defining the zone and a small set of resource records in the zone. This includes the SOA record, the appropriate NS records, and the A or AAAA glue records.

Rule: Do not configure any valuable A or AAAA resource records in the zone data files that ADNR will manage. ADNR deletes any type A or AAAA resource records that were not added by ADNR, with the exception of glue resource records (see [“Updates to an ADNR-managed zone”](#) on page 1240). These resource records are deleted when ADNR starts, or during MODIFY REFRESH processing.

Restriction: ADNR does not support DNSSEC signed zones.

Authorizing dynamic updates

Name servers can be configured to allow dynamic updates from only specific entities. If a name server that ADNR updates is configured to restrict which entities can update the name server, ADNR must be specifically permitted to update that name server. Name servers typically permit dynamic updates from a predetermined set of source IP addresses, sometimes referred to as an access control list (ACL), or they might require authentication with digital signatures, sometimes referred to as transaction signatures (TSIG). Authentication using digital signatures is much more secure than authenticating by source IP address, because the latter is subject to address spoofing. Furthermore, the source IP address that ADNR uses might not be entirely predictable, unless deliberate steps are taken in the TCP/IP profile to make it predictable through mechanisms like job-specific source IP address specification or other forms of SOURCEVIPA configuration. Other possible options for lessening the impact of the unpredictability of the source IP address that ADNR uses include using a subnet in the name server's ACL. However, this allows updates from any entity in that subnet, which compromises security.

Guideline: Digital signatures (TSIG authentication) provide more robust authentication than source IP address permissions (ACL).

For the BIND 9 name server, dynamic updates are allowed by ACL using the allow-update statement, or by digital signatures using the update-policy or the allow-update statement.

When dynamic updates are permitted using digital signatures (TSIG), the name server and ADNR must be configured with the same shared cryptographic key. You can generate the key using the dnssec-keygen utility. Then you define the key to the name server and reference the key from name server zone definitions that want to use it.

You must also define the TSIG key to ADNR using the key configuration statement, and then reference the TSIG key from the update_key keyword of the zone keyword of the dns statement. The key file should be protected from unauthorized access. ADNR must have read access to the file. Both the .key and the .private key files generated by the dnssec-keygen utility must be present for ADNR to properly communicate with the name server, even though only the .key key file name is actually specified on the update_key keyword.

Updates to an ADNR-managed zone

Typically, zones managed by ADNR should not be updated by any entity other than ADNR. This includes manual editing of the zone data file, or dynamic updates from any other source. Many name server

implementations strongly advise against manually editing the zone data file of a dynamic zone, such as the zones managed by ADNR. Editing these files has the potential to corrupt the file, or the updates can be lost. However, in general from a name server perspective, dynamic updates using a tool such as `nsupdate` are allowed for dynamic zones. In the case of ADNR-managed zones, certain types of dynamic updates can be made by entities other than ADNR. Table 66 on page 1241 shows which types of resource records can be dynamically added and deleted by entities other than ADNR.

Table 66. Dynamic updates of ADNR-managed zones by other entities	
Allowed dynamic updates	Disallowed dynamic updates
All resource record types other than A and AAAA	A and AAAA resource records that are not considered glue records
A and AAAA resource record types that are considered glue records	
Tip: Glue records are A or AAAA records that store the IP addresses of authoritative name servers.	

Any disallowed resource records that appear in dynamic update requests to ADNR-managed zones are accepted by the name server, but are subject to being deleted by ADNR at a later time.

Rule: ADNR uses a special domain name for determining whether a name server is active and configured correctly to allow dynamic updates. At times, ADNR dynamically performs an update-add and an update-delete of the following resource record:

```
ibmsaspddnsdnsprobe IN A 0.0.0.0
```

In the unlikely event that this same resource record is added to an ADNR-managed zone by an entity other than ADNR, it is subject to being deleted by ADNR in the future.

Update forwarding

Update forwarding is a DNS concept in some name server implementations that enables dynamic updates to be sent to a name server that is not the primary master name server for the zone being updated. The name server that receives the dynamic update request forwards the update to the primary master name server.

Rule: To avoid possible zone data-integrity issues, ADNR must be configured to update only the primary master name server for a zone. That is, the IP address of a name server on the `dns_id` keyword of the `dns` statement must be an address of the primary master name server for the zone identified on the `domain_suffix` keyword, and must not be the IP address of a secondary name server for that zone.

Authorizing zone transfers

Zone transfers are operations that are typically performed between authoritative name servers of a particular zone. A zone transfer occurs when all or part of the contents of a zone is sent from the name server to the requester. ADNR requests zone transfers from the primary master name server of the zones it manages. Name servers can be configured to allow zone transfers only from specific entities. If the name servers that ADNR is to update are configured to restrict which entities can perform zone transfers, ADNR must be specifically permitted to perform them. Name servers typically permit zone transfers from a predetermined set of source IP addresses, sometimes referred to as an access control list (ACL), or they can require authentication using digital signatures, sometimes referred to as transaction signatures (TSIG). Authentication using digital signatures is much more secure than authenticating by source IP address, because the latter is subject to address spoofing. Furthermore, the source IP address that ADNR uses might not be entirely predictable, unless deliberate steps are taken in the TCP/IP profile to make it predictable through mechanisms like job-specific source IP address specification or other forms of SOURCEVIPA configuration.

Guideline: Digital signatures (TSIG authentication) provide more robust authentication than source IP address permissions (ACL).

For the BIND 9 name server, zone transfers are allowed by ACL or by digital signatures, both by using the allow-transfer statement.

You must define the TSIG key to ADNR using the key configuration statement, and then reference the key from the transfer_key keyword of the zone keyword of the dns statement. The key file should be protected from unauthorized access. ADNR must have read access to the file. Both the .key and the .private key files generated by the dnssec-keygen utility must be present for ADNR to properly communicate with the name server, even though only the .key key file name is actually specified on the transfer_key keyword.

Limiting the duration of an outbound zone transfer

With some name server implementations, you can limit the amount of time that an outbound zone transfer is allowed to run. Setting this time interval to a value that is too short can have adverse affects on ADNR's ability to communicate with the name server. ADNR must request full zone transfers from the name servers it manages. If the period of time allowed for a zone transfer is shorter than the amount of time it normally takes to transfer an ADNR-managed zone, ADNR cannot successfully manage that zone; adjust the name server configuration to provide adequate time for a full zone transfer.

For the BIND 9 name server, the amount of time to allow for an outbound zone transfer is specified on the max-transfer-time-out option.

Limiting the total number of simultaneous outbound zone transfers

With some name server implementations, you can limit the total number of simultaneous zone transfer requests that are served. Setting this number too low can have adverse affects on ADNR's ability to communicate with the name server. When setting this limit, take into account the number of secondary name servers that use this name server as the master name server for their zones, as well as the number of ADNR-managed zones that are configured under this name server. During ADNR initialization and after a MODIFY REFRESH command, ADNR requests simultaneous zone transfer requests for each zone it manages. Consider the number of zones configured under the same dns statement when you are setting zone transfer limits in the name server.

For the BIND 9 name server, the total number of simultaneous outbound zone transfers allowed is specified on the transfers-out option.

The .digrc file

ADNR uses the z/OS UNIX **dig** command to perform zone transfers from managed zones. The z/OS UNIX .digrc file can provide defaults for each user for the **dig** command. This file is read and used if it appears in the user's home directory. Because this file can cause ADNR to function incorrectly, ADNR fails initialization if this file is found in ADNR's working directory. However, ADNR does not search for this file after initialization. ADNR's working directory is specified when ADNR is defined to the security server (RACF).

Rule: Do not put the .digrc file in ADNR's home directory.

Split DNS (views)

Split DNS is a method in some name server implementations that enables zone data to appear differently depending on which client queries the name server. For example, Internet clients might be restricted to a subset of resource records in a zone, while intranet clients might have access to all resource records in a zone.

The BIND 9 name server implementation supports split DNS through the view statement.

If you want to configure split DNS for an ADNR-managed zone, there are some special considerations. When implementing split DNS for a domain, the zone data is kept in separate files in the name server for each view of the zone. This implies that the data is disjointed, and in many respects ADNR must treat each view like a separate zone. When performing dynamic updates to a split DNS zone, the name server might determine which view to update based upon the source IP address of the nsupdate client. The BIND 9 name server uses this criteria to determine which view to update, and ADNR is the update client

in this regard. Therefore, ADNR must use separate source IP addresses to update each view. This can be accomplished in the following ways:

- Configure separate ADNR applications for each view.

By configuring an ADNR application for each view, a unique source IP address can be associated with each ADNR instance using job-specific source IP addressing. The source IP address assigned to ADNR needs to be configured appropriately in the name server. For the BIND 9 name server, the source IP address of the ADNR instance that you want to have update a specific view would appear in that view's match-clients statement.

The easiest way for each ADNR instance to use unique source IP addresses is to run each instance on separate systems or TCP/IP stacks. If each ADNR instance must run on the same TCP/IP stack, you can use job-specific source IP addressing to provide unique source IP addresses. This involves mapping the ADNR job names to the source IP address to be used using the JOBNAME entry in the SRCIP statement block of the TCP/IP profile. However, each ADNR instance creates multiple address spaces, whose job names are the ADNR start procedure name with a numerical digit appended (for example, the *ADNR* job creates the *ADNR1* and *ADNR2* jobs). To use this method, job-specific source IP addressing has to specify the ADNR start procedure name followed by a wildcard when specifying the job name. Also, to avoid conflicting job names of the spawned address spaces among the multiple ADNR instances, you need to name the start procedures of the ADNR jobs so that the spawned job names do not conflict. For example, the start procedure names of *ADNRP* and *ADNRT* create unique job names among their instances, such as *ADNRP1* and *ADNRT1*; create unique source IP addresses by coding JOBNAME ANDRP* *source_ip_address1* and JOBNAME ADNRT* *source_ip_address2*.

- Understand and exploit TCP/IP's source IP address selection algorithm.

By understanding and exploiting TCP/IP's source IP address selection algorithm you can configure ADNR and locate name servers in the network, so that ADNR uses appropriate source IP addresses to dynamically update the appropriate views. For more information, see [“Source IP address selection” on page 272](#).

This technique involves coding separate dns statements in the ADNR configuration file, specifying different IP addresses for each dns statement (of the same multi-homed name server) and using the separate dns statements to update different views. If configured correctly, and depending on the IP address of the name server, the source IP address of ADNR can be influenced to match the IP address in the match-clients statement of the appropriate view in the name server.

The most predictable way to assign the correct source IP address for each separate view in this scenario is to use the DESTINATION entry in the SRCIP statement block of the TCP/IP profile. For example, if two dns statements with different IP addresses are coded in the ADNR configuration file, where each represents different views in the same name server, two DESTINATION entries are coded in the SRCIP statement of the TCP/IP profile. One DESTINATION entry contains the IP address from one of the dns statements as the destination IP address, and the second DESTINATION entry contains the IP address from the other dns statement as the destination IP address. The source IP address contained in each DESTINATION entry matches one of the IP addresses in the match-clients statement in the name server configuration file of the appropriate view to be updated.

Zone transfer formats

Some name server implementations have the capability to send multiple resource records in a DNS message during a zone transfer operation, instead of just one resource record per DNS message. The process of sending multiple resource records per DNS message is described in RFC 2671, *Extension Mechanisms for DNS (EDNS0)*. For information about accessing RFCs, see [Appendix G, “Related protocol specifications,” on page 1439](#).

Sending multiple resource records per DNS message is more efficient than sending just one. ADNR performs zone transfer requests from the name servers it manages. ADNR supports receiving zone transfers in either format, but is more efficient at processing the format that contains multiple resource records per DNS message.

The BIND 9 name server sends multiple resource records per DNS message by default. However, some name server implementations do not support receiving zone transfers using this format. For this reason, some name servers might be configured to use the less efficient format when sending zone data to a secondary name server. The BIND 9 name server supports specification of the zone transfer format on the transfer-format option. This option can be specified on a server statement, which can be used to set the option only when sending zone transfer information to ADNR, so that other name servers are unaffected by the setting.

ADNR configuration considerations

This topic describes ways to change the ADNR configuration file and how to maintain zone data integrity.

Changing the ADNR configuration file

The ADNR MODIFY *procname*, REFRESH command provides a way to dynamically change the ADNR configuration file. Because the command does not support a file name or dataset specification, changes must be made to the same configuration file that was used when ADNR was started.

Restriction: Make all changes to the ADNR configuration file dynamically while ADNR is running. Changing the configuration file without using the MODIFY REFRESH command can create orphaned resource records in a name server. Orphaned resource records are resource records that are left in a name server and that ADNR has lost the ability to manage. The presence of these orphaned resource records might inaccurately direct client connections to sysplex resources that are not actually available.

Tip: Before making changes to the ADNR configuration file, save a backup copy of the original file under a different file name or dataset name.

You can make changes to the ADNR configuration file while ADNR is stopped, instead of using the MODIFY REFRESH command, if you take precautions to prevent orphaned resource records or you are sure that clients will no longer have their resolvers pointing to a name server with orphaned resource records. Unless you use the MODIFY REFRESH command to make changes, the following types of changes to the ADNR configuration file create orphaned resource records in name servers:

- Removing a dns statement
- Removing a zone keyword from a dns statement
- Changing the domain_suffix keyword value on a dns statement
- Changing the IP address or port of a name server on the dns_id keyword of a dns statement

Flushing a zone

Flushing a zone refers to deleting all ADNR-managed resource records from an ADNR-managed zone. Flushing a zone is not a normal occurrence, but might be a useful administrative tool in certain situations. You can flush all zones, or just specific zones.

Flush all zones by removing all host_group and server_group statements from the ADNR configuration file and issuing a MODIFY REFRESH command. You might flush all zones when resource records are inadvertently orphaned in a name server. The orphans can be removed by ADNR by restoring a copy of the previous configuration file, removing all host_group and server_group statements, and then issuing a MODIFY REFRESH command. When the command has completed, you can issue another MODIFY REFRESH command using the latest ADNR configuration file to return to the configuration that you want to use.

You flush individual zones in much the same way as you flush all zones. Instead of removing all host_group and server_group statements from the ADNR configuration file, you remove only those statements that reference the zone or zones that you want to flush.

Maintaining zone data integrity

To ensure the integrity of resource records in the name server zones that ADNR is managing, several guidelines should be followed.

Guidelines:

- Use the MODIFY REFRESH command to change the ADNR configuration.
- If you have modified the ADNR configuration, issue a MODIFY REFRESH command before stopping ADNR. Do not stop and restart ADNR before issuing this command.
- Do not stop ADNR until a MODIFY REFRESH command has completed.
- If message EZD1273I is issued indicating that ADNR was unable to delete a zone during a MODIFY REFRESH operation, take other steps to delete the resource records added by ADNR. This might include flushing the zone, after the underlying problem that prevented ADNR from deleting the zone is resolved. For more information, see [“Flushing a zone” on page 1244](#).
- Do not configure multiple zones for the same domain suffix that references the same multi-homed name server.
- Do not manually edit the name server's zone data file for any zone managed by ADNR.
- Do not allow any entity other than ADNR to perform dynamic updates to the zones managed by ADNR.
- Do not employ update forwarding for ADNR-managed zones.

Steps for using the ADNR application in a sysplex subplexing environment

In a sysplex subplexing environment, there are some additional considerations for using ADNR. These steps are described in detail in the following subtopics.

Before you begin

Each subplex containing resources that were managed by ADNR before the sysplex was split into subplexes requires its own set of z/OS Load Balancing Advisor and Agent applications, and its own ADNR application, to continue to enable ADNR to manage DNS names for those subplex resources. Each subplex ADNR instance will communicate with the Advisor application in its subplex. Each subplex ADNR instance will update separate DNS zones. The ADNR instances for different subplexes cannot update the same zone, because each zone can be updated by only one ADNR application and ADNR can communicate with only one Advisor instance. There must be a one-to-one correspondence between a subplex and a DNS zone.

Procedure

Perform the following steps to use ADNR in a sysplex subplexing environment.

1. Plan how the new subdomains representing each subplex will fit into your DNS hierarchy.
2. Configure the name servers that will be updated for the new subplex domains.
3. Define and configure one Advisor per subplex.
4. Update the Agent configuration files to communicate with the Advisor running in its subplex.
5. Define one ADNR application per subplex.
6. Assign the host_group and server_group statements from the sysplex ADNR configuration to their correct subplex domains.
7. Configure the new ADNR instances to update the name server and zone for its subplex.
8. Configure the new ADNR instances to communicate with the subplex Advisor.
9. (Optional) Update resolver configuration files.
10. Start the TCP/IP stacks, Advisor, Agent, ADNR, and target applications that ADNR will manage.
11. Verify that each subplex ADNR is functioning correctly.

Step 1: Plan how the new subdomains representing each subplex will fit into your DNS hierarchy

Decide whether the new subdomain names should exist at the same level as the existing subdomain representing the sysplex that is being divided into subplexes, whether the new subdomains should become child domains of the existing sysplex domain, or whether there will be a mixture of the two.

For example, if the existing subdomain for the sysplex is mvspsex.mycorp.com, the new subdomains that represent the subplexes can be at the same level in the DNS hierarchy, such as mvspsex1.mycorp.com and mvspsex2.mycorp.com. Alternatively, you can create the new subdomains as child domains of the existing sysplex domain, such as subplex1.mvspsex.mycorp.com and subplex2.mvspsex.mycorp.com.

For the following examples, assume that the sysplex and ADNR are configured as shown in [Table 67 on page 1246](#).

Table 67. Base sysplex and ADNR configuration	
Sysplex A Domain=mvspsex.mycorp.com	
Host1	Host2
z/OS Load Balancing Agent	z/OS Load Balancing Agent
z/OS Load Balancing Advisor for sysplex A	
ADNR for sysplex A updating zone mvspsex.mycorp.com	

To convert this sysplex to a subplexing environment, one of the subplexes can use the existing domain name as the existing sysplex, and the other subplexes become subdomains of that domain, as shown in [Table 68 on page 1246](#).

Table 68. ADNR application in a sysplex subplexing environment; Example 1	
Sysplex A (No DNS domain)	
Host1 Member of subplex EZBT0211 Domain=mvspsex.mycorp.com	Host2 Member of subplex EZBT0212 Domain=subplex0212.mvspsex.mycorp.com
z/OS Load Balancing Agent for subplex EZBT0211	z/OS Load Balancing Agent for subplex EZBT0212
z/OS Load Balancing Advisor for subplex EZBT0211	z/OS Load Balancing Advisor for subplex EZBT0212
ADNR for subplex EZBT0211 updating zone mvspsex.mycorp.com	ADNR for subplex EZBT0212 updating zone subplex0212.mvspsex.mycorp.com

Another possibility is to assign each subplex as a child domain of the original sysplex domain, as shown in [Table 69 on page 1247](#). In this case, the existing sysplex domain no longer contains any resource records that represent hosts or server applications, but instead is merely the parent of the new subplex subdomains.

Table 69. ADNR application in a sysplex subplexing environment; Example 2

Sysplex A Domain=mvspsex.mycorp.com (Only delegates the child domains. Contains no sysplex resources.)	
Host1 Member of subplex EZBT0211 Domain=subplex0211.mvspsex.mycorp.com	Host2 Member of subplex EZBT0212 Domain=subplex0212.mvspsex.mycorp.com
z/OS Load Balancing Agent for subplex EZBT0211	z/OS Load Balancing Agent for subplex EZBT0212
z/OS Load Balancing Advisor for subplex EZBT0211	z/OS Load Balancing Advisor for subplex EZBT0212
ADNR for subplex EZBT0211 updating zone subplex0211.mvspsex.mycorp.com	ADNR for subplex EZBT0212 updating zone subplex0212.mvspsex.mycorp.com

Another alternative is to create new domain names for each of the subplexes at the same level of the DNS hierarchy as the existing sysplex domain, and retire the existing sysplex domain name, as shown in [Table 70 on page 1247](#).

Table 70. ADNR application in a sysplex subplexing environment; Example 3

Sysplex A (No DNS domain)	
Host1 Member of subplex EZBT0211 Domain=mvspsex0211.mycorp.com	Host2 Member of subplex EZBT0212 Domain=mvspsex0212.mycorp.com
z/OS Load Balancing Agent for subplex EZBT0211	z/OS Load Balancing Agent for subplex EZBT0212
z/OS Load Balancing Advisor for subplex EZBT0211	z/OS Load Balancing Advisor for subplex EZBT0212
ADNR for subplex EZBT0211 updating zone mvspsex0211.mycorp.com	ADNR for subplex EZBT0212 updating zone mvspsex0212.mycorp.com

Step 2: Configure the name servers that will be updated for the new subplex domains

Configure the name server or name servers with the new zones to represent the new subdomain names created for the new subplexes.

You can use the same name server that was used for the sysplex zones, or another name server or name servers. These name servers must meet the existing requirements for ADNR, as specified in [“Step 3: Decide which name server or name servers are to be managed by ADNR” on page 1229](#). Configure any security requirements in the name server for the new zones, such as access control lists or shared keys. Delegate the new zones as child zones from their parent name servers.

If you are not planning to use the existing sysplex domain name, remove that zone from the name server configuration file on the primary and secondary name servers. Update the parent zone so that it no longer delegates to the zone that you are removing.

Step 3: Define and configure one Advisor per subplex

To configure one Advisor instance per subplex, see [“Steps for configuring automated domain name registration” on page 1227](#).

Configuration includes creating the start procedure JCL, performing the required security product commands (for example, RACF), performing the actions to make the Advisor highly available in case of application or system failure, customizing the TCP/IP profiles, customizing the WLM policies for the Advisor, and so on.

Step 4: Update the Agent configuration files to communicate with the Advisor running in its subplex

Update the security mechanisms that allow the Agent to communicate with its Advisor.

You might need to update the Agent's `host_connection` statement to point to the Advisor running in its subplex, and the Advisor's `agent_id_list` statement to allow a connection from this Agent.

If you are using AT-TLS for security, see [“Enabling TLS/SSL for ADNR” on page 1227](#) and [“Enabling TLS/SSL for z/OS Load Balancing Advisor \(optional\)” on page 1194](#).

Step 5: Define one ADNR application per subplex

If resources in a subplex were previously managed by ADNR, to define one ADNR application per subplex, see the following steps (in [“Steps for configuring automated domain name registration” on page 1227](#)):

- [“Step 7: Define security server profiles for ADNR” on page 1230](#)
- [“Step 8: Configure ADNR to automatically restart in case of application or system failure \(optional\)” on page 1231](#)
- [“Step 9: Configure and start syslogd \(optional, but required to have ADNR write log messages and trace data to syslogd\)” on page 1232](#)
- [“Step 10: Configure one ADNR application per subplex” on page 1232](#)
- [“Step 11: Customize the TCP/IP profiles of the TCP/IP stacks on which ADNR and the LBA applications are to run \(optional\)” on page 1236](#)

Also, for special considerations when migrating ADNR to a subplexing environment, see:

- [“Step 6: Assign the `host_group` and `server_group` statements from the subplex ADNR configuration to the correct subplex domains” on page 1248](#)
- [“Step 7: Configure the new ADNR instances to update the name server and zone for its subplex” on page 1249](#)
- [“Step 8: Configure the new ADNR instances to communicate with the subplex Advisor” on page 1249](#)

Guideline: In a Common INET (CINET) environment, use stack affinity to ensure that each subplex ADNR instance is using a TCP/IP stack that is in the subplex. For an example of the JCL to use to establish affinity, see `adnrproc.sample`.

Step 6: Assign the `host_group` and `server_group` statements from the subplex ADNR configuration to the correct subplex domains

For each `host_group` statement in the original ADNR configuration, identify the subplexes that contain the hosts that are in the group. Create a `host_group` statement in each new ADNR configuration file of the subplex that contains such a host. Configure the `zone_label` of each `host_group` statement to point to a zone statement that represents the zone that will represent the subplex. Configure the `dns_label` of the `host_group` statement to point to a `dns` statement that represents the name server that owns the specified zone. Create `ipaddrlist` statements that the `host_group` statements can reference, such that the IP addresses in them belong to the subplex.

For each `server_group` statement in the original ADNR configuration, identify the subplexes that contain the server instances that are in the group. Create a `server_group` statement in each new ADNR configuration file of the subplex that contains such a server instance. Configure the `zone_label` of each `server_group` statement to point to a zone statement that represents the zone that will represent the subplex. Configure the `dns_label` of the `host_group` statement to point to a `dns` statement that represents

the name server that owns the specified zone. Create `ipaddrlist` statements that the `server_group` statements can reference, such that the IP addresses in them belong to the subplex.

Step 7: Configure the new ADNR instances to update the name server and zone for its subplex

To configure the `dns` statements of each subplex ADNR instance so that the correct name server and zone are updated for each subplex, see [“Identifying the name servers to update and the zones to be updated in those name servers” on page 1233](#).

You specified the name server or name servers to be updated in [“Step 2: Configure the name servers that will be updated for the new subplex domains” on page 1247](#). The zones that will be updated for each subplex ADNR were determined in [“Step 1: Plan how the new subdomains representing each subplex will fit into your DNS hierarchy” on page 1246](#).

Step 8: Configure the new ADNR instances to communicate with the subplex Advisor

Configure the `gwm` statement of each new ADNR instance to communicate with the Advisor that represents that subplex.

Each subplex should have an Advisor that communicates with an ADNR instance, unless there are no resources in that subplex that are to be managed by ADNR. Each new ADNR instance should have a UUID on the `uuid` statement that is universally unique.

Step 9: Update resolver configuration files (optional)

Users who were using DNS names to connect to resources in the sysplex will be affected by converting to a sysplex subplexing environment. Some DNS names that existed before the migration will no longer exist, and users will need to use new DNS names to connect to the subplex resources.

For example, users that used the name `ftp.mvsplex.mycorp.com` might now need to use the domain name of the subplex that they are now required to use, such as `ftp.mvsplex0212.mycorp.com`. You can make some of this transition more transparent to the users by adding the new domain names to the resolver configuration files that are in use throughout your network. Consider adding the new domain names to the resolver configuration `SEARCH` directive.

Step 10: Start the TCP/IP stacks, Advisor, Agent, ADNR, and target applications that are to be managed by ADNR

See the following steps (in [“Steps for configuring automated domain name registration” on page 1227](#)):

- [“Step 12: Start the TCP/IP stacks on which ADNR and the LBA applications are to run” on page 1236](#)
- [“Step 13: Start the z/OS Load Balancing Advisor and Agent” on page 1237](#)
- [“Step 14: Start the target applications that are to be managed by ADNR” on page 1237](#)
- [“Step 15: Start the ADNR application” on page 1237](#)

Step 11: Verify that each subplex ADNR is functioning correctly

To verify that each subplex ADNR is functioning as expected, see [“Step 16: Verify that the ADNR system is functioning correctly \(optional\)” on page 1237](#).

Operating ADNR

When ADNR is operational, you can take the following actions:

- Change the logging level of ADNR to suit your needs (optional)
- Change the ADNR configuration dynamically

- Interpret ADNR display information

Changing the logging level of ADNR

Optionally, you can change the logging level of ADNR to suit your needs. The amount of information that is logged by ADNR can be modified dynamically using the following command:

```
MODIFY procname,DEBUG,LEVEL=debug_level
```

However, modifying the logging level should be carefully considered. The IBM default value of 7 should not be changed unless instructed to do so by an IBM Service representative. For things to consider before modifying this value, see [“Customizing optional statements” on page 1236](#).

Changing the ADNR configuration dynamically

You can change the ADNR configuration dynamically using the ADNR MODIFY *procname*,REFRESH command. For more information, see [“Changing the ADNR configuration file” on page 1244](#).

Interpreting ADNR display information

For information about the [MODIFY command for ADNR](#), including sample ADNR display information and descriptions of the output, see [z/OS Communications Server: IP System Administrator's Commands](#).

Diagnosing problems

ADNR must communicate with a GWM and at least one name server. Problems with this communication are obvious because there is an eventual action message on the console. Problems communicating with a name server are manifested as an eventual action message concerning the name server and separate messages for each zone under the name server, indicating that the zone is unresponsive. Configuration problems with one zone (for example, TSIG key mismatches) are manifested by an eventual action message regarding the name server and a message indicating that the particular zone is unresponsive. In all cases, successful resolution of the underlying problem results in the removal of the eventual action message. For problems communicating with the GWM and for problems communicating with a name server, see [z/OS Communications Server: IP Diagnosis Guide](#).

Regardless of the problem communicating with a name server, ADNR sends health probes in 60-second intervals to test the reachability of the name server and determine whether ADNR and the name server have been compatibly configured. If the problem is transient (for example, a network glitch, or the name server was stopped and quickly restarted), ADNR detects when the name server is again reachable and recovers. If the problem is not transient, it is possible that the ADNR configuration, name server configuration, or both need to be changed. If only the name server configuration needs to be changed, the health probes detect when ADNR and the name server have been compatibly configured and ADNR recovers.

After starting ADNR, after restarting ADNR's GWM, or after issuing a MODIFY REFRESH command, ADNR might be delayed for a period of time before its name servers are updated with the latest sysplex availability information. In all of these cases, after ADNR connects to a GWM, ADNR waits twice the GWM's polling interval before attempting to update its managed name servers. This period of time is called the convergence period. For the definition of convergence period, see [“Step 8: Configure ADNR to automatically restart in case of application or system failure \(optional\)” on page 1231](#). The purpose of the convergence period is to avoid making premature decisions about which sysplex resources are available or unavailable until all Agents in the sysplex have had sufficient time to receive the data registered by ADNR and report back to the Advisor, and in turn ADNR, on the availability status of those resources. After the convergence period has expired, ADNR updates its managed name servers with the latest sysplex availability information. Henceforth, ADNR updates its managed name servers immediately upon receiving updated status information from the GWM.

Upon starting ADNR or issuing a MODIFY REFRESH command, ADNR resynchronizes itself with its managed name servers. This process consists of performing an asynchronous zone transfer from the name servers of each zone managed by ADNR, and then updating the name servers using this data and

the latest ADNR configuration and sysplex resource availability information. Depending on the number of sysplex resources configured to ADNR and the `update_interval` value configured on the Advisor, the resynchronization and reconciliation process can take longer than the convergence period when the convergence period is short and the zones are large. When the zone status reaches `SYNCHRONIZED`, this process has completed and the zone should reflect the latest status information from the sysplex.

ADNR configuration example

This topic includes a specific configuration example of ADNR. This example assumes that the z/OS Load Balancing Advisor solution is installed.

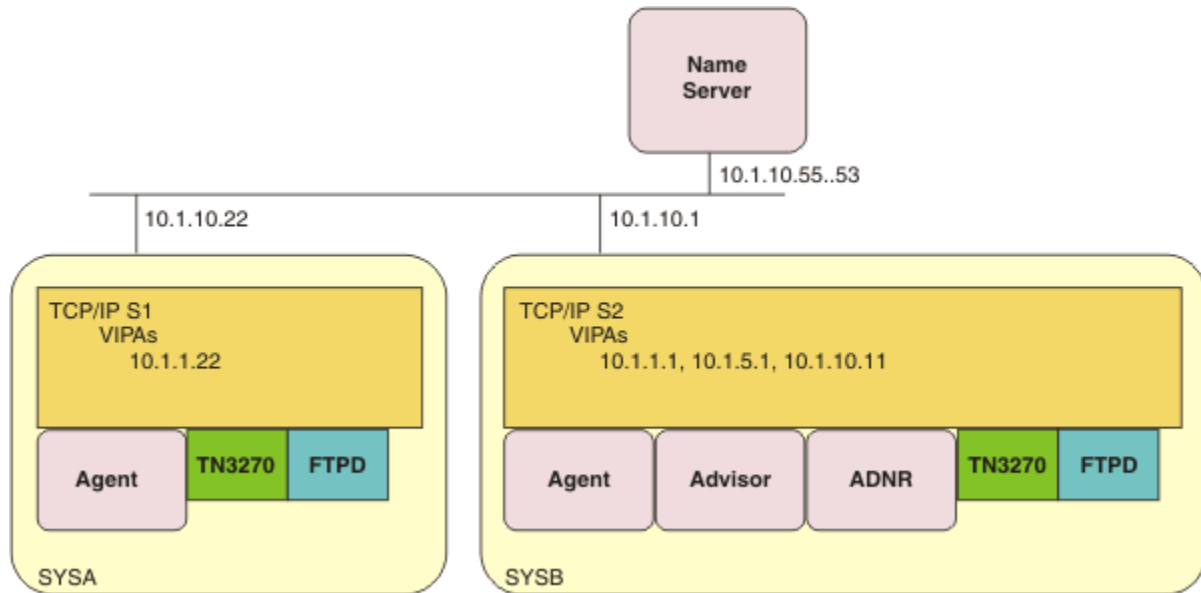

Figure 156. ADNR configuration example

In Figure 156 on page 1251, two systems, SYSA and SYSB, are in a sysplex. The z/OS Load Balancing Advisor solution is configured and deployed in the sysplex, with the Advisor and ADNR running on SYSB and an Agent running on both SYSA and SYSB. The TN3270E Telnet server and FTPD are active on both systems. ADNR manages a name server in the network.

The following example shows an ADNR configuration file. The numbers in the left margin were added for annotation purposes and are used in the description that follows the example. This example configuration does not use subplexing or AT-TLS.

```

001 debug_level          7                # Error, Warning, Event
002
003 uuid                 mycorp_sysplex_adnr

124     }
125 } # end of server_group

```

- Line 1:

In this example ADNR configuration file, the debug level is set to 7 in the optional `debug_level` statement on line 1. The value of 7 is the default value, so this statement is redundant but is shown for completeness. At the default level of 7, messages are written to the log if they are at error, warning, or event level. Messages at other debug levels, such as info or debug, are not written to the log file.

- Line 3:

The `uuid` statement on line 3 uniquely identifies this ADNR from all other ADNR instances and external load balancers. In this example, it is a character string giving some useful information about the location of the ADNR application.

- Line 5:

There is one name server that ADNR will manage in this example, which is represented by the `dns` statement on line 5. The statement is given a label of `network_name_server` that is used for references from other statements, like `host_group` and `server_group`, and might be used in display commands. This `dns` statement is referenced on lines 30, 82, and 114.

- Line 8:

The `dns_id` keyword within the `dns` statement on line 8 tells ADNR how to reach the name server. The name server configured is at address 10.1.10.55, listening on port 53. The port is not explicitly specified because the default port is being used.

- Line 10:

The `zone` keyword within the `dns` statement on line 10 indicates which zones ADNR manages at the name server indicated on the `dns_id` keyword. There can be multiple zone keywords in this statement. However, in this example, only one zone is managed by ADNR in this name server. The `zone` keyword has the label `mvspsex.mycorp.com_zone`, which is used for references from other statements like `host_group` and `server_group`. In this example, the zone is referenced on lines 31, 83, and 116.

- Line 14:

The `domain_suffix` keyword within the `zone` keyword on line 14 assigns the domain suffix to be used for all updates to the zone. In this example, the domain suffix of `mvspsex.mycorp.com` is appended to the host names that ADNR creates when it adds resource records to the name server. In this example, one of the resource records added to the name server is `ztelnet.mvspsex.mycorp.com`. Because the `zone` keyword containing this domain suffix is under the `dns` statement representing the name server at 10.1.10.55, this implies that the name server at 10.1.10.55 is configured as the primary master name server for the `mvspsex.mycorp.com` domain.

- Line 20:

The `gwm` statement on line 20 describes how ADNR communicates with the GWM. The `gwm` statement has a label of `z/os_lba_advisor`.

- Line 22:

The `gwm_id` keyword on line 22 identifies the IP address and port on which the GWM is listening for connections from load balancers. In this example, the GWM is located at 10.1.5.1 and is listening on port 3860 for load balancer connections. The port of 3860 on the `gwm_id` keyword does not need to be specified because that is the default port for this keyword. However, it is explicitly coded in this example for clarity. ADNR establishes a long-lived TCP connection to the GWM.

- Line 23:

The `host_connection_addr` keyword of the `gwm` statement on line 23 identifies the source IP address that ADNR uses when connecting to the GWM. The `host_connection_addr` keyword is optional if you are using AT-TLS. In this example, 10.1.10.11 is used. The GWM might require configuration to enable a load balancer to connect from this address. Because the Advisor is acting as the GWM, it requires either that the source IP address of all load balancers that connect to it appear in an access control list or that AT-TLS is used. This list is defined by the `lb_id_list` statement in the Advisor. Therefore, in this example, 10.1.10.11 must appear in the Advisor's `lb_id_list` statement to enable ADNR to connect to it.

- Line 26:

The `host_group` statement defines a set of IP addresses to potentially add to the ADNR-managed name server, which represents the hosts in the sysplex. They are used to map names for the hosts to IP addresses in the name server. This is one of the traditional uses of resource records in a name server. In this example, `production_sysplex` is the label for this `host_group` on line 26. This label can be used in display commands. There can be multiple `host_group` statements in an ADNR configuration file, although only one is shown in this example.

- Lines 29 and 31:

The `host_group_name` keyword identifies the DNS host name that is associated with all IP addresses identified in this `host_group` statement. The value of the `host_group_name` keyword, `prodplex` on line 29 in this example, is prepended to the domain suffix identified by the `zone` keyword of this `host_group` statement on line 31. In this example, all IP addresses identified by the `ipaddrlist` statements in this `host_group` statement have the potential to be added to the name server with the name `prodplex.mvsplex.mycorp.com`. The IP addresses that are actually added to the name server with this name are the intersection of all of the IP addresses identified in all `ipaddrlist` keywords in this `host_group` statement, with the addresses that exist in the union of all home lists in the sysplex. This assumes that an Agent is running on all systems in the sysplex. If an address is removed from the home list of a system in the sysplex (for example, using `VARY TCPIP,,OBEYFILE`), all resource records associated with that IP address are update-deleted from the ADNR-managed name server. Similarly, if an IP address is added to the home list of a system in the sysplex and that address is already represented in this `host_group` statement, one or more resource records with that IP address are update-added to the ADNR-managed name server. The number of resource records added depends upon ADNR configuration. Assuming that all IP addresses configured to this host group actually exist in the sysplex, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

```
prodplex.mvsplex.mycorp.com    IN A    10.1.1.22
prodplex.mvsplex.mycorp.com    IN A    10.1.10.22
prodplex.mvsplex.mycorp.com    IN A    10.1.1.1
prodplex.mvsplex.mycorp.com    IN A    10.1.10.1
```

Thus, the DNS name `prodplex.mvsplex.mycorp.com` can be used by a client to reach any system in the sysplex. Because there is no guarantee that a server is listening on each of these addresses, this DNS name should not be used by clients to connect to servers in the sysplex. This DNS name is probably most useful for utilities like ping and traceroute.

- Line 30:

The `dns` keyword in the `host_group` statement on line 30 identifies the name server that is to be updated for this host group. The `dns` keyword identifies this name server by the label `network_name_server`, which is a label on a `dns` statement (line 5 in this example). Thus, in this example, the names for this `host_group` statement are added to the name server located at 10.1.10.55.

- Line 31:

The zone keyword of the `host_group` statement on line 31 identifies the zone to which the names for this host group are to be added. In this example, the label `mvsplex.mycorp.com_zone` matches a zone keyword label in the `dns` statement on line 10. Because multiple zone keywords are possible in a `dns` statement, the zone within the `dns` statement must be identified from all `host_group` and `server_group` statements. The zone keyword in the `host_group` statement is how the domain suffix is determined for this `host_group` statement.

- Lines 36 and 45:

This `host_group` statement contains two member definitions on lines 36 and 45. Both of these member definitions are named members because they contain a `host_name` keyword. An unnamed member has no `host_name` keyword. You can code one unnamed member per `host_group`. However, if one is not coded, a virtual unnamed member is created for you. A virtual unnamed member contains the union of all IP addresses coded in named members within that host group. An explicitly coded unnamed member also contains the union of all IP addresses coded in the named members that belong to that host group, in addition to any IP addresses coded in the unnamed member itself. An explicitly coded unnamed member might be useful for configuring movable dynamic VIPAs that do not always belong to a specific host.

- Line 40:

The first member definition in this `host_group` statement contains the `host_name` keyword with a value of `sysa`. All IP addresses that are coded in this member belong to the `sysa` system. The value `sysa` of the `host_name` keyword on line 40 is prepended to the domain suffix for this host group to create the name `sysa.mvsplex.mycorp.com`. Assuming that all IP addresses configured to this member actually exist on `sysa`, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

```
sysa.mvsplex.mycorp.com    IN A 10.1.1.22
sysa.mvsplex.mycorp.com    IN A 10.1.10.22
```

Thus, the DNS name `sysa.mvsplex.mycorp.com` can be used to specifically connect to the `sysa` system. This name might be useful for ping or traceroute.

- Line 45:

The second member definition in the `host_group` statement on line 45 represents IP addresses that are to be associated with the `sysb` system, like the first member definition associated IP addresses with the `sysa` system. Assuming that all IP addresses configured to this member actually exist on `sysb`, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

```
sysb.mvsplex.mycorp.com    IN A 10.1.1.1
sysb.mvsplex.mycorp.com    IN A 10.1.10.1
```

Similar to the first member definition, the `sysb.mvsplex.mycorp.com` DNS name can be used to specifically connect to the `sysb` system.

- Lines 41, 42, 50, and 51:

The two `ipaddrlist` keywords in each of the two members of the `host_group` statement (lines 41, 42, 50, and 51) specify the IP addresses that belong to this host group. As this example shows, multiple `ipaddrlist` keywords are allowed and the group represents the union of all `ipaddrlist` statements in the `host_group` statement. Each `ipaddrlist` statement can contain multiple IP addresses, although this example has only one IP address per `ipaddrlist` statement. In this `host_group` statement, the two `ipaddrlist` keywords in the first member (lines 41 and 42) reference `ipaddrlist` statements with the labels `sysa_vipa_addrs` and `sysa_non_vipa_addrs` at lines 56 and 61, and the two `ipaddrlist` keywords in the second member (lines 50 and 51) reference the `ipaddrlist` statements with the labels `sysb_vipa_addrs` and `sysb_non_vipa_addrs` at lines 66 and 71. Thus, the IP addresses 10.1.1.22 and 10.1.10.22 are associated with this host group, as are the IP addresses 10.1.1.1 and 10.1.10.1, as reflected in the IP addresses associated with the name `prodplex.mvsplex.mycorp.com` as previously shown. Furthermore, the IP addresses of the first member, 10.1.1.22 and 10.1.10.22, are associated with system `sysa`, as reflected in the IP addresses associated with the name `sysa.mvsplex.mycorp.com`, and the IP

addresses in the second member, 10.1.1.1 and 10.1.10.1, are associated with system sysb, as reflected in the IP addresses associated with the name sysb.mvsplex.mycorp.com.

- Lines 56, 61, 66, and 71:

This example shows four `ipaddrlist` statements, each with one IP address, at lines 56, 61, 66, and 71. There can be multiple `ipaddrlist` statements and each can have multiple IP addresses. Each `ipaddrlist` statement has a label that is referenced from `host_group` and `server_group` statements. The labels in this example are `sysa_vipa_addrs`, `sysa_non_vipa_addrs`, `sysb_vipa_addrs`, and `sysb_non_vipa_addrs`. This example shows only IPv4 addresses, but IPv6 addresses can also be coded in `ipaddrlist` statements. The sample ADNR configuration file shows examples of IPv6 addresses coded in `ipaddrlist` statements. The sample ADNR configuration file can be found in the EZBADNRC member of SEZAINST.

- Lines 58, 63, 68, and 73:

The `ipaddr` keyword on lines 58, 63, 68, and 73 identifies a single IP address to register. This example shows only IPv4 addresses, but IPv6 addresses can also be coded in `ipaddrlist` statements. The sample ADNR configuration file shows examples of IPv6 addresses coded in `ipaddrlist` statements. The sample ADNR configuration file can be found in the EZBADNRC member of SEZAINST.

- Lines 76 and 108:

This example shows two `server_group` statements; one at line 76 to represent the TN3270E Telnet servers in the sysplex, and the other at line 108 to represent the FTP daemons in the sysplex. The `server_group` statements are used to create DNS names in the name server that map to IP addresses, which can actually be used to reach an active instance of the server.

- Line 76:

The first `server_group` statement on line 76 is given the label `tn3270_group`. This label can be used in display commands. This group represents TN3270E Telnet servers in the sysplex.

- Line 79:

The `port` keyword on line 79 in the first `server_group` statement indicates the port that the TN3270E Telnet servers listen on, which is 23 in this example.

- Line 80:

The `protocol` keyword on line 80 in the first `server_group` statement indicates the protocol of the listening application (TCP or UDP). Because the TN3270E Telnet server is a TCP application, the value for this keyword is TCP.

- Line 81:

The `server_group_name` keyword on line 81 identifies the DNS host name that is associated with all IP addresses identified in this `server_group` statement. The value of the `server_group_name` keyword, `ztelnet` in this example, is prepended to the domain suffix identified by the `zone` keyword of this `server_group` statement. In this example, all IP addresses identified by the `ipaddrlist` statements in this `server_group` statement have the potential to be added to the name server with the name `ztelnet.mvsplex.mycorp.com`. The IP addresses that are actually added to the name server with this name are the intersection of all of the IP addresses identified in all `ipaddrlist` keywords in this `server_group` statement, with the addresses on which the server instances in the sysplex are available. In the case of TCP applications, this is the set of IP addresses that the servers are listening on, and for UDP applications, this is the set of IP addresses to which the servers are bound. This assumes that an Agent is running on all systems in the sysplex. The TN3270E Telnet server listens on `INADDR_ANY`, so in effect, it listens on all IP addresses available. If a server instance is stopped (or abnormally terminates), all resource records associated with that server instance are update-deleted from the ADNR-managed name server. Similarly, if a new server instance in that group is started and an IP address on which that server instance is available is already coded in the `server_group` statement, one or more resource records with that IP address are update-added to the ADNR-managed name server. The number of resource records added depends upon ADNR configuration. Assuming the TN3270E

Telnet servers are running on sysa and sysb, the following resource records are added to the ADNR-managed name server (TTLs are omitted):

```
ztelnet.mvsplex.mycorp.com    IN A  10.1.1.22
ztelnet.mvsplex.mycorp.com    IN A  10.1.1.1
```

Thus, the DNS name ztelnet.mvsplex.mycorp.com can be used to reach any available TN3270E Telnet server in the sysplex.

- Lines 82 and 83:

On lines 82 and 83, the dns and zone keywords of the server_group statement serve the same purpose as those keywords on the host_group statement.

- Lines 87 and 97:

There are two named members defined in the server_group statement on lines 87 and 97. Named members contain a server_name keyword, but unnamed members do not. As in host_group statements, you can code one unnamed member per server group. However, if one is not coded, a virtual unnamed member is created for you. A virtual unnamed member contains the union of all IP addresses coded in named members within that server group. An explicitly coded unnamed member also contains the union of all IP addresses coded in the named members that belong to that server group, in addition to any IP addresses coded in the unnamed member itself. The IP addresses in the unnamed member, whether explicitly coded or not, are associated with the group name. In this example, the IP addresses of the unnamed member for this server_group statement are associated with the name ztelnet.mvsplex.mycorp.com. Coding an explicit unnamed member without any named members might suffice for servers where affinity to a particular instance is not needed. Also, if an application instance is freely movable from one system to another, or from one TCP/IP stack to another, coding an unnamed member without any named members might be acceptable. In this case, code the DVIAs on which the application could be reached in the unnamed member. If, however, it is important for clients to be able to connect to specific instances of a server, you must code separate named members for each instance.

- Line 91:

The first member definition in this server_group statement contains the server_name keyword with a value of telnetprimary at line 91. All IP addresses that are coded in this member are IP addresses that one instance of the TN3270E Telnet server could potentially be listening on. The value telnetprimary of the server_name keyword is prepended to the DNS name created for the server group to create the name telnetprimary.ztelnet.mvsplex.mycorp.com. Assuming that the IP address configured to this member actually exists on sysa, and that the TN3270E Telnet server is active on this system, the following resource record is added to the ADNR-managed name server (TTLs are omitted):

```
telnetprimary.ztelnet.mvsplex.mycorp.com    IN A  10.1.1.22
```

Thus, the DNS name telnetprimary.ztelnet.mvsplex.mycorp.com can be used to specifically connect to the TN3270E Telnet server instance on sysa.

- Line 97:

The second member definition in this server group on line 97 is similar to the first, with the exception that this member identifies an application instance on system sysb instead of the one on system sysa. Assuming that the IP address configured to this member actually exists on sysb, and that the TN3270E Telnet server is active on this system, the following resource record is added to the ADNR-managed name server (TTLs are omitted):

```
telnetsecondary.ztelnet.mvsplex.mycorp.com  IN A  10.1.1.1
```

Thus, the DNS name telnetsecondary.ztelnet.mvsplex.mycorp.com can be used to specifically connect to the TN3270E Telnet server instance on sysb.

- Line 108:

The second server_group statement on line 108 is similar to the server_group statement for the TN3270E Telnet servers, except that it represents FTP daemons in the sysplex. Thus, the value of the port keyword specifies the port number on which the FTP daemon listens. The server_group_name

value specifies a name that is appropriate to a group of equivalent FTP daemons. This server group has one unnamed member and no named members. Thus, the resource records that can potentially be added to the name server are as follows:

```
zftp.mvsplex.mycorp.com    IN A 10.1.1.22
zftp.mvsplex.mycorp.com    IN A 10.1.1.1
```

ADNR display examples

The displays in this topic use the example configuration described in “ADNR configuration example” on page 1251. The numbers in the left margin were added for annotation purposes and are used in the descriptions of the displays. Only a subset of the possible types of displays are shown in this example. For more examples of the MODIFY command for ADNR, see [z/OS Communications Server: IP System Administrator's Commands](#).

The following display shows information about the gwm:

```
01 F ADNR,DISP,GWM,DETAIL
02 E2D1254I GWM DETAIL
03 GWM LABEL      : Z/OS_LBA_ADVISOR
04 GWM STATUS     : CONVERGENCE_PENDING
05 GWM TIMESTAMP  : 10/19/05 18:32:52
06 GWM IPADDR..PORT: 10.1.5.1..3860
07 LOCAL IPADDR   : 10.1.10.11
08 UUID           : MYCORP_SYSPLEX_ADNR
09 UPDATE INTERVAL : 60
10 LAST UPDATE    : N/A
11 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:

The GWM LABEL field on line 3 is taken from the gwm statement label on line 20 of the example ADNR configuration file. All labels and names in ADNR displays are displayed in uppercase regardless of how they appear in the ADNR configuration file.

- Line 4:

The GWM STATUS on line 4 is CONVERGENCE_PENDING, which is a transient state meaning that the ADNR host_group and server_group information has successfully been registered with the GWM, and ADNR is waiting for a timer to expire before updating the name servers with information from this GWM.

- Line 5:

The GWM TIMESTAMP field on line 5 shows the date and time when the most recent update of the GWM STATUS field occurred.

- Line 6:

The GWM IPADDR..PORT field shows the IP address and port of the GWM. These values are taken from the gwm_id keyword of the gwm statement on line 22 of the example configuration file.

- Line 7:

The LOCAL IPADDR field is the source IP address that ADNR uses when communicating with the GWM. The value of 10.1.10.11 was taken from the host_connection_addr keyword on line 23 of the example configuration file

.

- Line 8:

The UUID field value on line 8 is taken from the uuid statement on line 3 of the example configuration file.

- Line 9:

The update interval of 60 seconds is determined by GWM configuration. For the z/OS Load Balancing Advisor, this value is determined by the Advisor's update_interval statement.

- Line 10:

The LAST UPDATE field on line 10 shows the most recent date and time that status information was received from the GWM on any of the sysplex resources that ADNR registered with the GWM. The value N/A indicates that no status updates have been received yet.

- Line 11:

The number of records displayed on line 11 indicates the number of GWMs actually displayed. Currently, this value is always 1, because only one GWM is supported.

The following display was created after the convergence timer expired. The GWM's status changes to GWM_ACTIVE on line 4. Any status updates from the GWM will now be reflected in the name servers, provided that the name servers are reachable and configured correctly.

```
01 F ADNR,DISP,GWM,DETAIL
02 EZD1254I GWM DETAIL
03 GWM LABEL      : Z/OS_LBA_ADVISOR
04 GWM STATUS     : GWM_ACTIVE
05 GWM TIMESTAMP  : 10/19/05 18:34:55
06 GWM IPADDR..PORT: 10.1.5.1..3860
07 LOCAL IPADDR   : 10.1.10.11
08 UUID          : MYCORP_SYSPLEX_ADNR
09 UPDATE INTERVAL : 60
10 LAST UPDATE    : 10/19/05 18:35:29
11 1 OF 1 RECORDS DISPLAYED
```

The following display summary shows the host groups and server groups that were defined:

```
01 F ADNR,DISP,GWM,GROUPS
02 EZD1254I GWM GROUP SUMMARY
03 GWM LABEL      : Z/OS_LBA_ADVISOR
04 GWM STATUS     : GWM_ACTIVE
05 GROUP LABEL    : PRODUCTION_SYSPLEX
06 GROUP NAME     : PRODPLEX
07 GROUP LABEL    : TN3270_GROUP
08 GROUP NAME     : ZTELNET
09 GROUP LABEL    : FTP_GROUP
10 GROUP NAME     : ZFTP
11 3 OF 3 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Lines 3 and 4:

Lines 3 and 4 show the same information as the DETAIL display.

- Lines 5, 7, and 9:

The GROUP LABEL fields on lines 5, 7, and 9 show the labels of the groups that were defined to ADNR on lines 26, 76, and 108, respectively, in the example ADNR configuration file.

- Lines 6, 8, and 10:

The GROUP NAME fields on lines 6, 8, and 10 show the names from the host_group_name or server_group_name keywords on lines 29, 81, and 113, respectively, of the example ADNR configuration file.

- Line 11:

The number of records displayed on line 11 indicates the number of groups actually displayed. When the number of groups defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of groups that were omitted from the display as a result of the MAX parameter value.

The following display shows the details of one group, and demonstrates how a label can be used in a display command:

```
01 F ADNR,DISP,GWM,GROUPS,GROUPID=PRODUCTION_SYSPLEX,DETAIL
02 EZD1254I GWM GROUP DETAIL
03 GWM LABEL      : Z/OS_LBA_ADVISOR
04 GWM STATUS     : GWM_ACTIVE
05 GWM TIMESTAMP  : 10/20/05 13:15:19
```

```

06 GWM IPADDR..PORT: 10.1.5.1..3860
07 LOCAL IPADDR    : 10.1.10.11
08 UUID            : MYCORP_SYSPLEX_ADNR
09 UPDATE INTERVAL : 60
10 LAST UPDATE     : 10/20/2005 13:17:21
11 GROUP LABEL     : PRODUCTION_SYSPLEX
12 GROUP NAME      : PRODPLEX
13 GROUP TYPE      : HOST
14 DNS LABEL       : NETWORK_NAME_SERVER
15 ZONE LABEL      : MVSPLEX.MYCORP.COM_ZONE
16 MEMBER HOSTNAME:
17   IPADDR        : 10.1.1.22
18   AVAIL         : YES
19   FLAGS         :
20   UPDATE COUNT  : 1
21   IPADDR        : 10.1.10.22
22   AVAIL         : YES
23   FLAGS         :
24   UPDATE COUNT  : 1
25   IPADDR        : 10.1.1.1
26   AVAIL         : YES
27   FLAGS         :
28   UPDATE COUNT  : 1
29   IPADDR        : 10.1.10.1
30   AVAIL         : YES
31   FLAGS         :
32   UPDATE COUNT  : 1
33 MEMBER HOSTNAME: SYSA
34   IPADDR        : 10.1.1.22
35   AVAIL         : YES
36   FLAGS         :
37   UPDATE COUNT  : 1
38   IPADDR        : 10.1.10.22
39   AVAIL         : YES
40   FLAGS         :
41   UPDATE COUNT  : 1
42 MEMBER HOSTNAME: SYSB
43   IPADDR        : 10.1.1.1
44   AVAIL         : YES
45   FLAGS         :
46   UPDATE COUNT  : 1
47   IPADDR        : 10.1.10.1
48   AVAIL         : YES
49   FLAGS         :
50   UPDATE COUNT  : 1
51 1 OF 1 RECORDS DISPLAYED

```

The following comments refer to the previous display:

- Lines 3–10:

Lines 3 through 10 show information described in previous display examples.

- Line 11:

The GROUP LABEL field on line 11 matches the value on the GROUPID keyword on the MODIFY DISPLAY command.

- Line 13:

The GROUP TYPE field on line 13 indicates that this group was defined as a host_group versus a server_group.

- Line 14:

The DNS LABEL field on line 14 is the label referenced by the dns keyword on line 30 of the example ADNR configuration file, which indicates which name server is to be updated with the information from this group.

- Line 15:

The ZONE LABEL field on line 15 is the label referenced by the zone keyword on line 31 of the example ADNR configuration file, which indicates which zone in the name server is to be updated with the information from this group.

- Line 16:

The MEMBER HOSTNAME field on line 16 is blank, indicating that this is the unnamed member for this group. Because an unnamed member was not explicitly configured for this group, this member represents the virtual unnamed member that is created for you.

- Lines 17, 21, 25, and 29:

The IPADDR values on lines 17, 21, 25, and 29 represent the IP addresses that are automatically added to the unnamed member. These four addresses represent the union of all IP addresses coded in all members of this group.

- Lines 18, 22, 26, and 30:

The AVAIL flags on lines 18, 22, 26, and 30 all indicate that the GWM has reported these resources as available. For IPADDRs in a host group such as this, this means the Agent owning these IP addresses is active and these addresses exist in a home list in the sysplex.

- Lines 19, 23, 27, and 31:

The FLAGS field for each of the IP addresses on lines 19, 23, 27, and 31 is empty. If the AVAIL flags were NO for any of these IP addresses, the FLAGS field would give an indication as to why. For a list of the possible flags that can appear for the [MODIFY command for ADNR](#), and their explanations, see [z/OS Communications Server: IP System Administrator's Commands](#).

- Lines 20, 24, 28, and 32:

The UPDATE COUNT fields on lines 20, 24, 28, and 32 indicate the number of times that the availability status, as sent from the GWM, has changed for these IP addresses.

- Lines 33 and 42:

The MEMBER HOSTNAME fields on lines 33 and 42 represent the named members that were configured in the group at lines 36 and 45 of the example ADNR configuration file. Only the IP addresses explicitly coded to these members appear in the display of these members, in contrast to the unnamed member. The remainder of the fields in these named members are equivalent to the information displayed in the unnamed member.

The following display shows information about the name server that ADNR is updating:

```
01 F ADNR,DISP,DNS,DETAIL
02 EZD1254I DNS DETAIL
03 DNS LABEL       : NETWORK_NAME_SERVER
04 DNS STATUS      : ACTIVE
05 DNS IPADDR..PORT: 10.1.10.55..53
06 ZONES DEFINED   : 1
07 ZONES ACTIVE    : 0
08 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:

The DNS LABEL field value NETWORK_NAME_SERVER is taken from the dns statement on line 5 of the example configuration file. For an explanation of all of the DNS states displayed on the [MODIFY command for ADNR](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

- Line 5:

The DNS IPADDR..PORT field value of 10.1.10.55..53 indicates that ADNR communicates with a name server at address 10.1.10.55 on port 53. This IP address and port are taken from the dns_id keyword on line 8 of the example configuration file.

- Line 6:

The ZONES DEFINED field on line 6 indicates that there is one zone configured under this dns statement in the ADNR configuration file.

- Line 7:

The ZONES ACTIVE field on line 7 indicates that the zone defined under this dns statement cannot yet be updated by ADNR. In a steady state environment, the number of active zones should match the number of defined zones. If the numbers do not match, this could be an indication of a configuration

problem, a network problem, or the zone could be in the middle of the resynchronization process. For more information on the resynchronization process, see [“Operating ADNR” on page 1249](#).

- Line 8:

The number of records displayed on line 8 indicates the number of DNSs actually displayed. When the number of DNSs defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of DNSs that were omitted from the display as a result of the MAX parameter value.

The following display shows summary information about the zones that ADNR is updating:

```
01 F ADNR,DISP,DNS,ZONES,SUMMARY
02 EZD1254I DNS ZONE SUMMARY
03 DNS LABEL      : NETWORK_NAME_SERVER
04 DNS STATUS     : ACTIVE
05 ZONE LABEL     : MVSPLEX.MYCORP.COM_ZONE
06 ZONE STATUS    : SYNCHRONIZED
07 1 OF 1 RECORDS DISPLAYED
```

The following comments refer to the previous display:

- Line 3:

The DNS LABEL field on line 3 indicates that information for a specific name server and its zones immediately follows. The field value is taken from the label on the dns statement on line 5 of the example configuration file. For an explanation of all of the DNS states displayed on the [MODIFY command for ADNR](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

- Line 5:

The ZONE LABEL field on line 5 indicates that information for the indicated zone follows. The value for this field is taken from the label on the zone keyword (line 10 of the example configuration file) of the dns statement.

- Line 6:

The ZONE STATUS field on line 6 shows the state of the zone. The value of SYNCHRONIZED is the expected, steady-state value for a zone. For an explanation of all of the zone states displayed on the [MODIFY command for ADNR](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

- Line 7:

The number of records displayed on line 7 indicates the number of zones actually displayed. When the number of zones defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of zones that were omitted from the display as a result of the MAX parameter value.

The following display shows the status of the resource records that ADNR manages in the name server:

```
001 F ADNR,DISP,DNS,ZONES,DETAIL
002 EZD1254I DNS ZONE DETAIL
003 DNS LABEL      : NETWORK_NAME_SERVER
004 DNS STATUS     : ACTIVE

139 1 OF 1 RECORDS DISPLAYED

```

The following comments refer to the previous display:

- Line 12:

The TSIG FLAGS field on line 12 indicates which type of TSIG keys are being used, if any. In this example, the update_key and transfer_key keywords were not specified for the zone under this DNS. If they had been specified, an indicator or indicators would be displayed on this line showing which types of TSIG keys are being used.

- Lines 13, 49, 67, 85, 103, 121, and 130:

The DNS RR LABEL fields indicate the portion of the DNS name of the resource record before the domain suffix is appended. Some unique examples are on lines 13, 49, 67, 85, 103, 121, and 130. Some of these labels can be compound, like TELNETPRIMARY.ZTELNET and TELNETSECONDARY.ZTELNET on lines 121 and 130. Compound labels are created for named members of server groups. The two named members were configured in a server_group statement on lines 87 and 97 of the example ADNR configuration file. The label PRODPLEX on line 13 represents the resource records for the virtual unnamed member of the host_group statement on line 26 of the example ADNR configuration file. The labels SYSA on line 49 and SYSB on line 67 represent the named members of the host group on line 36 and 45 of the example ADNR configuration file. The label ZFTP on line 85 represents the unnamed member of the server group on line 120 of the example ADNR configuration file. The label ZTELNET on line 103 represents the virtual unnamed member of the server group on line 108 of the example ADNR configuration file. The label TELNETPRIMARY.ZTELNET on line 121 represents the named member on line 87 of the example ADNR configuration file, and the label TELNETSECONDARY.ZTELNET on line 130 represents the named member on line 97 of the example ADNR configuration file.

- Line 14:

The fields labeled DNS RR STATUS (for example, line 14) indicate whether or not the resource record is present in the name server. Resource records representing available resources in the sysplex have a value of PRESENT, while resource records representing unavailable resources in the sysplex have a value of NOT_PRESENT.

- Line 15:

The fields labeled TTL (for example, line 15) indicate the time to live value associated with the resource record. For more information, see [“Near real-time availability information of sysplex resources”](#) on page 1239.

- Line 16:

The fields labeled CLASS (for example, line 16) indicate the resource record class. All ADNR-managed resource records have a class value of IN.

- Line 17:

The fields labeled TYPE (for example, line 17) indicate the resource record type. ADNR-managed resource records are either A for IPv4 addresses or AAAA for IPv6 addresses.

- Line 18:

The fields labeled RDATA (for example, line 18) contain the IPv4 or IPv6 address that is in the resource record.

- Line 19:

The fields labeled GWM LABEL (for example, line 19) match the label of the gwm statement on line 20 of the example ADNR configuration file.

- Line 20:

The fields labeled GROUP LABEL (for example, line 20) indicate the group definition that is responsible for the creation of the resource record. This makes it possible to correlate this resource record with the MODIFY ADNR,DISPLAY,GWM,GROUPS,GROUPID=PRODUCTION_SYSPLEX output to see the GWM data that is related to this resource record.

- Line 21:

The fields labeled LAST UPDATE (for example, line 21) indicate the most recent time that the status of the resource record has changed from PRESENT to NOT_PRESENT, or from NOT_PRESENT to PRESENT.

- Line 139:

The number of records displayed on line 139 indicates the number of zones actually displayed. When the number of zones defined exceeds the MAX parameter value (or the default of 100) of the MODIFY ADNR,DISPLAY command, the difference between the numbers on this line indicates the number of zones that were omitted from the display as a result of the MAX parameter value.

Chapter 23. Simple Network Management Protocol

This topic describes how to configure:

- Simple Network Management Protocol (SNMP) agent (osnmpd)
- z/OS UNIX **snmp** or **osnmp** command
- NetView SNMP command
- SNMP subagents
- Open Systems Adapter (OSA) support
- Trap forwarder daemon

Before you configure, read [“Understanding search orders of configuration information”](#) on page 13. It covers important information about data set naming and search sequences.

SNMP overview

SNMP is a set of protocols that describes management data and the protocols for exchanging that data between heterogeneous systems. The protocols include both the description of the management data, defined in the Management Information Base (MIB), and the operations for exchanging or changing that information. By implementing common protocols, management data can be exchanged between different platforms with relative ease.

SNMP defines an architecture that consists of:

- Network management applications
- Network management agents and subagents
- Network elements, such as hosts and gateways

The SNMP network management application can ask agents for specific information about network elements. Conversely, agents can tell the network management application when something happens to one or more network elements. The protocol used between the network management application and agents is SNMP. The transport protocol for SNMP requests is the User Datagram Protocol (UDP).

SNMP defines both the network management data and the ways in which the data is retrieved or changed by the network management application. Examples of network management data include device definitions, counts of packets received at the IP layer, TCP connection data, and so forth. The information about the network elements is stored in the Management Information Base (MIB), which is supported by the SNMP agent and its subagents. A MIB variable (or MIB object) is a specific instance of data in a collection of objects related to a common management area. The collection is called a MIB module. Each MIB object is identified by an object identifier (OID), which is a dotted-decimal value, and by a textual name. For example, the sysUpTime MIB object, which indicates how long ago the SNMP agent initialized, is defined as follows:

Textual name	Object identifier (OID)
sysUpTime	1.3.6.1.2.1.1.3

The z/OS Communications Server Network Management agent and subagents, also called SNMP agent and SNMP subagents, support many standard (RFC-based) MIB modules. The SNMP TCP/IP subagent also supports enterprise-specific MIB modules. For information on MIB modules supported by the z/OS Communications Server SNMP agent and subagents, see the SNMP agent capabilities statement, shipped as file /usr/lpp/tcpip/samples/mvstcpip.caps. Additionally, enterprise-specific MIBs are documented in the /usr/lpp/tcpip/samples directory. See [“TCP/IP subagent”](#) on page 1270 for more information on enterprise-specific MIB modules supported by the TCP/IP subagent. For a complete list of [MIB objects](#) supported by the SNMP agent and subagents shipped with z/OS Communications Server, see [z/OS Communications Server: IP System Administrator's Commands](#).

Network management application

The stations that monitor network elements run network management applications. In z/OS Communications Server, the z/OS UNIX **snmp** (or **osnmp**) command provides SNMP network management from the z/OS UNIX shell. The NetView SNMP command provides network management from the NetView command line. The z/OS UNIX **snmp** and **osnmp** commands perform exactly the same function. Both commands can be used to retrieve or change data from SNMP and monitor for asynchronous events known as notifications. An unconfirmed notification is called a trap. A confirmed notification is called an inform.

For information about the syntax and use of the **snmp** and NetView SNMP commands, see [z/OS Communications Server: IP System Administrator's Commands](#).

SNMP protocols

This topic provides an overview of the different SNMP protocols and their capabilities. For more detailed information on the security models for each of these SNMP protocols, see [“Overview of SNMP security models”](#) on page 1269.

SNMPv1

SNMPv1, standardized in 1988, is the first and most commonly used version. It became very popular and is probably the most widely deployed of the SNMP generations today. The SNMPv1 standards define support for SNMP GET, GETNEXT, and SET operations, and for asynchronous event notifications called TRAPs. However, SNMPv1 does not support some later MIB object types, such as 64-bit counters. SNMPv1 also uses community-based security, which is not very secure.

SNMPv2

The SNMPv2 protocol standards made several attempts to address the security issues associated with the SNMPv1 protocol, with the party-based security model SNMPv2p, the user-based security model SNMPv2u, and the community-based security model SNMPv2c.

Although these attempts were not successful in addressing the major security issues, SNMPv2 did provide several improvements over SNMPv1, especially in the area of data retrieval with the support of SNMP GETBULK operations, and SNMPv2 continued providing community-based security with SNMPv2c.

SNMPv3

SNMPv3 was designed in the late 1990s, and in December of 2002 become a standard. It is defined in RFCs 3410 through 3415 [see [Appendix G, “Related protocol specifications,”](#) on page 1439]. SNMPv3 uses the basic SNMP management system and operations of SNMPv1 and SNMPv2, but adds an entirely new security architecture. The SNMPv3 architecture is modularized so that portions of it can be enhanced over time without requiring that the entire architecture to be replaced. SNMPv3 defines a framework that, among other things, includes the following models:

- Message processing model (SNMPv3)
- User-based security model
- View-based access control model

The framework is structured so that multiple models can be supported concurrently and replaced over time. For example, although there is a new message format for SNMPv3, messages that are created with the SNMPv1 and SNMPv2c formats are still supported. Similarly, the user-based security model can be supported concurrently with previously used community-based security models. In addition, SNMPv3 added other key updates to the protocol, such as the following updates:

- Improved notification support

A new notification type, INFORM, is like a TRAP that requires an acknowledgement. If the acknowledgment is not received, the INFORM is resent.

- Trap filtering

With SNMPv3, a TRAP can also be filtered at the sender.

- Dynamic configuration

The SNMP agent can be dynamically configured using MIB modules defined in RFC 3584 and RFCs 3411 through 3415.

SNMP agent

In z/OS Communications Server, the SNMP agent is a z/OS UNIX application. It supports a maximum SNMP response packet size of 65535 bytes, and supports the following SNMP protocols:

- SNMPv1
- SNMPv2c
- SNMPv3

SNMPv2c offers protocol enhancements such as the GETBULK operation. SNMPv3 provides a network management framework that allows the use of user-based security in addition to, or instead of, the community-based security supported in SNMPv1 and SNMPv2c. The view-based access control model supported in SNMPv3 allows granular access control for MIB objects with either the user-based or community-based security models. SNMPv3 also enables dynamic changes to the SNMP agent configuration.

Overview of SNMP security models

SNMP security has evolved from community-based security to a modularized architecture that provides message security and access control.

SNMPv1 and SNMPv2c

The security model used by SNMPv1 and SNMPv2c is the community-based security model. In this model, an SNMP community is made up of an SNMP agent along with SNMP manager entities. Managers typically request management data from the agents. Each SNMP community is represented using an octet string called the community name. When the manager communicates with the agents, it uses the community name as a password to get access to the management resources. Because the community name is sent in every packet in clear view, these communications are not secure.

The access control mechanism provided by SNMPv1 is very simple. A community is allowed access to read or write objects in a management information base (MIB) tree. In most implementations, a community has access to all of the objects in the MIB, and you cannot restrict the access to a particular part of the MIB tree.

SNMPv3

SNMPv3 addresses the basic lack of security inherent in the previous SNMP versions by providing message security and access control. For message security, it introduces the User-Based Security Model (USM), which provides for authentication and privacy. Additionally, access control is provided with View-Based Access Control Model (VACM). Both USM and VACM provide for secure communications when you use SNMPv3.

User-Based Security Model (USM)

This model was designed to provide message security. USM supports both authentication (data integrity, data authentication) and privacy (protection against disclosure of message payload). For authentication, the protocols supported are HMAC-MD5 and HMAC-SHA. For privacy, CBC-DES 56-bit and AES 128-bit CFB mode are the supported symmetric encryption protocols. If you use the AES protocol, the z/OS Integrated Cryptographic Service Facility (ICSF) must be active. For detailed information about configuring ICSF, see [z/OS Cryptographic Services ICSF Administrator's Guide](#).

View-Based Access Control Model (VACM)

VACM is used to provide access control. With VACM, users are defined to groups that are allowed to access different views or parts of the management data (MIB objects), depending on defined data access privileges.

SNMP subagents

A subagent extends the set of MIB variables supported by an SNMP agent. z/OS Communications Server supports the following subagents:

- TCP/IP subagent
- OMPROUTE subagent
- TN3270E Telnet subagent
- Network SLAPM2 subagent

For a complete list of [MIB objects](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

The OSA Direct subagent is also shipped with the z/OS Communications Server product, but is supported by the System z OSA Support Group.

TCP/IP subagent

The TCP/IP subagent in z/OS Communications Server is a z/OS UNIX application that runs in its own task in the TCP/IP address space. This subagent supports many standard (RFC-based) MIB objects. In addition, it supports MIB objects in the following enterprise-specific MIB modules:

- The IBM 3172 enterprise-specific MIB.
- The IBM MVS TCP/IP enterprise-specific MIB. This MIB defines objects to extend standard MIB tables and supports retrieval and change of TCP/IP address space configuration parameters.

For a more detailed list of all the data supported by the [TCP/IP subagent](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

The TCP/IP subagent supports management data for OSA-Express. The OSA Direct subagent supports management data for both the OSA-Express and Network Express features. You should use the OSA Direct subagent to obtain this management data, for the following reasons:

- Because the OSA Direct subagent communicates directly with the OSA features, it does not require the OSA/SF and IOASNMP applications.
- The OSA Direct subagent provides more OSA management data than the TCP/IP subagent.
- Because of the support provided by the OSA Direct subagent, there will be no new enhancements to the OSA management data provided by the TCP/IP subagent, and support for this data will eventually be removed in a future release.

If you are using the TCP/IP subagent's OSA management data support, and decide to switch to using the OSA Direct subagent instead, you no longer need to start the OSA/SF address space and the OSA IOASNMP application. For more information about this subagent, see [“OSA Direct subagent” on page 1271](#). For information on the TCP/IP subagent's dependency on OSA/SF and IOASNMP, see [“Step 4: Configure the Open Systems Adapter support” on page 1291](#).

The TCP/IP subagent support evolves with each release. New MIB objects might be supported, and, occasionally, old ones might be removed for functions that are no longer relevant. This is particularly true for the MIB objects in the IBM MVS TCP/IP enterprise-specific MIB. This MIB's definition is shipped as file `/usr/lpp/tcpip/samples/mvstcpip.mi2`. For details of the changes for each release, see the REVISION sections of this MIB module file.

The TCP/IP subagent in z/OS Communications Server provides SET support, enabling remote configuration of some TCP/IP address space parameters. The TCP/IP subagent is configured and controlled by the SACONFIG statement in the PROFILE.TCPIP data set. Systems where SNMP support is not required can disable the subagent and save system resources.

OMPROUTE subagent

The OMPROUTE subagent implements the Open Shortest Path First (OSPF) MIB variable containing OSPF protocol and state information.

The OMPROUTE subagent supports selected MIB objects defined in RFC 1850.

For a detailed description of the OMPROUTE subagent, see [z/OS Communications Server: IP Configuration Reference](#).

TN3270E Telnet subagent

The SNMP TN3270E Telnet subagent provides Telnet transaction data for monitored Telnet connections using the SNMP protocol. For more information about configuring the TN3270E Telnet subagent, see the [TNSACONFIG](#) statement in [z/OS Communications Server: IP Configuration Reference](#).

Network SLAPM2 subagent

The z/OS Communications Server Network SLAPM2 subagent (nslapm2) enables network administrators to retrieve data to determine whether the current set of Network SLAPM2 policy definitions are performing as needed or whether adjustments need to be made. The Network SLAPM2 subagent supports the Network Service Level Agreement Performance Monitor (NETWORK-SLAPM2) MIB. For more information about the Network SLAPM2 MIB, see [usr/lpp/tcpip/samples/slapm2.mi2](#).

For a detailed description of the nslapm2 subagent, see the information on [Policy Agent and policy applications](#) in [z/OS Communications Server: IP Configuration Reference](#).

OSA Direct subagent

The OSA Direct subagent supports management data for both OSA-Express and Network Express features. The OSA Direct subagent is shipped with the z/OS Communications Server product, but is supported by the System z OSA Support Group. The MVS started procedure name of this subagent is IOBSNMP. For a complete understanding of the management data provided by the OSA Direct subagent, and information on configuring the subagent, see <https://www.ibm.com/docs/en/zos/2.3.0?topic=osa-z-systems-express-customers-guide-reference>.

Tip: The `-c` parameter in the IOBSNMP MVS started procedure, specifies the SNMP community name value for connections between the OSA Direct subagent and the SNMP agent, OSNMPD. If you want to avoid externalizing this value for security reasons, you can use the MVS JCL `PARMDD` parameter on the EXEC statement to pass all the parameters to the subagent in a data set. For example, you could set up your IOBSNMP started procedure as follows:

```
//IOBSNMP  PROC
//*
//* Using PARMINDD for the PARMS that were on the PROC line
//*
//IOBSNMP  EXEC PGM=IOBSNMP,TIME=1440,REGION=4096K,DYNAMNBR=5,
//          PARMDD=PARMINDD
//SYSPRINT DD  SYSOUT=*
//SYSUDUMP DD  SYSOUT=*
//PARMINDD DD  DISP=SHR,DSN=SYS1.IOBSNMP.PARMS

The SYS1.IOBSNMP.PARMS data set could contain:
-c my_community_name -d 0 -s TCPIP
```

For more information on the `PARMDD` parameter, see [z/OS MVS JCL Reference](#).

The OSA Direct subagent is required for Network Express and is optional for OSA-Express. The TCP/IP subagent also supports management data for OSA-Express features, but you should use the OSA Direct subagent to obtain this management data for the following reasons:

- The OSA Direct subagent communicates directly with the OSA-Express features and does not require the OSA/SF and IOASNMP applications.
- The OSA Direct subagent provides more OSA management data than the TCP/IP subagent.

- The TCP/IP subagent does not support management data for OSA-Express3 or later features.
- Because of the support provided by the OSA Direct subagent, there will be no new enhancements to the OSA management data provided by the TCP/IP subagent, and support for this data will eventually be removed in a future release.

If you are using the TCP/IP subagent's OSA management data support, and decide to switch to using the OSA Direct subagent instead, you no longer need to start the OSA/SF address space and the OSA IOASNMP application.

Key generation commands

The **pwtokey** and **pwchange** commands are provided to enable generation and change of keys used for authentication and encryption with SNMPv3.

For more information about **pwtokey**, see [z/OS Communications Server: IP Configuration Reference](#). For information about **pwchange**, see [z/OS Communications Server: IP System Administrator's Commands](#).

Distributed Protocol Interface

The DPI is an application interface used by the SNMP agent to communicate with subagents. With DPI, you can dynamically add, delete or replace management variables supported by the SNMP agent and its subagents. z/OS Communications Server provides DPI V2.0 for z/OS UNIX C socket users and DPI V1.1 for traditional C socket users. DPI V2.0 provides additional function, making it easier to write subagents and simplifying the task of developing and administering your application.

The SNMP agent also listens on a TCP ephemeral port number (>1023) that is used for subagent communication via the DPI. You cannot control this port number because of the way ephemeral ports are given out. When the SNMP agent asks for an ephemeral port, it gets the next one available. See RFC 1228 for more information.

For more information about the DPI, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Trap forwarder daemon

The trap forwarder daemon enables multiple SNMP managers to receive SNMP traps from the same TCP/IP stack. The trap forwarder daemon listens for traps on a port, usually the well-known port 162, and forwards the traps to all configured managers.

For more information about the trap forwarder daemon, see [z/OS Communications Server: IP Configuration Reference](#).

Processing an SNMP request

Figure 157 on page 1272 illustrates the flow of processing an SNMP request when the request is for data supported by the TCP/IP subagent.

Figure 157. Overview of SNMP support

The following list describes the sequence of events that occur from the time you issue an SNMP command until you receive the response:

1. The user issues a NetView SNMP command or a z/OS UNIX **snmp** command.
2. The command processor validates and encodes the request in a Protocol Data Unit (PDU), and sends it in a UDP packet to the SNMP agent. The SNMP agent can be on the same MVS image or on a different MVS image.
3. The SNMP agent validates the request and, if necessary, sends it to an SNMP subagent. Requests for agent-oriented objects are handled by the agent and all others are handled by a subagent. To determine which objects are handled by the agent and which objects are handled by a subagent, see the *Management Information Base (MIB) objects* appendix in [z/OS Communications Server: IP System Administrator's Commands](#).
4. The agent sends the response to the originator of the request. The command processor displays the response.

Tip: Although not shown in Figure 157 on page 1272, other subagents that are shipped as part of z/OS Communications Server, such as the OMPROUTE subagent, the Network SLAPM2 subagent, and the TN3270E Telnet subagent, also communicate with the SNMP agent using AF_UNIX socket calls from their own address spaces.

The SNMP agent and the SNMP subagents record trace information through the z/OS UNIX syslog daemon (syslogd) using the *daemon* facility. For more information about syslogd and specifying the daemon facility in the `/etc/syslog.conf` configuration file, see [“Logging of system messages”](#) on page 30.

Deciding on SNMP security needs

The SNMP agent supports SNMPv1, SNMPv2c, and SNMPv3 security.

Community-based security

SNMPv1 and SNMPv2c are community-based security, where a community name (or password) is passed with a request. If the community name is recognized as one that can be used by the IP address from which the request originates, the SNMP agent processes the request.

User-based security

SNMPv3 provides a more powerful and flexible framework for message security and access control. Message security involves providing:

- Data integrity checking, to ensure that the data was not altered in transit
- Data origin verification, to ensure that the request or response originates from the source from which it claims to have come
- Message timeliness checking and, optionally, data confidentiality, to protect against eavesdropping

Access control is the ability to control exactly what data an individual user can read or write.

The SNMPv3 architecture introduces the User-Based Security Model (USM) for message security and the View-Based Access Control Model (VACM) for access control. The architecture supports the concurrent use of different security, access control, and message processing models. For example, community-based security can be used concurrently with USM.

USM uses the concept of a user for which security parameters (levels of security, authentication and privacy protocols, and keys) are configured at both the agent and the manager. Messages sent using USM are better protected than messages sent with community-based security, where passwords are sent in the clear and displayed in traces. With USM, messages exchanged between the manager and the agent have data integrity checking and data origin authentication. Message delays and message replays (beyond what happens normally due to a connectionless transport protocol) are protected against with the use of time indicators and request IDs. Data confidentiality, or encryption, is also available.

The use of VACM involves defining collections of data (called views), groups of users of the data, and access statements that define which views a particular group of users can use for reading, writing, or receipt in a notification.

The SNMP agent can be configured to use USM and VACM by specifying SNMPD.CONF information. SNMPv3 also introduces the ability to dynamically configure the SNMP agent using SNMP SET commands against the MIB objects that represent the agent's configuration. These MIB objects are defined in RFC 3584 and RFC 3411 through 3415. This dynamic configuration support enables addition, deletion, and modification of configuration entries either locally or remotely. Remote modification of user keys can be especially useful.

Decide on your security needs - community-based or user-based

If you are satisfied with the security of your existing configuration, you can continue to use community-based security with no migration. If you would like to take advantage of USM or VACM, or if you have some SNMP managers that use SNMPv3, you will need to migrate your configuration. Note that USM can be used only when both the SNMP agent and the manager requesting the data support USM, as the z/OS Communications Server SNMP agent and the **snmp** command do. VACM can be used even for community-based requests, but doing so requires migration of existing community name and trap destination definitions in PW.SRC and SNMPTRAP.DEST to SNMPD.CONF.

Even if your managers continue to be community-based, there are important advantages to migrating your PW.SRC information to SNMPD.CONF format:

- Enables users to make use of the access control mechanism provided with SNMPv3 with community-based security.
- Provides the ability to dynamically configure the z/OS SNMP agent using MIBs.
- Provides a way of easing into SNMPv3 user-based security.
- Does not require any changes to the manager configuration.

The following tables list the advantages and disadvantages of using each type of security.

<i>Table 71. SNMPv1/SNMPv2c advantages and SNMPv3 disadvantages</i>	
SNMPv1/SNMPv2c advantages	SNMPv3 disadvantages
Widely implemented on many platforms.	Not yet implemented on many platforms.
Easy to configure.	More robust configuration options.

<i>Table 72. SNMPv1/SNMPv2c disadvantages and SNMPv3 advantages</i>	
SNMPv1/SNMPv2c disadvantages	SNMPv3 advantages
Legacy standards-based administrative model.	New standards-based administrative model.
SNMPv1 and SNMPv2c allow particular IP addresses to access all data or no data.	SNMPv3 allows a particular user to access particular data.
Not very robust (password sent in PDU).	Robust (data integrity and data origin authentication).
Any user that can read data can also change the data (for objects defined as read-write).	The ability to change data can be limited to specific users.
No data confidentiality.	Encryption available.
Configuration changes require restarting of SNMP agent.	Configuration changes for USM and VACM can be made dynamically, either locally or remotely.

For more information about security, see [“Creating user keys” on page 1281](#).

Step 1: Configure the SNMP agent

Figure 158. Configuration files for SNMP agent

Configure the SNMP agent (OSNMPD) based upon your security need. The SNMP agent accepts both SNMPv1 and SNMPv2c requests for community-based security. The SNMP agent can be configured to also use the User-based Security Model and the View-based Access Control Model. You should assign the SNMP agent and all the SNMP subagents to the same WLM service class so that they all have the same dispatching priority. Timeouts can occur if the SNMP subagents are set to a lower dispatching priority than the SNMP agent.

To configure the SNMP agent, perform the following tasks:

- [“Provide TCP/IP profile statements” on page 1275](#)
- Depending upon whether you want to use USM and VACM, see one of the following topics:
 - If you are using community-based security and do not need USM or VACM, see [“Provide community-based security and notification destination information” on page 1276](#).
 - If you want the flexibility of using USM or VACM or community-based security, see [“Provide community-based and user-based security and notification destination information” on page 1279](#).
- [“Provide MIB object configuration information” on page 1283](#)
- See [z/OS Communications Server: IP Configuration Reference](#) for more information about OSNMPD parameters.

Provide TCP/IP profile statements

Update the following configuration statements in `hlq.PROFILE.TCPIP`:

```
AUTOLOG
PORT
```

There are two primary TCP/IP ports used by the SNMP agent, one for receiving incoming requests and one for sending traps to managers.

The default port used by the SNMP agent to receive incoming requests is 161. If you want the agent to use port 161 for this purpose and want to ensure that no other application uses this port, you must specify the following PORT statement in your profile data set:

```
PORT
161 UDP OSNMPD ; SNMP Agent port for SNMP requests
```

If the agent will be started from the z/OS shell, reserve the port instead for z/OS UNIX by typing *OMVS* instead of *OSNMPD*.

If you want to define a port other than 161 for SNMP requests, take the following steps:

1. Start the agent with the *-p* parameter.
2. Configure management applications to use the new port:
 - For the **snmp** command, make an entry in the OSNMP.CONF file with the correct port number. For details on creating this entry, see the description for *targetAgent* in the OSNMP.CONF statement in the *z/OS Communications Server: IP Configuration Reference*.
 - Where supported, configure other management applications to use the new port.
3. Configure subagents to use the new port:
 - a. Specify the port number to use on the SACONFIG profile statement for the TCP/IP subagent.
 - b. Specify the port number to use on the ROUTESA_CONFIG profile statement for the OMPROUTE subagent.
 - c. Specify the port number to use on the *-p* parameter when starting the Network SLAPM2 subagent.
 - d. Specify the port number to use on the TNSACONFIG profile statement for the TN3270E Telnet subagent.
 - e. If you are using DPI subagents other than those supplied with z/OS Communications Server, set the SNMP_PORT environment variable to enable user-written subagents to connect to the agent.

The SNMP agent uses port 162, by default, for sending traps to the managers specified in SNMPTRAP.DEST or SNMPPD.CONF file. Port 162 should be reserved for the management application primarily responsible for trap processing. If your environment requires multiple management applications at the same IP address to receive traps, consider using the Trap Forwarder Daemon. See [“Step 5: Configure the trap forwarder daemon” on page 1294](#) for more details. If the SNMP query engine is typically used for processing traps and other applications, such as snmp, that are only occasionally used, the following port reservations are recommended.

```
PORT
162 UDP SNMPQE ; SNMPQuery Engine
```

You must also reserve additional ports for use by the **snmp** command by specifying

```
nnnnn UDP OMVS
```

where *nnnnn* is a number in the range 0–65535 and *nnnnn* is used as the *-p* parameter value on the **snmp trap** command.

If you want the SNMPQE and OSNMPD address spaces to be started automatically when the TCPIP address space is started, then include SNMPQE and OSNMPD in the AUTOLOG statement:

```
AUTOLOG
SNMPQE ; SNMP Query Engine
OSNMPD ; SNMP Agent
ENDAUTOLOG
```

Provide community-based security and notification destination information

If you are using only community-based security without the view-based access control model, see the following subtopics to configure the security and trap destinations.

Provide community name information

SNMP agents are accessed by remote network management stations and by SNMP subagents. To allow network management stations to send inquiries to the SNMP agent, and SNMP subagents to connect to the SNMP agent, you can provide PW.SRC information that defines a list of community names and IP addresses that can use these community names. The community name operates as a password when accessing objects on, or connecting to, a destination SNMP agent. The subagents pass the community name to the agent on the connect request.

Guideline: Because the community name of public is a well-known name, it should not be configured to the agent due to security considerations. IBM Health Checker for z/OS can be used to check whether the community name of public has been configured to the SNMP agent. For more details about IBM Health Checker, see [IBM Health Checker for z/OS User's Guide](#).

All of the z/OS Communications Server SNMP subagents connect to the agent using the IPv4 primary interface IP address of the stack with which the subagent is associated, and a community name. As long as SOURCEVIPA is not in effect on the IPCONFIG profile statement, this IP address is the source IP address that the agent uses, along with the community name, to verify the subagent's authority to connect to the SNMP agent. The IPv4 primary interface IP address is either the first IP address in the HOME list or the IP address specified on a PRIMARYINTERFACE TCP/IP profile statement. If SOURCEVIPA is in effect, the IP address used by the agent to verify the subagent's authority is the virtual IP address associated with the IPv4 primary interface IP address. For information on determining which virtual IPv4 address is associated with a physical IPv4 address, see the [HOME statement in z/OS Communications Server: IP Configuration Reference](#). Check the Netstat HOME/-h output to verify the IPv4 primary interface address of the stack.

The PW.SRC information is optional. If no PW.SRC information is found and no community name is specified for the -c parameter at agent invocation, then the SNMP agent will accept requests with a community name of 'public' from any IP address. If a PW.SRC file exists, but is empty, and if no community name is specified on the -c parameter at the agent invocation, then no requests will be accepted by the agent.

Note: Verify that there is no SNMPD.CONF file because this file can be used only with SNMPv3. If an SNMPD.CONF file is found, the PW.SRC file will not be used.

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

PW.SRC example

The PW.SRC statements could be specified as follows:

```
passwd1 9.0.0.0      255.0.0.0
passwd2 129.34.81.22 255.255.255.255
IPv6passwd3 12ab::0 16
IPv6passwd4 39B3::F430:03EE 128
```

The PW.SRC statements specify community names and hosts that can use each community name. The format of a statement is:

*community_name**desired_network**snmp_mask*

See [z/OS Communications Server: IP Configuration Reference](#) for more information about syntax.

The community name of an incoming SNMP request is compared to the known community names. If a match is found, then the IP address of the incoming request is logically ANDed with the *snmp_mask* of the PW.SRC statement. The result of the logical ANDing process is compared with the *desired_network*. If they match, the request is accepted.

In the case of a password definition to be used by an IPv6 address or range of IPv6 addresses, the *snmp_mask* can be specified as a prefix value. The prefix specifies the number of bits to be used to construct an IPv6 address mask.

In the preceding example, if a request for *community_name* passwd1 is received from the IP address 9.34.22.122, IP address 9.34.22.122 is ANDed with 255.0.0.0. The result is 9.0.0.0, which equals the specified *desired_network* for passwd1, so this request is accepted. In passwd2, if the *community_names* match, only requests from host 129.34.81.22 are accepted. The password IPv6passwd3 can be used by any IPv6 address that starts with 12ab.

If the *community_name* values do not match, or the IP address ANDed with the *snmp_mask* does not match, an AUTHENTICATION_FAILURE trap is sent if both of the following conditions are true:

- A destination entry exists in SNMPTRAP.DEST.
- Authentication failure traps have been enabled. These traps are enabled by either setting MIB object snmpEnableAuthenTraps.0 to 1, or specifying the following statement in the OSNMPD.DATA configuration information:

```
snmpEnableAuthenTraps 1
```

A *desired_network* and *snmp_mask* of all zeros allows anyone with the correct *community_name* to make requests. However, the passwords for IPv4 addresses and the passwords for IPv6 addresses are stored and handled separately. Defining a password for use by both IPv4 and IPv6 addresses requires two entries in PW.SRC. Likewise, defining a password to be used by all addresses (both IPv4 and IPv6) requires two entries as follows:

```
passwd5 0.0.0.0 0.0.0.0
passwd5 0::0 0
```

Note: By default, the SNMP agent and the **snmp** command send packets such that a VIPA address will be used as the originating address in the packet, if SOURCEVIPA is configured. This is a change introduced in V2R10; previously, the SNMP agent and the **snmp** command set a socket option to cause the physical interface addresses to be used as the originating addresses on packets they sent. That meant the PW.SRC file had to contain all of the possible physical interface addresses that might be used, rather than a smaller number of VIPA addresses. A customer can override this change in behavior, if wanted. This can be done for the SNMP agent by invoking it with the -a option. Similarly, you can do the same for the UNIX **snmp** command by either invoking it from the command line with the -a option, or by coding NOSVIPA in the command's OSNMP.CONF configuration file.

Provide trap destination information

Traps are unsolicited messages that are sent by an SNMP agent to an SNMP network management station. An SNMP trap contains information about a significant network event. The management application running at the management station interprets the trap information sent by the SNMP agent.

Note: When the SNMP agent starts, it retrieves an IP address for itself. If it retrieves an IPv6 colon-hexadecimal address, when it sends traps the source IP address in each trap will be 0.0.0.0.

For a detailed description of the SNMP trap types provided by z/OS CS, see [z/OS Communications Server: IP System Administrator's Commands](#).

The SNMP agent Distributed Protocol Interface allows subagents other than those shipped with z/OS Communications Server (which might be running on another host) to generate SNMP traps. This can allow for support of other types of traps. For more information about SNMP DPI, see the [z/OS Communications Server: IP Programmer's Guide and Reference](#).

To use traps, you must provide SNMPTRAP.DEST information defining a list of managers to which traps are sent. The SNMPTRAP.DEST information is optional. If no trap destination file is found, then the SNMP agent sends traps to the IP address of the SNMP agent and issues a warning message indicating that defaults are in effect. If a trap destination file exists, but is empty, no traps are sent.

Guideline: If you use SNMPTRAP.DEST to configure trap information, the agent uses the hardcoded community name of public in the outbound traps. Because the community name of public is a well-known name, it should not be used in SNMP traps due to security considerations. To configure specific community names for trap destinations, you must convert your SNMPTRAP.DEST information to a SNMPD.CONF configuration file format. For more information about how to accomplish this conversion,

see migrating `PW.SRC` and `SNMPTRAP.DEST` to `SNMPD.CONF` in [z/OS Communications Server: IP Configuration Reference](#).

Note: Verify that there is no `SNMPD.CONF` file. If an `SNMPD.CONF` file is found, the `SNMPTRAP.DEST` file will not be used.

If creating a data set, you can specify a sequential data set with the following attributes: `RECFM=FB`, `LRECL=80`, and `BLKSZ=3120`. Other data set attributes might also work, depending on your installation parameters.

SNMPTRAP.DEST example

The `SNMPTRAP.DEST` statements could be specified as follows:

```
# SNMP Trap Destination information
124.34.216.1 UDP
39B3::F430:03EE UDP
MVSSYS2      UDP
```

See [z/OS Communications Server: IP Configuration Reference](#) for more information about syntax.

Provide community-based and user-based security and notification destination information

If you want to use user-based security, either concurrently with or instead of community-based security, you must configure security definitions and notification destinations. To allow SNMP subagents to connect to the SNMP agent using user-based security, you must configure community-based security definitions. The SNMP subagents pass the community name to the agent on the connect request. The community name operates as a password when the SNMP subagents connect to the SNMP agent.

Guideline: Because the community name of `public` is a well-known name, it should not be configured to the agent due to security considerations. IBM Health Checker for z/OS can be used to check whether the community name of `public` has been configured to the SNMP agent. For more details about IBM Health Checker, see [IBM Health Checker for z/OS User's Guide](#).

All of the z/OS Communications Server SNMP subagents connect to the agent using the IPv4 primary interface IP address of the stack with which the subagent is associated, and a community name. As long as `SOURCEVIPA` is not in effect on the `IPCONFIG` profile statement, this IP address is the source IP address that the agent uses, along with the community name, to verify the subagent's authority to connect to the SNMP agent. The IPv4 primary interface IP address is either the first IP address in the `HOME` list or the IP address specified on a `PRIMARYINTERFACE` TCP/IP profile statement. If `SOURCEVIPA` is in effect, the IP address used by the agent to verify the subagent's authority is the virtual IP address associated with the IPv4 primary interface IP address. For information on determining which virtual IPv4 address is associated with a physical IPv4 address, see the `HOME` statement in [z/OS Communications Server: IP Configuration Reference](#). Check the `Netstat HOME/-h` output to verify the IPv4 primary interface address of the stack.

SNMPv3 provides the ability to configure the agent dynamically, from either a local or remote host, and to make changes in the configuration while the SNMP agent is running. Doing SNMP agent configuration dynamically requires a good understanding of how the SNMP SET commands can be issued to create new rows or to change or delete existing rows, as well as familiarity with the SNMP engine configuration tables defined in RFCs 3584 and 3411 through 3415. For information about accessing RFCs, see [Appendix G, "Related protocol specifications,"](#) on page 1439.

As an alternative to dynamically configuring the SNMP agent, z/OS Communications Server supports a configuration file to be read at agent initialization called the `SNMPD.CONF` file. Dynamic configuration changes made with SNMP SET commands to the SNMP agent configuration entries will be written out to the `SNMPD.CONF` file, so they will continue to be in effect even after the SNMP agent is restarted.

SNMPD.CONF file

The SNMPD.CONF file defines the SNMP agent security and notification destinations. If the SNMPD.CONF file exists, the agent can support SNMPv1, SNMPv2c, and SNMPv3 requests. If no SNMPD.CONF file exists, the agent will support only SNMPv1 and SNMPv2c requests. See [Coding the SNMPD.CONF entries in z/OS Communications Server: IP Configuration Reference](#) for descriptions of the SNMPD.CONF configuration statements.

Note: If the SNMPD.CONF file is found, the PW.SRC file and the SNMPTRAP.DEST files are not used.

SNMPD.CONF dynamic configuration

If the SNMPD.CONF information is located in an MVS data set rather than a z/OS UNIX file, special considerations must be made to support dynamic configuration changes to the SNMP agent's configuration. If dynamic configuration changes are made, the file is rewritten to reflect the changes. Therefore, consider the following items when allocating the SNMPD.CONF file to an MVS data set:

- The record length (LRECL) should be 512 bytes to accommodate the longest possible entry.
- The use of a member of a partitioned data set is tolerated but not recommended. Because the file might be rewritten often, frequent compression of the partitioned data set may become necessary. In addition, locking on the file is done at the data set level, not at the member level, so other members of the partitioned data set would not be usable while the SNMP agent was running (after a dynamic configuration change had been made).

SNMPD.CONF example

A sample SNMPD.CONF file is shipped as /usr/lpp/tcpip/samples/snmpd.conf.

See [z/OS Communications Server: IP Configuration Reference](#) for more information about syntax.

The sample OSNMP.CONF file used by the **snmp** command contains entries that match the sample SNMPD.CONF data set. See [“Configure the z/OS UNIX snmp command” on page 1286](#) for additional information on configuring the **snmp** command.

Note: By default, the SNMP agent and the **snmp** command send packets such that a VIPA address will be used as the originating address in the packet, if SOURCEVIP is configured. This is a change introduced in V2R10; previously, the SNMP agent and the **snmp** command set a socket option to cause the physical interface addresses to be used as the originating addresses on packets they sent. That meant the SNMPD.CONF file had to contain all of the possible physical interface addresses that might be used, rather than a smaller number of VIPA addresses. A customer can override this change in behavior, if wanted, by invoking the SNMP agent with the -a option or by using either the -a option or the NOSVIP option in the **snmp** command's OSNMP.CONF configuration file.

SNMPD.BOOTS

The SNMP agent uses the SNMPD.BOOTS configuration file to support SNMPv3 security. This file contains agent information used to authenticate the SNMPv3 requests. The SNMPD.BOOTS keeps the agent identifier and the number of times the agent reboots. If no SNMPD.BOOTS file exists when the agent is started, the agent creates one. You may want to add comments to the beginning of this file. If a file does exist, the agent uses the values specified in the file for setting its engineID and engineBoots values. If the file exists but contains incorrect values for engineID or engineBoots, the agent issues a message and terminates.

Notes:

1. The recommended approach is to allow the SNMP agent to create the file.
2. If the SNMPD.BOOTS file is not provided, the SNMP agent creates the file. If multiple SNMPv3 agents are running on the same MVS image, use the environment variable to specify different SNMPD.BOOTS files for the different agents. For security reasons, ensure unique engineIDs are used for different SNMP agents.

Creating user keys

- Authentication

Authentication is generally required for SNMPv3 requests to be processed (unless the security level requested is 'noAuth'). When authenticating a request, the SNMP agent verifies that the authentication key sent in an SNMPv3 request can be used to create a message digest that matches the message digest created from the authentication key defined for the user.

The **snmp** command uses the authentication key found on an entry in the OSNMP.CONF configuration file. It needs to correlate with the authentication key specified on a USM_USER entry for that user in the agent's SNMPD.CONF configuration file.

As an alternative to storing authentication keys in the client configuration file, the **snmp** command allows user passwords to be stored. If the **snmp** command is configured with a password, the code generates an authentication key (and privacy key if requested) for the user. These keys must, of course, produce the same authentication values as the keys configured for the USM_USER in the agent's SNMPD.CONF file or configured dynamically with SNMP SET commands. However, the use of passwords in the client configuration file is considered less secure than the use of keys in the configuration file.

The authentication key is generated from two pieces of information:

- The specified password.
- The identification of the SNMP agent at which the key will be used. If the agent is an IBM agent and its engineID was generated using the vendor-specific engineID formula, the agent may be identified by IP address or host name. Otherwise, the engineID must be provided as the agent identification.

A key that incorporates the identification of the agent at which it will be used is called a localized key. It can be used only at that agent. A key that does not incorporate the engineID of the agent at which it will be used is called nonlocalized.

Keys stored in the **snmp** command's configuration file, OSNMP.CONF, are expected to be nonlocalized keys. Keys stored in the SNMP agent's configuration file, SNMPD.CONF, can be either localized or nonlocalized, though the use of localized keys is considered more secure.

- Encryption

Keys used for encryption are generated using the same algorithms as those used for authentication. However, key lengths might differ. For example, an HMAC-SHA authentication key is 20 bytes long, but a localized encryption key used with HMAC-SHA is only 16 bytes long. The SNMP agent, z/OS UNIX **snmp** command, and the SNMP manager API use the first 16 bytes of the HMAC-SHA authentication key as the localized encryption key (also called the privacy key).

z/OS Communications Server provides a facility called *pwtokey* that enables conversion of passwords into localized and nonlocalized authentication and privacy keys. The pwtokey procedure takes as input a password and an identifier of the agent and generates authentication and privacy keys. Because the procedure used by the pwtokey facility is the same algorithm used by the **snmp** command, the person configuring the SNMP agent can generate appropriate authentication and privacy keys to put in the SNMPD.CONF file for a user, given a particular password and the IP address at which the agent will run.

Use the **pwtokey** command to convert passwords into authentication and privacy keys. See [z/OS Communications Server: IP System Administrator's Commands](#).

Migrating community-based configuration to SNMPD.CONF format

If you want to continue to use community-based security but take advantage of some of the new SNMPv3 functions, or if you want to use the new SNMPv3 user-based security along with community-based security, you need to migrate your current configuration, defined in PW.SRC and SNMPTRAP.DEST, to SNMPD.CONF format. For information about the necessary steps for [migrating PW.SRC and SNMPTRAP.DEST to SNMPD.CONF](#), see [z/OS Communications Server: IP Configuration Reference](#).

Provide secure access to agent from subagents

An SNMP subagent can connect to the z/OS Communications Server SNMP agent by using the DPI API (the DPI API is documented in [z/OS Communications Server: IP Programmer's Guide and Reference](#)) and specifying either a z/OS UNIX or a TCP connection. You can control access to the agent from subagents for both types of connections.

Connecting to the agent through z/OS UNIX

For subagents that specify a z/OS UNIX connection to the agent, a z/OS UNIX path name is used for the connection. You can configure this path name by either specifying it on the `-s` agent initialization parameter or specifying it as the value of the `dpiPathNameForUnixStream` MIB object in `OSNMPD.DATA`. The default path name is `/var/dpi_socket`.

The SNMP agent creates this path name every time it initializes. For subagents to successfully connect to the agent using this path name, either the subagents must be defined with superuser authority or the read and write file access permission bits for the path name must be set as follows:

- If the user ID of a subagent is associated with the same security product group as the agent, read and write access must be set in the Group section of the file access permission bits.
- If the user ID of a subagent is not associated with the same security product group as the agent, read and write access must be set in the Other section of the file access permission bits.

You can configure the read and write access by specifying the `-C` agent initialization parameter.

For more detailed information about file access permission bits and [handling security for your files](#), see [z/OS UNIX System Services User's Guide](#). If you need to change the file access permission bits for the path name after the agent has initialized, you can use the z/OS UNIX **chmod** command. For more information about the `chmod` - Change the mode of a file or directory command, see [z/OS UNIX System Services Command Reference](#).

Connecting to the agent through TCP

For subagents specifying a TCP connection, you can use the installation's SAF-compliant security product [such as the z/OS Security Server (RACF)] to control which of the SNMP subagents are permitted to connect to the SNMP agent. One security product resource name can be created per TCP/IP stack per MVS image. The security product resource name is specified in the following format:

```
EZB.SNMPAGENT.sysname.tcpprocname
```

where *sysname* is the name of the MVS system image and *tcpprocname* is the TCP/IP started procedure name.

The profile must be created under the SERVAUTH class. After creating the profiles, use the security product to define the user IDs of those subagents which should be permitted to connect via TCP to the SNMP Agent. Authorization failures are documented by security product failure messages and SNMP agent traces.

Note: If you use this authorization function, only SNMP subagents which are associated with the same TCP/IP stack as the SNMP agent will be permitted to connect to the agent. Local SNMP subagents that are associated with other TCP/IP stacks, or remote SNMP subagents, will not be permitted to connect. The following ICH0408I RACF error message is issued:

```
ICH0408I JOB(OSNMPD ) STEP(OSNMPD )
EZB.SNMPAGENT.sysname.tcpprocname CL(SERVAUTH)
INSUFFICIENT ACCESS AUTHORITY
FROM EZB.SNMPAGENT.** (G)
ACCESS INTENT(READ ) ACCESS ALLOWED(NONE )
```

In the ICH0408I message, only the JOB and STEP names are displayed instead of a user ID. Because the subagent was not associated with the same TCP/IP stack as the SNMP agent, the agent could not obtain the user ID.

Also, any subagents which connected to the SNMP agent before the agent security product resource name was created will not have been authorized via the security product.

You can use the control statements in the sample JCL job provided in SEZAINST(EZARACF) to define this authorization. For example, if you wanted to permit any SNMP subagents associated with a user ID of USER2 to connect to the SNMP agent you could use the following definitions:

```
RDEFINE SERVAUTH EZB.SNMPAGENT.MVSA.TCP1 UACC(NONE)
PERMIT EZB.SNMPAGENT.MVSA.TCP1 ACCESS(READ) CLASS(SERVAUTH) ID(USER2)
```

Allowing subagents with duplicate identifiers to connect

When an SNMP subagent connects to the SNMP agent, an SNMP object identifier (OID) value is used as the subagent identifier. For subagents connecting using the DPI V2.0 API, the subagent supplies its OID during the connection process. All the Communications Server subagents use the DPI V2.0 API when connecting to the agent.

For subagents connecting using the DPI V1.1 API, the agent assigns a constant OID value to the subagent. Therefore, if more than one DPI V1.1 subagent connects to the agent, all the DPI V1.1 subagents are identified with the same OID value.

The SUBAGENT-MIB, supported by the SNMP agent, defines the MIB object, saAllowDuplicateIDs, that can be used to configure whether the agent should allow subagents with duplicate OID values to connect. By default, the SNMP agent sets the value of this object to 1, which allows subagents with duplicate OID values to connect. You can configure the value of this MIB object using the OSNMPD.DATA configuration file. For more information about this file, see [“Provide MIB object configuration information” on page 1283](#). If you do not want the agent to allow subagents with duplicate OID values to connect, set the value of this MIB object to 2.

Provide MIB object configuration information

An installation can set values for selected MIB objects by providing OSNMPD.DATA information. A sample of OSNMPD.DATA is installed as file /usr/lpp/tcpip/samples/osnmpd.data. See [z/OS Communications Server: IP Configuration Reference](#) for syntax information. If no OSNMPD.DATA file is found, the defaults for these MIB objects are as follows:

Object

Default

dpiPathNameForUnixStream

The default is /var/dpi_socket. This is the z/OS UNIX path name that is used in accepting requests from subagents that communicate with the agent over z/OS UNIX connections.

The SNMP agent creates this path name every time it initializes. For subagents to successfully connect to the agent using this path name, either the subagents must be defined with superuser authority or the read and write file access permission bits for the path name must be set as follows:

- If the user ID of a subagent is associated with the same security product group as the agent, read and write access must be set in the Group section of the file access permission bits.
- If the user ID of a subagent is not associated with the same security product group as the agent, read and write access must be set in the Other section of the file access permission bits.

You can configure the read and write access by specifying the -C agent initialization parameter.

For more detailed information about file access permission bits and [handling security for your files](#), see [z/OS UNIX System Services User's Guide](#). If you need to change the file access permission bits for this path name after the agent has initialized, you can use the z/OS UNIX **chmod** command. For more information about the chmod - Change the mode of a file or directory command, see [z/OS UNIX System Services Command Reference](#).

sysDescr

If the environment variable HOSTNAME exists, its value is used. Otherwise, the default value identifies the z/OS system under which the agent is running. The maximum length of this object is 255 octets.

sysContact

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysLocation

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysName

"SNMPBASE-Unspecified". The maximum length of this object is 255 octets.

sysObjectId

1.3.6.1.4.1.2.3.13

Note: sysObjectID is defined as the vendor's authoritative identification of the network management subsystem contained in the entity. That is, it is intended to uniquely identify the SNMP agent. Changing this value is not recommended and will be disabled in a subsequent release.

sysServices

A single octet with a default of 0. See the RFC 1907 description for this object.

snmpEnableAuthenTraps

Default value is 2, which means traps are disabled.

saDefaultTimeout

5 seconds.

saMaxTimeOut

600 seconds.

saAllowDuplicateIDs

Default is 1, which means multiple instances of a subagent (that is, where the subagent identifier for all the subagents is the same) are allowed to connect to the SNMP agent. To prevent multiple instances of a subagent from connecting to the SNMP agent, set the value to 2.

Note: Because a subagent identifier cannot be specified for subagents connecting using the DPI V1.1 API, the SNMP agent assigns the same constant identifier for all DPI V1.1 subagents. Therefore, this object must be set to 1 to allow multiple DPI V1.1 subagents to run concurrently. For more information about subagent identifiers, see [“Allowing subagents with duplicate identifiers to connect” on page 1283](#).

For information about where these MIB objects are defined, see [z/OS Communications Server: IP User's Guide and Commands](#).

If creating a data set, you can specify a sequential data set with the following attributes: RECFM=FB, LRECL=80, and BLKSZ=3120. Other data set attributes might also work, depending on your installation parameters.

Common INET considerations

If you have configured a common INET (CINET) environment where multiple TCP/IP stacks are active, and you want to run multiple SNMP agents, each associated with a specific stack, review the following additional configuration steps:

- You probably need to create a separate set of SNMP agent configuration files for each SNMP agent that you are going to start.
- If you want to start SNMP subagents that connect to the agent using a z/OS UNIX path name, then you need to perform the following tasks:
 - Define a unique path name for each stack.
 - Specify this path name on the SNMP agent -s start parameter.

See [OSNMPD parameters](#) in [z/OS Communications Server: IP Configuration Reference](#) for more information about this parameter.

All of the z/OS Communications Server SNMP subagents connect to the agent using a z/OS UNIX path name.

Start the SNMP agent

The SNMP agent (OSNMPD) runs in a separate address space that executes load module EZASNMPD. OSNMPD can be started with or without parameters. When starting OSNMPD from MVS, add the parameters to the PARM= keyword on the EXEC statement of the OSNMPD cataloged procedure. When starting OSNMPD from z/OS UNIX, specify the parameters on the **osnmpd** command. See [OSNMPD parameters in z/OS Communications Server: IP Configuration Reference](#) for the command syntax.

For information about starting the SNMP agent in a common INET (CINET) environment, see [“Common INET considerations” on page 1284](#).

If the SNMP agent encounters any errors processing its configuration files, error messages are written to the syslog daemon, not to the console.

Sample JCL procedure for starting OSNMPD from MVS

Update cataloged procedure OSNMPD by copying the sample in SEZAINST(OSNMPDPR) to your system or recognized PROCLIB. Change the data set names as required to suit your local configuration. The OSNMPD address space requires access to the z/OS XL C/C++ run-time library data sets during execution.

You can pass parameters to the agent on the PARM= keyword on the EXEC statement of the OSNMPD cataloged procedure. See [z/OS Communications Server: IP Configuration Reference](#) for the command syntax and parameter information. You can specify any agent parameters that you want, as shown in the following example:

```
//OSNMPD EXEC PGM=EZASNMPD,REGION=4096K,TIME=NOLIMIT,  
// PARM='-c abc -d 255 -p 761'
```

In this example, the agent will use port 761 to accept requests, community name abc will be added to the list of community names supported by the agent, and all agent traces will be activated. For more information on tracing, see the [z/OS Communications Server: IP Diagnosis Guide](#).

Starting OSNMPD from z/OS UNIX

To run the SNMP agent in background, you must add an ampersand (&) to the command and the issuer of the command must be in z/OS UNIX superuser mode. For a detailed explanation of the parameters, see [z/OS Communications Server: IP Configuration Reference](#).

Any agent parameters that you want to specify can be added as shown in the following example:

```
osnmpd -c abc -d 255 -p 761
```

In this example, the agent will use port 761 to accept requests, community name 'abc' will be added to the list of community names supported by the agent, and all agent traces will be activated. For more information on tracing, see [z/OS Communications Server: IP Diagnosis Guide](#).

Step 2: Configure the SNMP commands

The two SNMP client applications provided with z/OS Communications Server are:

- **snmp** command in the z/OS shell
- SNMP command from the NetView environment

The SNMP command in the NetView environment requires the use of the NetView product. It supports SNMP version 1. The **snmp** command in the z/OS shell supports SNMP versions 1, 2, and 3. Depending on your requirements, you might decide to configure either or both of these clients, or to use an SNMP client on another platform.

Configure the z/OS UNIX snmp command

Figure 159. Configuration files for **snmp**

The z/OS UNIX **snmp** command is used to send SNMP requests to SNMP agents on local or remote hosts, or to receive SNMP traps or notifications. You can also use the synonym, **osnmp**, as the name of this command. The requests can be SNMPv1, SNMPv2c, or SNMPv3. For SNMPv2c and SNMPv3 requests, the OSNMP.CONF configuration file is required. The *winSNMPname* specified on an OSNMP.CONF statement can be used as the value of the **-h** parameter on the **snmp** command. For a detailed explanation of the parameters you can specify on the **snmp** command, see [z/OS Communications Server: IP System Administrator's Commands](#).

To configure the **snmp** command, perform the following tasks:

- The **snmp** command needs to be able to resolve the name of the host, on which the command is executing, to the host's IP address. You can provide this information either by configuring a domain name server or by configuring local host files. For information about the search order used to locate local host files, see the local host tables entry in [Table 37 on page 798](#). As part of its support for the SNMPv3 protocol, the command also uses this IP address when creating its SNMPv3 engineID value.
- Provide **snmp** configuration information
- Provide user MIB object information

Provide snmp configuration information

The OSNMP.CONF file is used to define target agents and, for SNMPv3, the security parameters to be used in sending requests to them.

The contents of the file, regardless of location, are the same. Only the first file found is used. A sample of this file is installed as file `/usr/lpp/tcpip/samples/snmpv2.conf`. This sample should be copied and modified for your installation. See [z/OS Communications Server: IP Configuration Reference](#) for more information.

Examples

- Example 1:

The following entry defines an SNMPv2c node for **snmp**:

```
mvs1      9.67.113.79 snmpv2c
```

where *mvs1* is the name used with the **-h** parameter on the **snmp** command and *9.67.113.79* is the IP address of the SNMPv2c agent.

- Example 2:

The following entry defines an SNMPv3 node:

```
v3mak 127.0.0.1 snmpv3 u1 - - AuthNoPriv HMAC-MD5 7a3e34265e0e029f27d8b4235ecfa987 - -
```

where *v3mak* is the name used on the *-h* parameter of the **snmp** command. An SNMP request sent using this entry uses USM user name *u1* using HMAC-MD5 authentication but no encryption.

- Example 3:

The following entry defines an SNMPv3 node. The needed authentication and privacy keys will be generated from the password *u6password*.

```
v3sap 127.0.0.1 snmpv3 u6 u6password - AuthNoPriv HMAC-SHA - - -
```

The USM user is *u6*. The authentication protocol is HMAC-SHA, and no encryption is used.

- Example 4:

The following entry defines an SNMPv3 node:

```
v3mpk_ipv6 ::1 snmpv3 u1 - - AuthPriv HMAC-MD5 7a3e34265e0e029f27d8b4235ecfa987 DES eac02a0d9fe90eca7911fdcaba20deae
```

where *v3mpk_ipv6* is the name used on the *-h* parameter of the **snmp** command. An SNMP request sent using this entry uses USM user name *u1* using HMAC-MD5 authentication and CBC 56-bit DES encryption.

Provide MIB object information in MIBS.DATA

Like other SNMP managers, when you enter the z/OS UNIX **snmp** command you can specify the object identifier (OID) of the MIB object whose value you want to retrieve. If the MIB object is supported by one of Communication Server's SNMP functions, you can also use the MIB object textual name on the z/OS UNIX **snmp** command, instead of the object identifier. All the MIB objects supported by Communications Server functions are listed in the [MIB objects](#) appendix in [z/OS Communications Server: IP System Administrator's Commands](#).

For example, to retrieve the SNMP agent sysUpTime MIB object, you can enter either of the following commands:

- ```
snmp -v get sysUpTime.0
sysUpTime.0 = 289700
```
- ```
snmp -v get 1.3.6.1.2.1.1.3.0
sysUpTime.0 = 292700
```

The 1.3.6.1.2.1.1.3 value is the OID for the sysUpTime MIB object.

If you have user-defined MIB objects or MIB objects from other products, and you want to use the textual names for these MIB objects on the z/OS UNIX **snmp** command, you can define these objects to the **snmp** command using the MIBS.DATA file. A sample of the MIBS.DATA file is installed as file */usr/lpp/tcpip/samples/mibs.data*. Copy this sample and modify it for your installation. For the search order used to locate the MIBS.DATA file, see [“Understanding search orders of configuration information” on page 13](#).

If other products provide files using MIBS.DATA syntax, append the statements from their files to your MIBS.DATA file so that these statements are accessible to the **snmp** command. For example, the IBM OSA Direct subagent provides a file in MIBS.DATA syntax so that the textual names of its OSA management data can be used with the z/OS UNIX **snmp** command. For information about how to obtain this file, see <https://www.ibm.com/docs/en/zos/2.3.0?topic=osa-z-systems-express-customers-guide-reference>.

MIBS.DATA statement syntax

The format of a statement in the MIBS.DATA file is:

```
character_object_name object_identifier object_type
```

See [z/OS Communications Server: IP Configuration Reference](#) for more information about syntax.

Configure the NetView SNMP command

Figure 160. Configuration files for NetView SNMP

The SNMP command in the NetView environment can be used to send SNMP version 1 requests to SNMP agents on either local or remote hosts. The SNMP command requires the command processor itself, the SNMPIUCV task for inter-address space communication, and the SNMP query engine, which creates the packets sent to the SNMP agent. The NetView SNMP command and the SNMP query engine support only community-based security.

Configure the SNMP query engine

Update the SNMPQE cataloged procedure by copying the sample in SEZAINST(SNMPPROC) to your system or recognized PROCLIB. Specify SNMP parameters and change the data set names as required to suit your local configuration. The SNMPQE address space requires access to the z/OS XL C/C++ run-time library data sets during execution.

The SNMP query engine (SQESERV) needs access to the *hlq*.MIBDESC.DATA data set for the MIB variable descriptions. You can find a sample of this data set in SEZAINST(MIBDESC).

MIBDESC.DATA data set

The MIBDESC.DATA data set defines the short names for MIB variables. Short names are the character representation for the ASN.1 variable names. For example, sysUpTime is the short name for 1.3.6.1.2.1.1.3.0 (the MIB variable that stores the time since the SNMP agent was last restarted). Short names are generally shown as a combination of upper and lowercase characters, though SNMP on z/OS Communications Server ignores these case distinctions. Variable names must always be in ASN.1 language when they are sent to an SNMP agent. You can always use ASN.1 language to specify the variable names in an enterprise-specific tree (assuming that the agent supports them). You can use these short names to specify the MIB variables.

When you issue an SNMP GET, GETNEXT, or SET command, and specify the variable name in ASN.1 notation, the SNMP Query Engine uses that name and sends it in the SNMP packet to the agent. When you issue an SNMP GET, GETNEXT, or SET command, and specify the short name for the variable (for example, sysDescr), the SNMP Query Engine looks for that name in the MIBDESC.DATA data set and uses the ASN.1 name specified in the data set when it sends the SNMP packet to the agent.

The SNMPQE address space must be able to access the MIBDESC.DATA data set.

You can change the short names in the MIBDESC.DATA data set to the equivalent in your national language. You can also leave the current names and add the equivalent names in your national language. However, the SNMP MIBVNAME function returns only the first entry found in the data set that satisfies the

search. In addition, all enterprise-specific variables used by hosts in your network should be added to this data set.

Entries in the data set do not need to be in a specific sequence. Each name starts on a new line. The following entry shows the line format.

```
short_name asn.1_name type time_to_live
```

Each variable on the line is separated by either one or more spaces or tabs. An asterisk (*) in column 1 indicates that the line is a comment line.

The following sample is a MIBDESC.DATA line with a sysDescr variable translated in Dutch and a few enterprise variables added (in this example, company ABC received 1.3.6.1.4.1.42 as the ASN.1 number for their enterprise):

```
*-----*
* MIB Variable name | ASN.1 notation      | Type   | TTL | *
*-----*
* Following is Dutch name for sysDescr
systeemBeschrijving 1.3.6.1.2.1.1.1.   display 900
sysDescr            1.3.6.1.2.1.1.1.   display 900
...
other entries
...
* Following are Enterprise-Specific variables for company ABC
ABCInfoPhone        1.3.6.1.4.1.42.1.1   display 900
ABCInfoAddress       1.3.6.1.4.1.42.1.2   display 900
```

The TTL field contains the number of seconds that a variable lives in the Query Engine's internal cache. If there are multiple requests for the same variable within the TTL period, the variable value is obtained from the cache, and unnecessary network traffic is avoided.

You can define multiple short names or text names for the same variable, as shown with the Dutch translation of the sysDescr variable. In this case, the SNMP Query Engine returns the first value in the table on an SNMP MIBVNAME request. In the previous example, the SNMP Query Engine would return systeemBeschrijving and not sysDescr. The name returned is in mixed case.

When the SNMP Query Engine receives a short name or text name in a GET, GETNEXT, or SET request, it compares the name against the entries in the MIBDESC.DATA data set. This comparison is not case-sensitive. For example, a request for SYSDSCR, SysDescr, or sysDescr matches the sysDescr entry with an ASN.1 notation of 1.3.6.1.2.1.1.1..

When the SNMP Query Engine receives an SNMP response, it looks up the variable in the MIBDESC.DATA table Type field for information about translating the value into displayable characters. The information contained in the Type field is case-sensitive and must be specified in lowercase.

Note: If you are using SNMP to receive response or trap PDUs which contain enterprise-specific variables, the variables must be added to the MIBDESC.DATA data set.

Specifying the SNMPQE parameters

The SQESERV module can be configured to start without parameters or you can add any of the following parameters to PARMS=' in the PROC statement of the SNMPQE cataloged procedure. For example,

```
//SNMPQE PROC MODULE=SNMPQE,PARMS='-h MVSA'
```

See [z/OS Communications Server: IP Configuration Reference](#) for the command syntax.

See [z/OS Communications Server: IP Diagnosis Guide](#) for more information on tracing.

Setting up authorization for SNMPQE

To create RAW sockets necessary for SNMP PING requests, the user ID associated with the SNMPQE started task must have superuser authority (z/OS UNIX UID of 0), or must be permitted to become a superuser by having READ access to the BPX.SUPERUSER resource in the FACILITY class.

Configure NetView as an SNMP monitor

To configure the NetView interface as an SNMP monitor, perform each of the following tasks:

- Configure for SNMPIUCV
- Configure for the SNMP command processor
- Configure for the SNMP messages
- Update the SNMP initialization parameters

Configure for SNMPIUCV

SNMPIUCV is the NetView optional task that handles IUCV communication between the NetView program and the SNMP query engine. SNMPIUCV is in the SEZADSIL data set.

Add the following TASK statement for SNMPIUCV to the DSIDMN member of the data set specified by the DSIPARM DD statement in the NetView start procedure.

```
TASK  MOD=SNMPIUCV,TSKID=SNMPIUCV,PRI=5,INIT=Y
```

This statement causes SNMPIUCV to start automatically when the NetView program is started.

If you specify INIT=N instead of INIT=Y in the TASK statement for SNMPIUCV, a NetView operator can start the SNMPIUCV task by entering the following command:

```
START TASK=SNMPIUCV
```

The SNMPIUCV task tries to connect through IUCV to the SNMP query engine. If this fails, it tries the connect again as specified by the SNMPQERT keyword in the SNMPARMS member of the SEZADSIP data set. The default is every 60 seconds.

Configure for the SNMP command processor

SNMP is the command processor that allows NetView operators and CLISTs to issue SNMP commands. SNMP is in the SEZADSIL data set. This data set should be concatenated to the STEPLIB DD statement in the NetView start procedure.

Add the following statement to the DSICMD member of the data set specified by the DSIPARM DD statement in the NetView start procedure.

```
SNMP  CMDMDL  MOD=SNMP,ECHO=Y,TYPE=R,RES=Y
```

After the SNMPIUCV task is started, you can issue the SNMP command. The SNMP command passes a request to the SNMPIUCV task to forward to SNMPQE. The return code represents a request number that is associated with the request. The responses are returned asynchronously and contain this request number. The operator or CLIST must use the request number to correlate the response to the request.

Configure for the SNMP messages

The NetView SNMP messages are in the SEZADSIM data set as DSISNM nn , where nn is the number of the member. The valid message members are DSISNM00 through DSISNM05, DSISNM10, DSISNM12, and DSISNM99. The data set containing these members should be added to the DSIMSG DD statement in the NetView start procedure.

Update the SNMP initialization parameters

SNMPIUCV reads the SNMPARMS member in the SEZADSIP data set at startup. This data set contains the initialization parameters for SNMP. The data set containing SNMPARMS should be added to the DSIPARM DD statement in the NetView startup procedure. See [z/OS Communications Server: IP Configuration Reference](#) for detailed information for the SNMP parameter data set (SNMPARMS).

Step 3: Configure the SNMP subagents

There are several SNMP subagents shipped with z/OS Communications Server:

- The TCP/IP subagent reports information about the TCP/IP stack. For details on configuring this subagent, see [“TCP/IP subagent configuration” on page 1291](#).
- The OMPROUTE subagent reports information specific to OSPF. The ROUTESA_CONFIG statement is used in the OMPROUTE configuration file to configure the OMPROUTE subagent. For details on ROUTESA_CONFIG, see [z/OS Communications Server: IP Configuration Reference](#).
- The Network SLAPM2 subagent reports information about defined policies and performance statistics related to traffic using those policies. For configuration information about the Network SLAPM2 subagent, see [Chapter 15, “Quality of service,” on page 857](#).
- The TN3270E Telnet subagent reports information about TN3270E Telnet server connections and monitoring values. For information on the TNSACONFIG statement and the parameters needed to start the TN3270E Telnet subagent, see [z/OS Communications Server: IP Configuration Reference](#).
- The OSA Direct SNMP subagent is also shipped with z/OS CS but is supported by the System z OSA Support Group. The OSA Direct SNMP subagent and the OSA MIB provided by the System z OSA Support Group can be used with Communications Server SNMP support to provide SNMP management data for some OSA adapters. For details regarding the OSA Direct SNMP subagent and OSA MIB, see <https://www.ibm.com/docs/en/zos/2.3.0?topic=osa-z-systems-express-customers-guide-reference>.

These subagents use the stack's IPv4 primary interface IP address when connecting to the SNMP agent. The IPv4 primary interface IP address is either the first IPv4 IP address specified in the HOME profile statement, or the IP address of the IPv4 interface specified on a PRIMARYINTERFACE profile statement. If the subagents cannot obtain the IPv4 primary interface IP address, they will use the IPv4 loopback IP address, 127.0.0.1, to connect to the agent. For information on using the IPv4 primary interface IP address and a community name to permit the subagents to connect to the SNMP agent, see [“Provide community name information” on page 1277](#) or [“Provide community-based and user-based security and notification destination information” on page 1279](#).

TCP/IP subagent configuration

There are two statements in the profile data set used to configure the TCP/IP subagent, the SACONFIG and ITRACE statements.

- SACONFIG

Use the SACONFIG statement to configure the subagent. The SACONFIG parameters determine whether or not the subagent is automatically started at TCP/IP initialization, what port number to use to contact the agent, and other configuration values. For a detailed explanation of this statement, see [z/OS Communications Server: IP Configuration Reference](#).

- ITRACE

Use the ITRACE statement to determine what trace information, if any, should be recorded by the subagent. For a detailed explanation of this statement, see [z/OS Communications Server: IP Configuration Reference](#).

Step 4: Configure the Open Systems Adapter support

The TCP/IP subagent can retrieve SNMP management data from the Open Systems Adapter Support Facility (OSA/SF) for several OSA adapters.

The OSA product also provides an SNMP subagent, the OSA Direct subagent, that supports management data for OSA adapters. You can use the OSA Direct subagent with Communications Server SNMP support to retrieve the management data. Use the OSA Direct subagent for OSA management data, rather than the TCP/IP subagent, for the following reasons:

- The OSA Direct subagent communicates directly with the OSA adapters and does not require the OSA/SF and IOASNP applications.

- The OSA Direct subagent supports all OSA adapters. The TCP/IP subagent does not support OSA-Express3 or later adapters.

For more information about the management data provided by the OSA Direct subagent, see <https://www.ibm.com/docs/en/zos/2.3.0?topic=osa-z-systems-express-customers-guide-reference>.

Restriction: The TCP/IP subagent does not support OSA-Express3 or later adapters.

The TCP/IP subagent retrieves the data using the OSA/SF components IOAOSASF (OSA/SF application) and IOASNMP (OSA/SF socket application). For more information on these components, see “OSA/SF prerequisites” on page 1292. Specifying the SACONFIG profile statement, with the OSAENABLED and OSASF parameters, in the TCP/IP profile data set causes the TCP/IP subagent to try to connect to the OSA/SF socket application, IOASNMP, using the TCP protocol and the port number specified on the OSASF parameter. If the subagent connects successfully, the following message is issued:

```
EZZ3218I SNMP SUBAGENT: CONNECTED TO OSA/SF
```

Because of timing considerations, the TCP/IP subagent might not be able to connect to IOASNMP at initialization. If this occurs, the subagent will attempt to connect when the first request for OSA MIB data is received. Therefore, the EZZ3218I message might not always be issued during subagent initialization.

When retrieving management data from the OSA adapters, the TCP/IP subagent sends a request to IOASNMP for the data, passing the adapter's portname as an identifier. The portname is obtained from the INTERFACE statements used to define the adapter to the TCP/IP stack. The IOASNMP socket application uses APPC to pass the request to the OSA/SF application. The OSA/SF application then retrieves the data from the adapter and returns it to IOASNMP. IOASNMP uses its TCP connection to the TCP/IP subagent to return the data to the subagent. If this configuration is active and either the IOASNMP application or the TCP/IP subagent terminates, the subagent will issue the following message:

```
EZZ3219I SNMP SUBAGENT: DISCONNECTED FROM OSA/SF
```

To obtain the management data, the adapters must be defined to the TCP/IP stack where the subagent is active, through IPAQENET or IPAQENET6 INTERFACE statements in the TCP/IP profile.

If the port name is manually configured at the adapter, then management data can be retrieved from the adapter even if it is not active and not in use by any TCP/IP stack or by VTAM. If the port name is dynamically configured, then the adapter has to be active to some TCP/IP stack to retrieve the management data.

Current support consists of:

- OSA Channel and Performance tables from the IBM MVS Enterprise-Specific MIB for OSA Gigabit Ethernet and Fast Ethernet adapters. The performance MIB object values in the `ibmMvsOsaExpChannelTable`, and all of the MIB object values in the `ibmMvsOsaExpPerfTable`, are only available from OSA adapters on which a microcode level of 1.31 or later is installed, and that are active on a System z processor.
- OSA Ethernet Port table from the IBM MVS Enterprise-Specific MIB for OSA Gigabit Ethernet and Fast Ethernet adapters.
- OSA Ethernet SNA table from the IBM MVS Enterprise-Specific MIB for OSA Fast Ethernet adapters.
- `dot3StatsTable` from EtherLike-MIB in RFC2665 for OSA Gigabit Ethernet and QDIO Fast Ethernet adapters.

OSA/SF prerequisites

The TCP/IP subagent provided by z/OS Communications Server will connect to OSA/SF to obtain management data. For a subagent to establish a connection to OSA/SF, two OSA/SF components must be started:

- IOAOSASF

IOAOSASF is a sample JCL procedure that can be used to start the main OSA/SF address space. The sample has a job name of OSASF1.

- IOASNMP

IOASNMP is a sample JCL procedure that starts the OSA/SF-provided z/OS UNIX socket application that interconnects the TCP/IP subagent with OSASF1.

These sample procedures and all entities that they call are provided with OSA/SF. For a detailed explanation of how to set up OSA/SF on your MVS system, see <https://www.ibm.com/docs/en/zos/2.3.0?topic=osa-z-systems-express-customers-guide-reference>. The primary purpose of OSA/SF is to manage OSA Adapters. It has been extended to support OSA management via SNMP. An instance of IOAOSASF, IOASNMP, the TCP/IP stack, the TCP/IP subagent, and the SNMP agent must be started on every MVS image where OSA management support is needed.

The recommended startup order is:

1. Start IOAOSASF and wait until it completely initializes. IOAOSASF must be started before IOASNMP.
2. Include OSNMPD (the CS SNMP agent) and IOASNMP on the AUTOLOG profile statement for your TCP/IP stack. This ensures that they will be started by autolog processing when TCP/IP is started. For additional profile statement requirements, see [“Required TCP/IP profile statements” on page 1293](#). Start the TCP/IP stack.

On an MVS image only a single instance of either IOAOSASF or IOASNMP can (or should) be started. An attempt to start multiple copies of IOAOSASF will be rejected. Starting multiple copies of IOASNMP will yield unpredictable results.

Ensure that OSA/SF is at Version 2 Release 1 level or higher with the OSA/SF APAR OW45237 applied.

Required TCP/IP profile statements

For a detailed description of the statements mentioned here, see [z/OS Communications Server: IP Configuration Reference](#). The following TCP/IP profile statements must be updated for OSA management support:

- SACONFIG

On the SACONFIG statement, OSA Management support must be enabled by specifying OSAENABLED. Omission of OSAENABLED when TCP/IP is started will result in no OSA management support. The SACONFIG statement controls the operation of the subagent that runs in a TCP/IP address space as a separate task.

The OSASF parameter specifies which port IOASNMP should use to Listen for connections from subagents to OSA/SF. For an explanation of the usage of this parameter when starting multiple TCP/IP instances, see [“Subagent connection to OSA/SF when there are multiple TCP/IP instances” on page 1294](#). It is recommended that the OSASF port be reserved by also specifying it on a PORT statement.

For example:

```
SACONFIG OSAENABLED OSASF 721
```

- PORT

Prereserve the port to be used in communication with OSA/SF.

For example:

```
PORT
  721 TCP IOASNMP ; OSA/SF TCP/IP Communications
```

In this example, because IOASNMP runs as a z/OS UNIX application, the port could have been reserved for z/OS UNIX. Review the /etc/services file to ensure that there are no port conflicts.

- INTERFACE

Provide INTERFACE statements for any OSA Express Ethernet adapter for which you want SNMP Ethernet management data. For example:

```
INTERFACE DEFINE IPAQENET PORTNAME portname IPADDR ipv4addr NONROUTER
```

Subagent connection to OSA/SF when there are multiple TCP/IP instances

When multiple z/OS Communications Server instances are active in the same MVS image, only one of the TCP/IP instances is connected to IOASNMP. For a TCP/IP instance to connect to IOASNMP, the OSASF parameter must be specified on the SACONFIG profile statement.

IOASNMP connects to a TCP/IP instance and acts as a server, receiving connections from those TCP/IP subagents where OSAENABLED was specified on the SACONFIG Profile statement. The result is that all these subagents connect through the same TCP/IP to IOASNMP in order to retrieve OSA information from OSA/SF. For a depiction of this process, see [Figure 161 on page 1294](#).

Figure 161. Subagent connection to OSA/SF

If IOASNMP loses its connection to TCP/IP it terminates and needs to be restarted.

If the currently connected TCP/IP terminates, IOASNMP will attempt to connect to another TCP/IP instance for which the OSASF parameter was specified on the SACONFIG Profile statement, using the port number specified for the OSASF parameter. The subagents will also attempt to reconnect to OSA/SF via IOASNMP using this same OSASF port number. For this reason it is recommended that the same OSASF port number be used on the SACONFIG statement of every TCP/IP instance where the OSASF parameter is specified.

Whenever a socket error occurs on the OSA/SF socket, the connected subagents will issue the following message:

```
EZZ3219I SNMP SUBAGENT: DISCONNECTED FROM OSA/SF
```

When the subagent connection is reestablished, the following message is issued:

```
EZZ3218I SNMP SUBAGENT: CONNECTED TO OSA/SF
```

Step 5: Configure the trap forwarder daemon

Most SNMPv1 agents forward traps to port 162. If a manager needs to listen for these traps, it has to bind to port 162 and listen for it. When a manager has already issued a bind it is impossible for another manager to listen for the same traps. The Trap Forwarder daemon eliminates this problem by listening for traps on port 162 and forwarding them to all the configured managers.

You can configure the Trap Forwarder daemon to receive a trap on a specified port and forward it to multiple other ports on the same host and on different hosts. This will allow multiple SNMP managers on z/OS to be able to receive all the traps sent to one port.

To configure the Trap Forwarder daemon, perform the following tasks:

1. Provide PROFILE.TCPIP statements.
2. Provide Trap Forwarder configuration.
3. Start the Trap Forwarder daemon (TRAPFWD).

Provide PROFILE.TCPIP statements

Add or update the following PORT configuration statements in *hlq.PROFILE.TCPIP*.

The default port used by the trap forwarder daemon to receive trap datagrams is UDP port 162. If you want to ensure that no other application uses this port, you must specify the following PORT statement:

```
PORT
  162      UDP      TRAPFWD          ; Trap Forwarder daemon
```

If the daemon will be started from the z/OS shell, reserve the port for z/OS UNIX by changing OMVS instead of TRAPFWD. Note that by doing so, the **snmp** command could make use of the port if it is started (with the trap option) before TRAPFWD is started.

Provide trap forwarder configuration information

The TRAPFWD.CONF file defines the configuration parameters for trapfwd daemon.

A sample of the TRAPFWD.CONF is shown below:

```
#
# A sample configuration file for trapfwd
#
# Syntax : ip_address/host_name      port_number      option
#
9.67.113.79      1064      ADD_RECVFROM_INFO
myHost          1066      ADD_RECVFROM_INFO
myHost          1067      ADD_RECVFROM_INFO
myHost          1099
9.67.35.37      1064      ADD_RECVFROM_INFO
-              1065
-              1068      ADD_RECVFROM_INFO
12ab::2         1069
```

For more information about the statement syntax, see [z/OS Communications Server: IP Configuration Reference](#).

Starting and stopping the trap forwarder daemon

The Trap Forwarder daemon can be started from the z/OS UNIX shell or from the MVS console.

Starting the trap forwarder daemon from z/OS UNIX

This example starts the Trap Forwarder daemon on the standard port (port 162).

```
# trapfwd
```

This example starts the Trap Forwarder daemon on a particular port (port 5062).

```
# trapfwd -p 5062
```

Starting the trap forwarder daemon from an MVS console

Update cataloged procedure TRAPFWD by copying the sample in SEZAINST(EZASNTRA) to your system. See [z/OS Communications Server: IP Configuration Reference](#) for more information about this cataloged procedure.

Stopping the trap forwarder daemon

From MVS:

```
P TRAPFWD
```

If TRAPFWD was started from a cataloged procedure, *procname* is the member name of that procedure. If TRAPFWD was started from the z/OS shell, *procname* is based on the *userid*. If the *userid* is 8 characters long, the *procname* is the *userid*. If the *userid* is less than 8 characters long, the *procname* is *useridX*, where X is the sequence number set by the system. To determine the sequence number issue **d omvs u=userid** from the console. This will show the programs running under the user ID.

From UNIX:

```
kill < pid >
```

Issue the **kill** command to the process ID (PID) associated with TRAPFWD. To find the PID issue the **ps -ef** command from the z/OS shell.

Tracing

The MODIFY command can be used to display the existing tracing level and also to change the tracing level.

The following example sets the trace level of the Trap Forwarder Daemon to 1.

```
MODIFY TRAPFWD,TRACE,LEVEL=1
```

The following example displays the level of tracing set for the Trap Forwarder Daemon.

```
MODIFY TRAPFWD,TRACE,QUERY
```

See [z/OS Communications Server: IP Configuration Reference](#) for more information about syntax.

Dynamically refreshing configuration

The MODIFY command can be used to dynamically refresh the configuration information. When this is done, the old configuration information is discarded completely. The configuration file is read again and the daemon is initialized.

The following example refreshes the configuration by reading the configuration file.

```
MODIFY TRAPFWD,REFRESH
```

See [z/OS Communications Server: IP Configuration Reference](#) for more information about syntax.

Chapter 24. Remote print server

Read [“Understanding search orders of configuration information”](#) on page 13. It covers important information about data set naming and search sequences.

The remote print server supports the line print daemon (LPD) and allows you to print on JES controlled printers from any host in your IP network that implements the line print client functions. These client functions are invoked with the LPR command. LPR is available as a TSO command, and the LPD server is implemented as a started z/OS task.

See [z/OS Communications Server: IP System Administrator's Commands](#) for information on starting and stopping the TCP/IP print server (LPD). When LPD is stopped by the MVS operator with the *P procname* command, LPD will terminate any TCP/IP connections currently transferring data. Before ending, LPD will finish spooling to JES any print jobs that it has received and is currently spooling. JES will handle these jobs after LPD ends.

This topic describes how to configure the LPD server. To operate the LPD server after it is running, see [z/OS Communications Server: IP Configuration Reference](#).

The LPD server uses the Pascal socket API, so VMCF must be started for the server to successfully initialize. If VMCF is not started, message EZY1980E will be issued and the server will terminate.

Configuring the Remote Print Server

Procedure

Perform the following steps to configure the Remote Print Server:

1. Specify AUTOLOG and PORT statements in PROFILE.TCPIP.
2. Update the LPD server cataloged procedure.
3. Update the LPD server configuration data set.
4. Create a banner page (optional).

Results

For information about operating and controlling the LPD server, see [z/OS Communications Server: IP Configuration Reference](#).

Step 1: Configuring PROFILE.TCPIP for LPD

If you want the LPD server started automatically when the TCPIP address space is started, include the name of the member containing the LPD server cataloged procedure in the AUTOLOG list in *hlq.PROFILE.TCPIP*. For example:

```
AUTOLOG
  LPSERVE
ENDAUTOLOG
```

To ensure that port TCP 515 is reserved for the LPD server, also add the name of the member containing the LPD cataloged procedure to the PORT statement in *hlq.PROFILE.TCPIP*. For example:

```
PORT
  515 TCP LPSERVE
```

See the [z/OS Communications Server: IP Configuration Reference](#) for more information about the AUTOLOG and PORT statements.

Step 2: Updating the LPD server cataloged procedure

Update the LPD server cataloged procedure to suit your local configuration by copying the sample to your system or recognized PROCLIB from SEZAINST(LPSPROC) and modifying the sample. Specify LPD parameters, and change the data set names as required. See [“Specifying LPD server parameters” on page 1298](#) for more information on the LPD server parameters.

Specifying LPD server parameters

The system parameters required by the LPD server are passed by the PARM option on the EXEC statement of the LPD cataloged procedure. Update the following parameters as required.

LPDDATA='data_set_name'

Specifies the fully qualified name of the data set containing the LPD configuration statements. This data set can be sequential or a member of a PDS.

LPDPRFX='PREFIX your_prefix'

Specifies the high-level qualifier to be used for temporary data sets created by the LPD server. Include both the PREFIX keyword and your qualifier in the quoted string. The qualifier may be up to 26 characters. If it is blank, the default is the procedure name. The LPD task requires the authority to create and modify data sets with this prefix.

DIAG='options'

Specifies any of the following diagnostic options in a quoted string of keywords separated by blanks. For example, DIAG= 'VERSION TRACE '

VERSION

Displays the version number.

TYPE

Activates high-level trace facility in the LPD server. Significant events, such as the receipt of a job for printing, are recorded in the //SYSOUT DD data set specified in your LPD server cataloged procedure.

TRACE

Causes a detailed trace of activities within the LPD server to record in the //SYSOUT DD data set specified in your LPD server cataloged procedure. The detailed tracing can also be activated with the DEBUG statement in the LPD server configuration data set and with the TRACE command of the SMSG interface.

Note: The JCL PARM= statement has a limit of 100 characters.

Configuring LPDDATA

Use a DD card that requires the LPD configuration file to be in a data set.

```
//SYSLPDD DD DISP=SHR,DSN=TCPIP.SEZAINST(LPDDATA)
```

Using this example, the DD card must be specified as SYSLPDD, but the data set name can be any valid data set name with a member specified up to 44 characters.

To use the DD card method, you must comment out or remove the LPDDATA= parameter from the PROC statement and remove the "&LPDDATA" PARM from the LPD EXEC statement.

Note: The search order for the configuration file is:

1. LPDDATA= on the PARM= statement
2. //SYSLPDD DD statement
3. hlq.LPD.CONFIG

If both the LPDDATA= statement on the PARM= statement and the //SYSLPDD DD statement are specified, the data set name specified on LPDDATA= is used.

The LPD server does not limit the number of print jobs it handles per connection. This can cause a memory abend to occur if too many print jobs are sent in one connection. Certain LPR clients, such as SUN UNIX, are set up to send multiple jobs in one connection. It is recommended that the LPD start procedure be started with a region size of 6M and the LPR client send no more than 50 print jobs in one connection.

Step 3: Updating the LPD server configuration data set

The LPD configuration data set defines the local, NJE, and remote services (printers and punches) used by the LPD server. To update the LPD server configuration data set, copy the sample provided in SEZAINST(LPDDATA) and modify it to suit your installation. See [z/OS Communications Server: IP Configuration Reference](#) for more details.

- To define a printer or punch:
 - Include a SERVICE statement with the appropriate parameters for each printer or punch your are defining.
 - Specify the type of service with the LOCAL, NJE, or REMOTE parameter in the SERVICE statement.
 - For local or NJE services, include any of the optional parameters to further define the service: EXIT, FAILEDJOB, FILTERS, LINESIZE, PAGESIZE and RACF.
 - For remote services, specify the destination printer and host. Any additional specifications are defined on the remote system and are not necessary in the SERVICE statement.
- To turn on LPD server tracing, include the optional DEBUG statement.
- To authorize users for the SMSG interface, include the optional OBEY statement.
- Printer names cannot contain an at sign (@).

Step 4: Creating a banner page (optional)

LPBANNER is the name of the default program that is provided in executable form in the SEZATCP data set. This program is specified on the EXIT parameter in the SERVICE statement. LPBANNER prints a separator page that contains, in large letters, a banner stating “LPD BANNER”, the user ID, the job name, and the job class. Field headings of HOST, USER, JOB, and CLASS appear in smaller letters.

The sample exit LPBANNER uses machine carriage control and is designed to be used with the SERVICE PRINTER LOCAL or SERVICE PRINTER NJE statements. To use this sample exit, both SERVICE statements require a printed LINESIZE of 78 or greater. Banner pages are usually not used with the SERVICE PUNCH or SERVICE RECFMU statements; however, if you want to have banner pages (headers) for the SERVICE PUNCH or SERVICE RECFMU devices, a user created banner exit is required.

You can either use the executable form or copy and modify the sample source provided in SEZAINST(EZAAE04S) and SEZAINST(EZAAE04T) to create a banner. If you are changing the source to create your own banner, assemble and link-edit these data sets as reentrant. You can modify and use the following JCL to do this. Changing the ENTRY and NAME to something other than LPBANNER will avoid possible maintenance problems in the future.

```
//ASMLNK JOB MSGLEVEL=(1,1),MSGCLASS=A,CLASS=A,REGION=1024K
//ASM1 EXEC PGM=ASMA90,PARM='OBJECT,XREF(FULL)'
//STEPLIB DD DISP=SHR,DSN=HLA.OSV1R4.SASMMOD1
//* ASSEMBLER H
//SYSLIB DD DSN=tcPIP_hlq.SEZACMAC,DISP=SHR
// DD DSN=SYS1.MACLIB,DISP=SHR
// DD DSN=SYS1.MODGEN,DISP=SHR
//SYSUT1 DD UNIT=SYSDA,SPACE=(CYL,(5,5)),DSN=&&SYSUT1
//SYSPUNCH DD DUMMY,DCB=BLKSIZE=80
//SYSPRINT DD SYSOUT=A
//SYSLIN DD DSN=&&OBJECT(EZAAE04S),DISP=(,PASS),UNIT=SYSDA,
// SPACE=(CYL,(5,5,1)),DCB=BLKSIZE=400
//SYSIN DD DSN=tcPIP_hlq.SEZAINST(EZAAE04S),DISP=SHR
/*
//ASM2 EXEC PGM=ASMA90,PARM='OBJECT,NODECK,XREF'
//STEPLIB DD DISP=SHR,DSN=HLA.OSV1R4.SASMMOD1
//* ASSEMBLER H
//SYSLIB DD DSN=tcPIP_hlq.SEZACMAC,DISP=SHR
```

```

//      DD DSN=SYS1.MACLIB,DISP=SHR
//      DD DSN=SYS1.MODGEN,DISP=SHR
//SYSUT1 DD UNIT=SYSDA,SPACE=(CYL,(5,5)),DSN=&&SYSUT1
//SYSPUNCH DD DUMMY,DCB=BLKSIZE=80
//SYSPRINT DD SYSOUT=A
//SYSLIN DD DSN=&&OBJECT(EZAAE04T),DISP=(OLD,PASS)
//SYSIN DD DSN=tcPIP_hlq.SEZAINST(EZAAE04T),DISP=SHR
/*
//LNK EXEC PGM=IEWL,PARM='LIST,NCAL,RENT,LET'
//SYSPRINT DD SYSOUT=A
//SYSUT1 DD UNIT=SYSDA,SPACE=(CYL,(1,1))
//SYSLMOD DD DSN=tcPIP_hlq.SEZATCP,DISP=SHR
//AEZAMODS DD DSN=tcPIP_hlq.AEZAMODS,DISP=SHR
//OBJECT DD DSN=&&OBJECT,DISP=(OLD,DELETE)
//SYSLIN DD *
ORDER EZBOECPR
INCLUDE AEZAMODS(EZBOECPR)
INCLUDE OBJECT(EZAAE04S)
INCLUDE OBJECT(EZAAE04T)
MODE AMODE(24),RMODE(24)
ENTRY LPBANNER
NAME LPBANNER(R)
/*

```

Chapter 25. Remote procedure calls

This topic contains information to help you configure the following applications and interface:

- PORTMAP
- UNIX PORTMAP
- rpcbind
- NCS

Restriction: PORTMAP, UNIX PORTMAP, and rpcbind cannot be run concurrently, because all three applications listen on the well known /etc/services sunrpc port of 111. You must determine which server will service your RPC applications.

For information about rpcbind configuration and setup in a multilevel secure environment, see [“z/OS UNIX rpcbind server”](#) on page 228.

Read [“Understanding search orders of configuration information”](#) on page 13. It covers important information about data set naming and search sequences.

Steps for configuring the PORTMAP address space

The PORTMAP address space runs the Portmapper function. Portmapper is the software that supplies client programs with the port numbers of server programs.

About this task

Clients contact server programs by sending messages to port numbers where receiving processes receive the message. Because you make requests to the port number of a server rather than directly to a server program, client programs need a way to find the port number of the server programs that they want to call. Portmapper standardizes the way clients locate the port number of the server programs supported on a network.

Procedure

Perform the following steps to configure PORTMAP:

1. Specify AUTOLOG and PORT statements in *hlq.PROFILE.TCPIP*.
2. Configure security server (or RACF equivalent) items.
3. Update the PORTMAP cataloged procedure.
4. Define the data set for well-known procedure names.

Step 1: Configuring PROFILE.TCPIP for PORTMAP

If you want the PORTMAP server to start automatically when the TCPIP address space is started, you should include PORTMAP in the AUTOLOG statement in the *hlq.PROFILE.TCPIP* data set.

```
AUTOLOG
  PORTMAP
ENDAUTOLOG
```

Note: If your system is using the Network File System (NFS) server, you must start the PORTMAP address space. See [z/OS Network File System Guide and Reference](#) for more information.

To ensure that port UDP 111 and TCP 111 are reserved for the PORTMAP server, also add the name of the member containing the PORTMAP cataloged procedure to the PORT statement in *hlq.PROFILE.TCPIP*:

```
PORT
  111 UDP PORTMAP
  111 TCP PORTMAP
```

See the [z/OS Communications Server: IP Configuration Reference](#) for more information about the AUTOLOG and PORT statements.

Step 2: Configuring security server (or RACF equivalent) items

The PORTMAP cataloged procedure assumes that the procedure has the authority to run as a started task. To ensure that the PORTMAP procedure has the appropriate security server access, enter the following commands as shown in SEZAINST(EZARACF):

```
ADDUSER PORTMAP DFLTGRP(OMVSGRP) OMVS(UID(0))
HOME(' / ')NOPASSWORD
RDEFINE STARTED PORTMAP.* STDATA(USER(PORTMAP))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

Step 3: Updating the PORTMAP cataloged procedure

Update the PORTMAP cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(PORTPROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Change the data set names as required. See [z/OS Communications Server: IP Configuration Reference](#) for more details.

Step 4: Defining the data set for well-known procedure names

z/OS Communications Server includes a data set that contains a list of commonly used procedure names. This data set is used by the RPCINFO command to resolve remote program numbers into their equivalent program names.

To create the data set, copy SEZAINST(ETCRPC) to the default data set called *hlq.ETC.RPC*. If a user has a *user_id.ETC.RPC* data set defined, it takes precedence over the preceding data set.

Normally, you would not change this data set except to add a new application to the list. To add a new application, add a line that contains the following items:

- The *program_name* of the new application or procedure
- The *program_number* of the new application or procedure
- Any comments regarding the description of the program

The items are variable in format, each separated by a blank.

The SEZAINST(ETCRPC) data set contains the well-known procedure names. The following sample is the ETCRPC sample.

```
# z/OS Communications Server
# SMP/E distribution path: /usr/lpp/tcpip/samples/IBM/EZA0ERPC
# SMP/E distribution path: SEZAINST(EZAEB01X)

Starting the PORTMAP address space

If you did not include PORTMAP in the AUTOLOG statement, you can start PORTMAP with the START command. For example:

```
START PORTMAP
```

Steps for configuring the z/OS UNIX PORTMAP address space

The z/OS UNIX PORTMAP address space runs the Portmapper function.

Procedure

Perform the following steps to configure z/OS UNIX PORTMAP:

1. Specify PORT statements in *hlq.PROFILE.TCPIP*.
2. Update the PORTMAP cataloged procedure.

Results

Step 1: Configuring PROFILE.TCPIP for UNIX PORTMAP

If you want the PORTMAP server to start automatically when the TCPIP address space is started, you should include PORTMAP in the AUTOLOG statement in the *hlq.PROFILE.TCPIP* data set.

```

AUTOLOG
  PORTMAP JOBNAME PORTMAP1
ENDAUTOLOG

```

To ensure that port UDP 111 and TCP 111 are reserved for the z/OS UNIX PORTMAP server, add the z/OS UNIX PORTMAP server jobname to the PORT statement in *hlq.PROFILE.TCPIP*. If you use the sample cataloged procedure, PORTMAP, to start the z/OS UNIX PORTMAP server, the jobname is PORTMAP1:

```
PORT
  111 UDP PORTMAP1      ; Portmapper Server
  111 TCP PORTMAP1      ; Portmapper Server
```

See the [z/OS Communications Server: IP Configuration Reference](#) for more information about the PORT statement.

Step 2: Updating the PORTMAP cataloged procedure

Update the PORTMAP cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(OPORTPRC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Change the data set names as required. See [z/OS Communications Server: IP Configuration Reference](#) for more details.

Starting the PORTMAP address space

There are two ways to start the portmapper as a z/OS UNIX socket application:

- From the z/OS shell
- As a started task

To start the portmapper from the z/OS shell, the user ID must be an authorized superuser. The authorized superuser ID can issue **oportmap &** to start the portmapper. For the authorization procedure, see [z/OS UNIX System Services Planning](#).

You can also start PORTMAP as a started task with the START command as follows:

```
START PORTMAP
```

Note: If your system is using the Network File System (NFS) server, see [z/OS Network File System Guide and Reference](#) for more information.

Steps for configuring the rpcbind address space

The rpcbind software supplies client programs with the universal addresses of RPC server programs.

Before you begin

The z/OS rpcbind server supports the portmapper binding protocol (RPC Binding Protocol Version 2) as well as other RPC binding protocols. This means you can run rpcbind instead of portmapper. Portmapper and rpcbind cannot be run at the same time, because they both listen on /etc/services sunrpc port 111.

About this task

RPC server applications do not have well-known port numbers. Instead, they obtain an ephemeral port number, create a universal address, and register that address with rpcbind. Clients contact server programs by obtaining the universal address of the server from rpcbind, and sending messages to the universal address of the server.

Procedure

Perform the following steps to configure the rpcbind address space.

1. Configure the PROFILE.TCPIP data set for rpcbind.
2. Configure security server (or RACF equivalent) items.
3. Update the RPCBIND cataloged procedure.
4. Update the /etc/services file.

5. Configure SYS1.PARMLIB for rpcbind.

Step 1: Configuring the PROFILE.TCPIP data set for rpcbind

Guideline: The rpcbind server is a generic server, as described in [“Generic servers in a CINET environment”](#) on page 49.

- In a single stack environment, you can use the AUTOLOG statement to automatically start generic servers.
- In a multiple stack environment, it is not advisable to use the AUTOLOG statement to start generic servers. You can use an operations automation software package that IBM or other companies provide to automatically start generic servers.

If you want the rpcbind server to start automatically when the TCPIP address space is started, include rpcbind in the AUTOLOG statement in the PROFILE.TCPIP data set.

```
AUTOLOG
  RPCBIND JOBNAME RPCBIND1
ENDAUTOLOG
```

To ensure that port UDP 111 and TCP 111 is reserved for the rpcbind server, add the rpcbind server job name to the PORT statement in the PROFILE.TCPIP data set. If you use the sample cataloged procedure, RPCBIND, to start the rpcbind server, the job name is RPCBIND1.

```
PORT
  111 UDP RPCBIND1      ; rpcbind server
  111 TCP RPCBIND1      ; rpcbind server
```

If you start the rpcbind server from the z/OS UNIX shell, the job name is OMVS.

```
PORT
  111 UDP OMVS          ; rpcbind server OMVS
  111 TCP OMVS          ; rpcbind server OMVS
```

For more information about the [PORT statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Step 2: Configuring security server (or RACF equivalent) items

The RPCBIND cataloged procedure assumes that the procedure has the authority to run as a started task. To ensure that the RPCBIND procedure has the appropriate security server access, enter the following commands as shown in SEZAINST(EZARACF):

```
ADDUSER RPCBIND DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0) HOME('/'))
RDEFINE STARTED RPCBIND.* STDATA(USER(RPCBIND))
SETOPTS RACLIST(STARTED) REFRESH
SETOPTS GENERIC(STARTED) REFRESH
```

You can define the SAF resource profile EZB.RPCBIND.*sysname.rpcbindname*.REGISTRY in the SERVAUTH class to control which users can register or deregister applications with rpcbind. You can use wildcards. For example, if you use wildcard values for *sysname* and *rpcbindname*, the profile name is as follows:

```
EZB.RPCBIND.*.*.REGISTRY
```

In this example, suppose the MVS system name is MVS000 and the RPCBIND cataloged procedure is used to start the rpcbind server. This procedure uses the job name RPCBIND. RPCBIND is fewer than 8 characters, so the *rpcbindname* is RPCBIND1, and the profile name is as follows:

```
EZB.RPCBIND.MVS000.RPCBIND1.REGISTRY
```

The profile EZB.RPCBIND.*sysname.rpcbindname*.REGISTRY is optional. If it is not defined, all users can register and deregister applications with rpcbind. If the profile is defined, only users granted at least READ access to this resource profile can register or deregister applications with rpcbind.

In this example, if your SAF security product is RACF and you want only the RPC server TRUESERV running under user ID TRUESERV to be able to register and deregister applications with rpcbind, you can use the following commands to define the profile EZB.RPCBIND.*.*.REGISTRY in the SERVAUTH class and grant TRUESERV read access to the profile:

```
RDEFINE SERVAUTH EZB.RPCBIND.*.*.REGISTRY UACC(NONE)
PERMIT EZB.RPCBIND.*.*.REGISTRY ID(TRUESERV) ACCESS(READ) CLASS(SERVAUTH)
```

Requirements for a multilevel secure environment:

- The profile EZB.RPCBIND.*sysname.rpcbindname*.REGISTRY is mandatory, and you must grant user IDs associated with trusted RPC servers at least READ access to this profile. For more information about running rpcbind in a multilevel secure environment, see [“z/OS UNIX rpcbind server” on page 228](#).
- If the SAF FACILITY class resource profile BPX.POE is defined, and your installation directs target assistance calls to rpcbind, you must grant the user ID assigned to rpcbind at least READ access to this profile. For more information on [target assistance](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

Tips:

- The target assistance RPCs PMAPPROC_CALLIT, RPCBPROC_CALLIT, RPCBPROC_BCAST, and RPCBPROC_INDIRECT are defined in RFC 1833 (*Binding Protocols for ONC RPC Version 2*).
- The RPC library routines clnt_broadcast and pmap_rmtcall() issue a target assistance request on behalf of the caller.
- The rpcinfo utility issues a target assistance call when it is invoked with the -b option.

Guideline: If RPCBIND is the user ID assigned to the rpcbind server, you can use the following command to grant the user ID READ access to the profile:

```
PERMIT BPX.POE CLASS(FACILITY) ID(RPCBIND) ACCESS(READ)
```

Step 3: Updating the RPCBIND cataloged procedure

Update the RPCBIND cataloged procedure to suit your local conditions by copying the sample provided in SEZAINST(RPCBIND) to your system or recognized PROCLIB, and modifying it as necessary. Change the data set names as required. For further information, see [“Starting the rpcbind address space” on page 1307](#). A copy of [RPCBIND](#) is also available in [z/OS Communications Server: IP Configuration Reference](#).

Step 4: Updating the /etc/services file

Update /etc/services to ensure that the sunrpc service is reserved for TCP and UDP port 111:

```
sunrpc    111/tcp
sunrpc    111/udp
```

Restriction: If you change the sunrpc port, rpcinfo on that host will not be able to contact the rpcbind server.

Step 5: Configure SYS1.PARMLIB for rpcbind

The rpcbind server uses semaphore sets and shared memory segments. Inspect your BPXPRMxx member in SYS1.PARMLIB and verify that the following statements are configured such that rpcbind will be able to obtain three shared memory segments of one page each, and three semaphore sets:

```
IPCSHMMPAGES
IPCSHMNSEGS
IPCSEMNIDS
IPCSEMNSEMS
```

For more information about these [SYS1.PARMLIB statements](#), see [z/OS MVS Initialization and Tuning Reference](#).

Tip: You can issue the operator command to display these values.

Starting the rpcbind address space

There are two ways to start rpcbind as a z/OS UNIX socket application:

- From the z/OS shell
- As a started task

It cannot be started from TSO.

To start rpcbind from the z/OS shell, the user ID must be an authorized superuser. The authorized superuser ID can issue to start rpcbind. For information about [Superusers in z/OS UNIX](#), see [z/OS UNIX System Services Planning](#).

You can also start rpcbind as a started task from the MVS console with the START command, as follows:

```
START RPCBIND
```

You can specify the following options when you are starting rpcbind:

- Specify -d for rpcbind to send trace information to the daemon facility of syslogd.
 - -df sends flow information.
 - -dl sends log information of all RPC procedures called.
 - -dx sends XDR information.
- The -i option enables you to specify the z/OS UNIX file system directory to which the pid file is written. The pid file name is always rpcbind.pid. If -i is not specified, the rpcbind process ID is written to /etc/rpcbind.pid.

Restriction: The directory path name must be an absolute path name. That is, it must begin with the forward slash (/) character, as shown in the following example:

```
rpcbind -i /tmp
```

- The -n option enables you to direct rpcbind to run in a non-swappable environment. A process might need to run as non-swappable to ensure that it is available during periods of high CPU usage. However, a non-swappable process might convert real storage in the system to preferred storage. Because preferred storage cannot be configured offline, allowing rpcbind to run in a non-swappable state can reduce the future ability of your installation to reconfigure storage.

If you do specify the -n option, ensure that the user ID associated with rpcbind has at least READ access to the resource profile BPX.STOR.SWAP in the FACILITY class. The default is to start rpcbind as swappable.

- The -s option specifies the number of statistics entries per binding protocol that rpcbind maintains. Valid values are in the range 113 – 500. Statistics that are maintained by the rpcbind server are used to reply to the RPCBPROC_GETSTAT request. For more information about statistics that are maintained by the rpcbind server, see RFC 1833.

Result: Rpcbind calculates the number of pages that are needed to store statistics for the value that is specified, and obtains that number of pages of shared memory for statistics. Rpcbind rounds up the number of statistics entries it tracks to fully use the shared memory.

Tip: Rpcbind does not start unless it can obtain sufficient shared memory to maintain statistics for the number of entries you specify. You configure the number of pages of shared memory available to z/OS with the IPCSSHMPAGES parameter in the BPXPRMxx member of SYS1.PARMLIB.

- To display help information, specify the -? option.

Tip:

- If your system is using the Network File System (NFS) server, for more information about [initialization attributes for the z/OS client and Network File System operation](#), see [z/OS Network File System Guide and Reference](#).
- The rpcbind server uses ENF event code 80 to send signals when rpcbind completes initialization and when rpcbind is stopping. For more information, see [Using ENF event code 80 to listen for rpcbind events in z/OS Communications Server: IP Programmer's Guide and Reference](#).

Restriction: Portmapper and rpcbind cannot be run at the same time, as they both listen on `/etc/services` port 111.

Steps for configuring the NCS interface

This topic describes how to configure the Network Computing System (NCS).

NCS is the Remote Procedure Call (RPC) implementation of Apollo's Network Computing Architecture (NCA**).

NCS includes:

1. RPC runtime library
2. Location broker
3. Network Interface Definition Language (NIDL) compiler

The RPC runtime library and the location broker provide runtime support. Together these two elements make up the Network Computing Kernel (NCK) which includes all the software necessary to run a distributed application. The NIDL compiler is a tool for developing NCS-based applications.

In order to execute NCS applications in an MVS environment, you must start a local location broker (LLBD). One of the hosts in your IP network must also start the global location broker (GLBD). Both the LLBD and the NRGLBD maintain information about active NCS server applications.

- LLBD server

The LLBD manages the LLB database which stores information for the NCS-based servers running on this host.

Your host must run LLBD if you want to support the location broker forwarding function or allow remote access to the LLB database. The LLBD function must be started on the host before any other NCS-based servers are started and before the NRGLBD is started.

The LLB database is stored in the data set `ADM@SRV.LLB@LL.DATABASE`, which is not created until an entry is registered with the LLBD. This data set can be administered using the `lb@admin` tool.

- NRGLBD server

The NRGLBD manages the NCS global location broker (GLB) database. The GLB helps clients locate servers on a network or internet.

There are two versions of the GLB daemon: replicated GLBD and NRGLBD. The replicated GLBD is available only on Apollo, SunOS, and Ultrix systems. For other systems, such as IBM, only the NRGLBD is available. The advantage of replicated GLBD over NRGLBD is that the GLBD can be run at the same time on several network hosts, providing greater availability in the event that one of the hosts running GLBD fails or if there is a partial network failure.

You cannot use the NRGLBD on your system if:

- The replicated version of GLBD can run on some other host in your network
- Another host in your network is already running NRGLBD

The GLB database is stored in a data set `ADM@SRV.LLB@LG.DATABASE`. This data set is not created until an entry is registered with the NRGLBD.

The record structure for the LLBD and the NRGLBD databases is identical.

Perform the following steps to configure NCS:

1. Specify AUTOLOG and PORT statements in *hlq.PROFILE.TCPIP*.
2. Update the NRGLBD cataloged procedure in SEZAINST(NRGLBD).
3. Update the LLBD cataloged procedure in SEZAINST(LLBD).

For more information about NCS, see *Network Computing System Reference Manual*.

Step 1: Configuring PROFILE.TCPIP for NCS

If you want LLBD and NRGLBD to start automatically when the TCPIP address space is started, then you should include the names of the members containing the LLBD and NRGLBD cataloged procedures in the AUTOLOG statement in the *hlq.PROFILE.TCPIP* data set.

The LLBD must be running before you start NRGLBD. Therefore, you must put LLBD before NRGLBD in the AUTOLOG statement.

```
AUTOLOG
  LLBD
  NRGLBD
ENDAUTOLOG
```

To ensure that port UDP 135 is reserved for the LLBD server, add the name of the member containing the LLBD cataloged procedure to the PORT statement in the *hlq.PROFILE.TCPIP* data set.

```
PORT
  135 UDP LLBD
```

See the [z/OS Communications Server: IP Configuration Reference](#) for more information about the AUTOLOG and PORT statements.

Step 2: Updating the NRGLBD cataloged procedure

Update the NRGLBD cataloged procedure by copying the sample provided in SEZAINST(NRGLBD) to your system or recognized PROCLIB and modifying it to suit your local conditions. See the NCS topic in [z/OS Communications Server: IP Configuration Reference](#) for more details.

Step 3: Updating the LLBD cataloged procedure

Update the LLBD cataloged procedure by copying the sample provided in SEZAINST(LLBD) to your system or recognized PROCLIB and modifying it to suit your local conditions. See the NCS topic in [z/OS Communications Server: IP Configuration Reference](#) for more information.

Chapter 26. Mail on z/OS

This topic describes how to configure the Communications Server SMTP (CSSMTP) application and popper.

CSSMTP is the strategic mail program for z/OS Communications Server and should be used for forwarding mail from your NJE network or from local applications that write mail to a JES spool file, using the existing SMTP batch interface to forward the mail to other gateway servers. CSSMTP provides the easiest and simplest solution for this purpose.

The sendmail to CSSMTP bridge is a replacement for the z/OS UNIX sendmail command for sending mail:

- The sendmail bridge processes the sendmail command input options (supported command line switches and configuration statements), reads the mail file, and constructs a CSSMTP compatible file with SMTP commands.
- Basic sendmail commands that use the sendmail bridge should function seamlessly, but more advanced options might require alternate solutions.
- The sendmail bridge requires CSSMTP to be configured and running.

Note: CSSMTP and the sendmail bridge don't provide support for receiving mail for delivery to local TSO/E or z/OS UNIX System Services user mailboxes, or for forwarding mail to other destinations

Configuring the CSSMTP application

Communications Server Simple Mail Transfer Protocol (CSSMTP) is a mail-forwarding SMTP client application. CSSMTP processes data sets containing mail messages on the spool file and forwards them to a target message transfer agent (MTA) without resolving each recipient. CSSMTP can improve the performance, scalability, and availability of the client function, but it does not act as a listening MTA server. Multiple instances of CSSMTP can run on a single host. [Figure 162 on page 1311](#) shows how CSSMTP fits into a network.

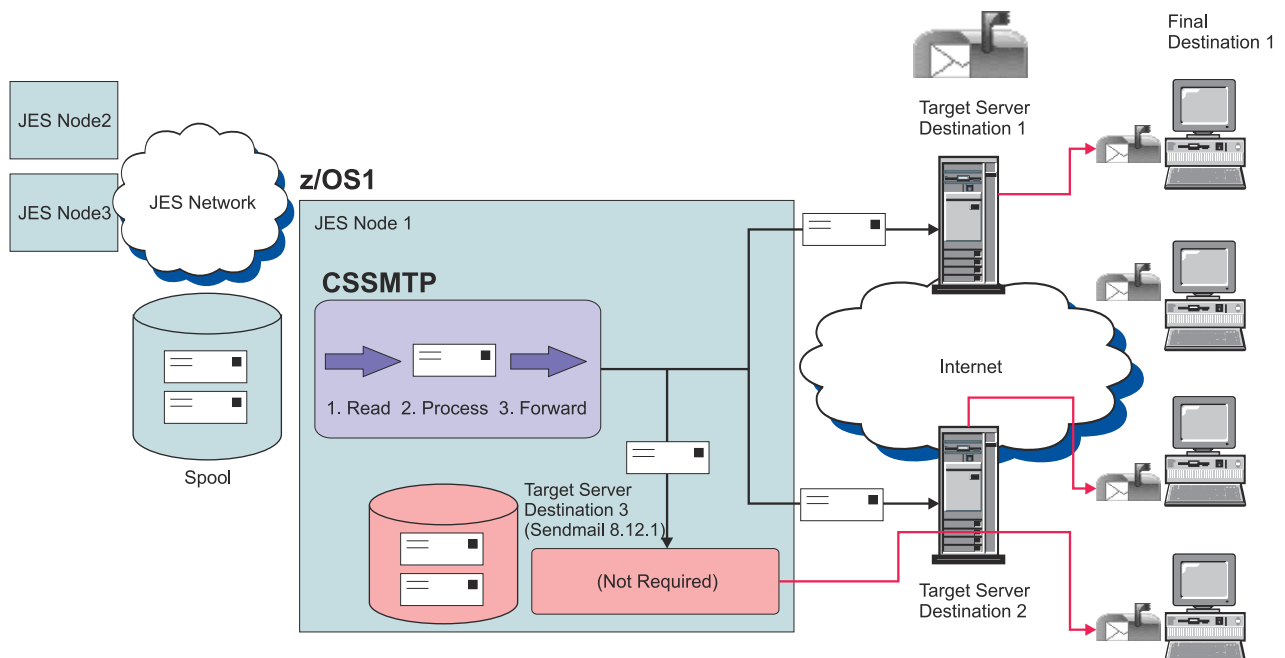

Figure 162. CSSMTP forwards mail messages from spool to the network

CSSMTP implements RFC 2821 and RFC 2822 for interacting with server MTAs, and supports additional RFCs for message size (RFC 1870) and security (RFC 3207). CSSMTP is not a fully capable MTA and

functions as an outbound forwarder, sending mail messages from the JES spool data set to the Internet. As the mail messages are read from the spool file, CSSMTP functions like a TCP/IP SMTP client and interacts with one or more configured target servers. When processing mail messages from the spool file, CSSMTP does not resolve mail message recipients, but transfers mail messages to one or more configured, next-hop servers (fully capable MTAs) that might or might not be the final destination.

CSSMTP provides the following capabilities:

- Checkpoint capabilities

If you need to restart CSSMTP, it does not have to reprocess the entire spool file, which will reduce duplicate mail that is received by message recipients.

- Long retry and extended retry capabilities

- The long retry capability is available for up to 5 days, and is intended to compensate for short-term target server outages.
- The extended retry capability is available for a longer period or for an indefinite period, and is intended to compensate for extended target server outages.

For more information, see [“Customizing the CSSMTP configuration file to try mail again”](#) on page 1317.

- Multiple security capabilities

See [“Security for CSSMTP”](#) on page 1320.

- SMF recording of CSSMTP events

See [“Steps for configuring SMF records for CSSMTP \(optional\)”](#) on page 1325.

As stated in RFC 2821, SMTP clients that transfer all traffic, regardless of the target domain names that are associated with the individual mail messages, or that do not maintain queues for trying mail message transmissions again that initially cannot be completed, might otherwise conform to this specification but are not considered fully capable. CSSMTP does not implement all aspects of RFC 2821.

Terms and concepts

The following terms and concepts are used in this information:

Backpressure

CSSMTP stops processing the JES spool file when mail cannot be sent to the target because the connection to a target server is down or unresponsive. CSSMTP resumes processing the JES spool file when a target server connection becomes active.

Bad spool file

A bad spool file is a JES spool file that cannot be processed as the result of security, configuration, syntax, readability, or delivery issues. The action taken by CSSMTP is subject to the setting of the BadSpoolDisp statement. For more information about the [BadSpoolDisp statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Checkpointing

If checkpointing is enabled using the CHKPOINT DD statement in the CSSMTP started procedure and there are partially processed spool files on the spool when restarting, CSSMTP attempts to send only the mail from these spool files that was not previously sent, which reduces the duplicate mail that is received by recipients. If CSSMTP is started cold using the `-f` option, any existing checkpoint records are flushed before CSSMTP is restarted. For information about using the CHKPOINT DD statement in the [CSSMTP started procedure](#) and about [starting CSSMTP](#) with the `-f` start option, see [z/OS Communications Server: IP Configuration Reference](#).

Dead letter

A dead letter is created and stored for the following reasons:

- An undeliverable mail notification cannot be returned to the originator
- The original mail message was undeliverable, but did not specify an originator
- An error report cannot be delivered to the mail administrators

To ensure that dead letters are stored, configure Store on the DeadLetterAction parameter of the Undeliverable statement. For information about the [Undeliverable statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

For examples of customizing the configuration to handle undeliverable mail, see [“Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1318](#).

ESMTP

Extended Simple Mail Transfer Protocol

Extended retry

If a mail message is not sent to all recipients because the target servers replied with a retry reply code, another attempt to send the message is made after the delay that is defined by the RetryLimit statement. If the long retry limits that are defined by the RetryLimit statement are exceeded, the mail is placed in the extended retry state. The mail is saved in a z/OS UNIX file system directory for extended retry as defined by the ExtendedRetry statement. If the extended retry limit is exceeded, the mail is marked as undeliverable. For more information about mail retry, see [“Customizing the CSSMTP configuration file to try mail again” on page 1317](#). For information about using the [RetryLimit statement](#) and the [ExtendedRetry statement](#) to configure the retry limits, see [z/OS Communications Server: IP Configuration Reference](#).

Long retry

See the definition for extended retry.

Mail administrator

The mail administrator is a special user ID for mailing systems, to which CSSMTP delivers error reports for problems detected while processing a spool file from the JES spool data set. For information about using the [MailAdministrator statement](#) to configure up to four mail administrator addresses, see [z/OS Communications Server: IP Configuration Reference](#).

Message content

The headers and the structured body of a mail message. A separate Multipurpose Internet Mail Extensions (MIME) specification provides the definitions for structured bodies.

MTA

Message transfer agent

SMTP

Simple Mail Transfer Protocol

SMTP AUTH

A mechanism used by to CSSMTP to authenticate with a mail server. CSSMTP supports AUTH PLAIN and AUTH LOGIN.

SMTP command

A command sent from the client to the SMTP server that lets the server know what information is being sent. For example, MAIL FROM: is a command.

SMTP reply

The acknowledgement, positive or negative, sent from an SMTP server. Replies are in the ASCII character set of the target server.

SMTP server

A network application implementing the SMTP protocol that accepts mail messages from SMTP clients.

Target server

A target server is the resolved or configured IP address from a TargetServer statement. The first four target servers are used by CSSMTP. For information about using the [TargetServer statement](#) to configure a target server, see [z/OS Communications Server: IP Configuration Reference](#).

Undeliverable mail

Mail messages that cannot be delivered. CSSMTP processes and tries to send all mail messages in the spool file. Sometimes, one or more of these mail messages might be undeliverable. Examples of what causes undeliverable mail include:

- A problem with the mail message itself, such as the message size

- A problem with the recipient record (RCPT TO:), such as an unknown mailbox
- A mail message requires a secure connection and none of the target servers support the STARTTLS SMTP command
- Security problems
- A networking problem, such as being unable to reach a target host that has the capabilities that are needed for the mail message

For examples of customizing the configuration to handle undeliverable mail, see [“Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1318.](#)

Undeliverable mail notification

CSSMTP creates an undeliverable mail notification when the ReturnToMailFrom parameter is set to YES on the Undeliverable statement and the mail message cannot be delivered. This notification contains the reply from the target server, describing the reason that the mail message was undeliverable and the text of the original mail message. If the undeliverable mail notification cannot be sent immediately, it is not tried again and is subject to the setting of the DeadLetterAction parameter of the Undeliverable statement.

For examples of customizing the configuration to handle undeliverable mail, see [“Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1318.](#)

Setting up CSSMTP

To set up CSSMTP to process and forward your mail, you must take the following actions:

- Configure and start CSSMTP.

See [“Steps for configuring and starting CSSMTP” on page 1314.](#)

- Create mail on the JES spool data set for CSSMTP.

See [“Steps for creating mail on the JES spool data set for CSSMTP” on page 1315.](#)

Steps for configuring and starting CSSMTP

You can use CSSMTP to process and forward your mail. These steps provide the minimum information that you need to configure and start CSSMTP.

Procedure

Perform the following steps to configure and start CSSMTP:

1. Create a new data set member in your procedure library for the CSSMTP JCL.

A sample job is in SEZAINST(CSSMTP). Because the CSSMTP JCL sample contains a JOB card, you should define the procedure library that you use in the IEFJOBS or IEFPSI concatenation of the master JCL, or put the new data set member in a subsystem procedure library such as SYS1.PROCLIB.

2. Define explicit authority for all user IDs that you want to be able to start CSSMTP.

See [“Steps for granting authority to start CSSMTP” on page 1319.](#)

3. Customize the CSSMTP configuration file and set up at least one valid target server IP address using the TargetServer statement.

A sample CSSMTP configuration file is included in member CSSMTPCF in SEZAINST. A target server is defined as the IP address that is resolved from or configured on the TargetServer statement. For information about using the [TargetServer statement](#) to configure a target server, see [z/OS Communications Server: IP Configuration Reference](#). For information about other [configuration statements used by CSSMTP](#), see [z/OS Communications Server: IP Configuration Reference](#). For information about handling undeliverable mail, see [“Customizing the CSSMTP configuration file to handle undeliverable mail” on page 1318.](#)

CSSMTP configuration statements are processed during the initialization of CSSMTP or when you issue the MODIFY *procname*,REFRESH command.

4. Set up the resolver search order.

Use the default search order unless there are special circumstances that require you to use unique parameters. For example, if the resolver has parameters that are used only when the resolver is called by CSSMTP, you need to define those unique parameters. Define the unique parameters in a data set that is specified on the SYSTCPD DD statement in the CSSMTP procedure JCL. For more information about resolvers and resolver configuration files, see [Chapter 13, “The resolver,” on page 753](#).

5. Optionally, set up additional security for CSSMTP.

See [“Security for CSSMTP” on page 1320](#).

6. Optionally, allocate and define a Virtual Storage Access Method (VSAM) linear data set for the checkpoint function.

A sample job is in SEZAINST(CSSMTPVL).

7. Set up the timezone using the TZ environment variable.

If you do not set up the timezone, the timezone is not shown in the Received header line, which is used to indicate that CSSMTP has picked up a mail message. The default time value is used if the DATE header is not specified in the mail message.

8. Start CSSMTP by issuing the following command, where *csproc* is the CSSMTP procedure member name:

```
START csproc
```

Results

You know you are done when initialization is complete and you have successfully connected to the specified target server for processing mail, as indicated by the following messages:

```
EZD1802I csproc INITIALIZATION COMPLETE FOR extWrtName
EZD1821I csproc ABLE TO USE TARGET SERVER ipAddress
```

Steps for creating mail on the JES spool data set for CSSMTP

This topic provides the minimum information that you need to create mail that can be processed and forwarded by CSSMTP.

Before you begin

You need to know the external writer name of the CSSMTP application that you want to process your mail data set. If the external writer name is not configured for CSSMTP using the ExtWrtName statement, then the default is the job name. For information about configuring the external writer name using the ExtWrtName statement, see [z/OS Communications Server: IP Configuration Reference](#).

For more information about creating mail using CSSMTP commands, see [z/OS Communications Server: IP User's Guide and Commands](#).

Procedure

Perform the following steps to create mail on the JES spool data set for CSSMTP:

1. Set up JES so that CSSMTP can create, read, write, and purge data from the JES spool data set.

See [“Steps for initial setup for CSSMTP” on page 1316](#).

2. Set up the mail to conform to the standardized syntax for text messages that are sent across networks.

Mail messages have an envelope and contents. Envelopes contain all necessary information to accomplish transmission and delivery of the mail message content. The fields in the envelope are in a standard format.

3. Configure code page support.

- If multi-byte character support is required, configure the MBCS YES statement.

- Configure the code page of the input spool files with the TRANSLATE statement. The spool file must be written by using a code page that is supported by z/OS Unicode Services. The default TRANSLATE code page is IBM-1047. If MBCS YES is configured, the TRANSLATE code page must be a multi-byte character set code page.
- Configure the code page used by the mail servers with the Charset parameter defined on the TargetServer statements. The default Charset code page is ISO8859-1.
- If MBCS YES is configured, configure the code page used by the mail servers with the MBCharset parameter defined on the TargetServer statements. The MBCharset code page must be a multi-byte character set code page.

The spool file that contains the mail commands and body is recognized and translated by the Language Environment iconv function to the following code pages:

- The mail commands are translated from the TRANSLATE code page to EBCDIC (IBM-1047) for inspection by CSSMTP and then from IBM-1047 to the Charset code page before sending to the target server.
- The mail headers are translated from the TRANSLATE code page to EBCDIC (IBM-1047) for inspection by CSSMTP and then from the TRANSLATE code page to the Charset or MBCharset code page before sending to the target server.
- The mail body is translated from the TRANSLATE code page to the Charset or MBCharset code page before sending to the target server.

For information about Unicode Services, see [z/OS Unicode Services User's Guide and Reference](#). For information about configuring the code page by using the [MBCS statement](#), the [Translate statement](#), and the Charset and MBCharset parameters on the [TargetServer statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

4. Set up the mail in one of the following formats:

- A flat file generated using the sendmail bridge command that writes to the SYSOUT data set

For information about using the sendmail bridge command, see [Sendmail to CSSMTP bridge in z/OS Communications Server: IP User's Guide and Commands](#).

- A flat file generated using the IEBGENER utility or batch jobs that write to the SYSOUT data set

For information about [using the IEBGENER utility to copy a mail file to a JES SYSOUT data set](#), see [z/OS Communications Server: IP User's Guide and Commands](#).

- Netdata generated from SMTPNOTE or from TSO xmit

For information about [using the SMTPNOTE command to compose a single mail message to one or more recipients](#) and about [using the TSO TRANSMIT \(XMIT\) command to send a mail file](#), see [z/OS Communications Server: IP User's Guide and Commands](#).

You must copy and customize the SMTPNOTE CLIST on every system where users can send mail with the SMTPNOTE command. For more information, see [“Steps for customizing the SMTPNOTE CLIST \(optional\)” on page 1317](#).

Results

You know you are done when mail is on the JES spool data set ready to be processed by CSSMTP.

Steps for initial setup for CSSMTP

Set up JES so that CSSMTP can create, read, write, and purge data from the JES spool data set.

Procedure

Perform the following steps to set up JES:

1. Set up JES2 initialization parameters so that CSSMTP can interface with JES utilities to create, read, write, and purge data from the JES spool data set.

For information about JES2 initialization, see [z/OS JES2 Initialization and Tuning Guide](#). For information about [Providing security for JES](#), see [z/OS Security Server RACF Security Administrator's Guide](#).

2. Verify that JES exit programs do not interfere with the function of CSSMTP.
For JES2 exit and exit routine association, see [z/OS JES2 Initialization and Tuning Reference](#).
3. Set up security authorization for the CSSMTP started task name in your definitions of authorized users.
If you are using RACF for security, see [z/OS Security Server RACF Security Administrator's Guide](#) for information about [Providing security for JES](#).
4. Set up CSSMTP for warm starts by configuring the CHKPOINT DD statement.
Checkpointing enables CSSMTP to recognize partially processed spool files, so that CSSMTP does not reprocess the entire spool file when restarting. This reduces the duplicate mail messages that are received by mail message recipients. Warm starts work only when restarting CSSMTP with the same job name and external writer name. If CSSMTP is started cold using the `-f` option, any existing checkpoint records are flushed before CSSMTP is restarted. For information about using the CHKPOINT DD statement in the [CSSMTP started procedure](#) and about [starting CSSMTP](#), see [z/OS Communications Server: IP Configuration Reference](#).

Steps for customizing the SMTPNOTE CLIST (optional)

Perform these steps for every system from which mail can be sent using the SMTPNOTE command.

Before you begin

If the ExtWrtName statement is specified in the CSSMTP configuration file, you should change the configured SMTPJOB value in the SMTPNOTE CLIST to match the ExtWrtName name of CSSMTP. If the ExtWrtName statement is not specified, you should customize the SMTPJOB name to match the CSSMTP job name. The SMTPJOB name must not be defined as a node name to JES and cannot begin with the characters R, RM, or RMT, because SMTPNOTE uses TSO XMIT to transmit the mail to CSSMTP.

Procedure

Perform the following steps to customize the SMTPNOTE CLIST:

1. Copy SEZAINST(SMTPNOTE) into the system CLIST data set.
2. Customize the variables in the SMTPNOTE CLIST, including the SMTPJOB variable so that it uses the CSSMTP job name. DOMAIN should also be set when using CSSMTP. For more information, see *Step 3: Customize the SMTPNOTE CLIST and modify parmlib data sets*.

Customizing the CSSMTP configuration file to try mail again

When mail servers reply to commands that resources are temporally unavailable, CSSMTP can try sending mail messages again. CSSMTP implements the following two types of retry:

- Long retry, defined by the RetryLimit statement

When you configure long retry, mail messages are saved in CSSMTP memory while they await retry. The originating spool file is also held by CSSMTP until every mail message is delivered or until an undeliverable notice is sent. Because the originating spool file is held during retry processing, you should configure the RetryLimit statement to a time span that is shorter than the time span that you configure for extended retry. For example, the time span on the RetryLimit statement might be several hours.

- Extended retry, defined by the ExtendedRetry statement

When you configure extended retry, mail messages that were undeliverable at the end of the long retry period are tried again for an extended period after the originating spool file is released. During the extended retry period, mail messages are saved in a z/OS UNIX file system directory. Because the originating spool file is released during extended retry processing, you can configure the ExtendedRetry statement to a longer time span than the time span that you configure for long retry. For example, the time span on the ExtendedRetry statement might be several days.

You can use these statements individually or at the same time to provide the best system environment for mail processing.

For example, the following statements set long retry to 1 hour and extended retry to 3 days:

```
RetryLimit
{
  Count 6
  Interval 10
}
ExtendedRetry
{
  Age 3
  Interval 60
  MailDirectory /var/cssmtp/CSSMTP/mail/
}
```

Tip: Because CSSMTP is a mail forwarder, the likelihood of receiving retry reply codes from a message transfer agent (MTA) is low. You are most likely to receive these errors when the MTA is also the home mail server for the mail recipients and the MTA reports errors that are related to the mailboxes of the recipients on the MTA. One possible error is that the mailbox is full.

Customizing the CSSMTP configuration file to handle undeliverable mail

CSSMTP provides configuration options to indicate how it handles undeliverable mail messages. You can configure CSSMTP to send individual undeliverable mail notifications or not to send them. You can also configure CSSMTP to create a report describing errors that were found while processing mail messages; this report can be created on the spool or sent to the configured mail administrators.

The following examples describe the configuration options for handling undeliverable mail. For more information about the [BadSpoolDisp](#) statement, the [Undeliverable](#) statement, the [MailAdministrator](#) statement, the [ReportMailFrom](#) statement, and the [Report](#) statement, see [z/OS Communications Server: IP Configuration Reference](#).

- Example 1 — Configuring CSSMTP to not return an undeliverable mail notification to the originator and to hold the original spool file on the JES spool data set:

```
BadSpoolDisp      Hold
Report            Admin
MailAdministrator myuserId@ibm.us.com
ReportMailFrom    userID@ibm.us.com
Undeliverable
{
  ReturnToMailFrom No
}
```

To configure the application to not send an undeliverable mail notification to the originator, you need to set the `ReturnToMailFrom` value to `No`. This example might be useful if the mail messages do not specify an originator, or if the spool file is for sending bulk mail that does not typically require a reply to the originator. This example has optionally configured that a report be sent to the specified mail administrator. If the Mail From of the error report is empty, it will use the mail address in `ReportMailFrom` if it has been configured.

Tips:

- The mail administrator can use the received report to determine which mail messages were undeliverable in the original spool file.
- When the examination of this JES spool file is complete, the mail administrator should delete the JES spool file, which is now in a hold state.

Results:

- CSSMTP tries to send all mail messages, and if any of the mail is undeliverable, CSSMTP does not create and send an undeliverable mail notification.
- Because the `BadSpoolDisp` statement is set to `Hold`, CSSMTP does not delete the JES spool file.

- Example 2 — Configure CSSMTP to send an undeliverable mail notification to the originator, and to hold the original spool file on the JES spool data set if necessary:

```
BadSpoolDisp      Hold
Report            None
Undeliverable
{
  ReturnToMailFrom  Yes
  DeadLetterAction  Store
  DeadLetterDirectory /var/cssmtp/myDir/
}
```

This example is useful if the originator of the mail messages needs to be informed that the messages cannot be delivered. If you determine that it is not necessary to inform the originator of failed deliveries, set the ReturnToMailFrom value to No. No report is created in this example.

Tip: When spool files contain many mail messages, this configuration should be used with caution because a failure can cause many individual undeliverable mail notifications to be maintained in storage while trying to return them to the originator.

Results:

- CSSMTP builds an undeliverable mail notification and attempts to notify the originator of the mail message failure.
- Because the ReturnToMailFrom value is Yes, if the original spool file contains no errors other than undeliverable mail errors, CSSMTP always deletes the spool file even when the BadSpoolDisp value is set to Hold.
- If the original spool file contains both undeliverable mail errors and syntax errors, CSSMTP holds the spool file because the BadSpoolDisp value is set to Hold.
- If the undeliverable mail notification cannot be returned to the originator of the mail message, then this undeliverable mail notification becomes a dead letter. The action taken by CSSMTP is based on the value configured on the DeadLetterAction parameter. In this example, because the DeadLetterAction value is set to Store, CSSMTP stores the dead letters in the /var/cssmtp/myDir directory:

```
/var/cssmtp/myDir/TESTMAIL.SYS00006.Sep302008.160454.541437.1U
/var/cssmtp/myDir/TESTMAIL.SYS00006.Sep302008.160454.541999.1U
```

- Because None is specified on the Report statement, the log must be inspected for messages about any problems found in the JES spool file.

Steps for granting authority to start CSSMTP

Define explicit authority for all user IDs that you want to be able to start CSSMTP.

Procedure

Perform the following steps to grant authority to a user ID to start CSSMTP:

1. Ensure that the OPERCMDS class is active and RACLISTed, and that RACLIST processing is enabled.
2. Define the OPERCMDS class profile using a security product like RACF.
3. Grant CSSMTP access to the OPERCMDS class and then refresh the OPERCMDS class.

Results

Depending on how you start CSSMTP, some RACF profiles that restrict who can issue the START, CANCEL, MODIFY, or STOP operator commands are as follows:

```
MVS.START.STC.CSSMTP.*
MVS.START.STC.CSSMTP

MVS.CANCEL.STC.CSSMTP.*
MVS.CANCEL.STC.CSSMTP
```

```

MVS.MODIFY.STC.CSSMTP.*
MVS.MODIFY.STC.CSSMTP

MVS.STOP.STC.CSSMTP.*
MVS.STOP.STC.CSSMTP

```

For more information about protecting operator commands, see [z/OS MVS Planning: Operations](#).

Security for CSSMTP

Consider the following additional security measures for CSSMTP:

- For spool files from NJE nodes, the user ID associated with the spool file must be defined by SAF. For more information about the protection of SYSOUT data sets, see the following topics:
 - [Protecting Data Sets on Spools in z/OS Security Server RACF Security Administrator's Guide](#)
 - [Authorizing SYSOUT in z/OS Security Server RACF Security Administrator's Guide](#)
 - [Authorizing Network Jobs and SYSOUT \(NJE\) in z/OS Security Server RACF Security Administrator's Guide](#)
 - [Authorizing SYSOUT in z/OS JES2 Initialization and Tuning Guide](#)
- If your installation protects access to the JESSPOOL class of resources, provide ALTER access to the CSSMTP user ID so that it can read and delete spool files. An example JESSPOOL definition follows:

```

//CSSMTP EXEC PGM=IKJEFT01
//SYSTSPRT DD SYSOUT=*
/* The PERMIT for CLASS(JESSPOOL) is needed only if it has already
/* been activated.
//SYSTSIN DD *
  SETROPTS CLASSACT(STARTED)
  SETROPTS RACLIST(STARTED)
  SETROPTS GENERIC(STARTED)
  ADDUSER CSSMTP DFLTGRP(OMVSGRP) OMVS(UID(nn) HOME('/')) -
  NOPASSWORD NAME('Simple Mail Transfer') OWNER(OMVSGRP)
  RDEFINE STARTED OWNER(SYS1) CSSMTP.* STDATA(USER(CSSMTP))
  RDEFINE JESSPOOL localnodeid.** UACC(READ)
  PERMIT localnodeid.** -
  CLASS(JESSPOOL) ID(CSSMTP) ACCESS(ALTER)
  SETROPTS GENERIC(JESSPOOL) REFRESH
  SETROPTS RACLIST(STARTED) REFRESH
  SETROPTS GENERIC(STARTED) REFRESH

```

- When CSSMTP is defined with a nonzero UID value, Delete Operator Message (DOM) messages are prefixed with message BPXM023I. To remove the prefix, you must authorize the CSSMTP procedure user ID to use the UNIX System Services console service. You can authorize CSSMTP to use the console service by entering the following commands:

```

RDEFINE FACILITY BPX.CONSOLE UACC(NONE)
PERMIT BPX.CONSOLE -
CLASS(FACILITY) ID(CSSMTP) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH

```

- You can control whether CSSMTP reads and processes the spool files created by specific users by creating one or more resource profiles in the SERVAUTH class.

The format of the SERVAUTH profile name is *EZB.CSSMTP.sysname.writername.originJESnode*, where *sysname* is the system name defined in the sysplex, *writername* is the CSSMTP configured external writer name, and *originJESnode* is the JES node that originated the spool file. If this profile is created with UACC(NONE), then only user IDs permitted to the resource are able to have spool files processed by CSSMTP.

For examples of the resource profile definitions, see the EZARACF sample in data set SEZAINST. For information about configuring the external writer name using the [ExtWrtName statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Tips:

- You can specify a wildcard on segments of the profile name, as shown in the following example:

```

SETR GENERIC(SERVAUTH) GENCMDS(SERVAUTH)
SETR CLASSACT(SERVAUTH)
RDEFINE SERVAUTH EZB.CSSMTP.sysname.writername.originJESnode -
    UACC(NONE)
PERMIT EZB.CSSMTP.sysname.writername.originJESnode -
    CLASS(SERVAUTH) ID(userid) ACCESS(READ)

PERMIT EZB.CSSMTP.sysname.writername.* -
    CLASS(SERVAUTH) ID(userid) ACCESS(READ)

SETRPTS RACLIST(SERVAUTH) REFRESH

```

- You can define multiple profiles. For example, if this CSSMTP instance processes spool files from local jobs and from remote systems, you can define a profile for the local system and for each JES node that originates spool files. The spool file is matched to the most specific RACF profile, and then the user ID associated with the spool file is validated against that profile.

Result: If the profile is active with UACC(NONE), then when the spool file is received on the JES spool data set, CSSMTP checks to determine whether a profile is defined for the originating node or for any originating node (*), and then checks whether the user ID associated with the job that created the spool file is permitted to the profile:

- If the user ID is permitted, the spool file is processed by CSSMTP.
- If the user ID is not permitted, the spool file is considered to be a bad spool file and is subject to the action specified by the BadSpoolDisp statement. For more information about the [BadSpoolDisp statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

If the profile is not defined, then the spool file is processed as if the user ID is permitted.

- You can write a CSSMTP user exit or use the existing SMTPD user exit to inspect mail before it is sent to a target server.

For example, you can create an exit to check the MAIL FROM: string on outbound mail. The mail originator, recipients, and other information can be inspected by the exit, and the entire JES job or a single mail message can be discarded.

You can control the user exit that is used with the UserExit statement:

- If you want to use a user exit that you have written for CSSMTP, then specify Version3 on the UserExit statement. You need to use this version if you want to use both RFC 821 and RFC 2821 commands to read and process from the JES spool data set. For more information about the [CSSMTP exit](#), see [z/OS Communications Server: IP Configuration Reference](#).
- If you want to continue using your SMTPD user exit and use only RFC821 commands, then specify Version2 on the UserExit statement.

For more information about the [UserExit statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

- You can enable the SMTP server and client to use Transport Layer Security (TLS) to provide private, authenticated communication over the Internet using RFC 3207, *SMTP Service Extension for Secure SMTP over Transport Layer Security*. For more information, see [“Steps for using Transport Layer Security for CSSMTP” on page 1321](#).
- You can enable CSSMTP to use SMTP AUTH to authenticate with a mail server. CSSMTP supports AUTH PLAIN and AUTH LOGIN. For more information, see [“Steps for CSSMTP AUTH configuration” on page 1323](#).

Steps for using Transport Layer Security for CSSMTP

You can enable the SMTP server and client to use Transport Layer Security (TLS) to provide private, authenticated communication over the Internet.

Procedure

Perform the following steps to use Transport Layer Security (TLS) for CSSMTP:

1. Set up secure mail using the YES option on the Secure parameter of the TargetServer statement, the STARTTLS command in the JES batch job, or both.

Table 73 on page 1322 shows whether TLS is required between CSSMTP and a target server based on various JES batch job and CSSMTP configuration combinations.

Table 73. JES batch job and CSSMTP configuration combinations for secure mail		
STARTTLS command?	Secure parameter value	TLS required?
Yes	YES	Yes
No	YES	Yes
Yes	NO	Yes
No	NO	No

If secure communication is required according to Table 73 on page 1322 and no available target servers support TLS (as indicated by server capabilities in response to the EHLO command), the mail message fails and is not delivered.

For information about the TargetServer statement, see [z/OS Communications Server: IP Configuration Reference](#). For information about the STARTTLS command, see [z/OS Communications Server: IP User's Guide and Commands](#).

2. See the following simple example to get started with TLS.

For more information about TLS, see [Chapter 20, "Application Transparent Transport Layer Security data protection,"](#) on page 1149.

In this example, assume the following characteristics:

- The mail contains sensitive data, and you want CSSMTP to communicate with only TLS protocols.
- CSSMTP is using port 25 to communicate with a target server on another platform.
- There is only one TCP/IP stack over which mail is delivered, referred to as the client stack.

To set up TLS for this sample environment, take the following actions:

- a. Create the key ring.

The client key ring needs the root certification used to sign the server certificates. For a TLS/SSL primer and some step-by-step examples, see [Appendix B, "TLS/SSL security,"](#) on page 1359. For more information about using RACDCERT to administer certificates, see [z/OS Security Server RACF Security Administrator's Guide](#). For more information about managing key rings and certificates with gskkyman, see [z/OS Cryptographic Services System SSL Programming](#).

- b. Configure CSSMTP to require secure communication. Configure the TargetServer statement with the Secure parameter set to YES, which specifies that TLS protocols are always required. For information about the TargetServer statement, see [z/OS Communications Server: IP Configuration Reference](#).

- c. Configure the client system to use TLS with AT-TLS policies as follows:

- i) Specify TTLS on the TCPCONFIG statement in the TCP/IP profile for the client stack. For information about the TCPCONFIG statement, see [z/OS Communications Server: IP Configuration Reference](#).
- ii) Block the ability of applications to open a socket before AT-TLS policy is loaded into the TCP/IP stack by setting up EZB.INITSTACK.sysname.tcpname for the client stack.
- iii) Create a main Policy Agent configuration file containing a TcpImage statement for the client stack, and create a TcpImage policy file for the client stack. For more information about AT-TLS policy statements, see [z/OS Communications Server: IP Configuration Reference](#).
- iv) Add a TTLSConfig statement to each TcpImage policy file to identify the TTLSConfig policy file location:

```
TTLSSConfig clientPath
```

v) Add the AT-TLS policy statements to the *clientPath* file:

```
TTLSSRule
{
    RemotePortRange      25
    Direction            Outbound
    TLSGroupActionRef    CSSMTPGroup
    TLSEnvironmentActionRef CSSMTPEnvironment
}
TLSGroupAction
{
    TLSEnabled          On
}
TLSEnvironmentAction
{
    HandshakeRole Client
    TLSKeyRingParms
    {
        Keyring          CSSMTP/client_key_ring
    }
    TLSEnvironmentAdvancedParms
    {
        ApplicationControlled On
    }
}
```

Tip: You can use the IBM Configuration Assistant for z/OS Communications Server to generate the AT-TLS Policy Agent files. For information about the IBM Configuration Assistant for z/OS Communications Server, see [“Option 1: Use the IBM Configuration Assistant for z/OS Communications Server”](#) on page 1150.

3. If the server requires an EHLO command to be sent after a successful TLS negotiation, configure TLSEhlo Yes on the Options statement in the CSSMTP configuration. For more information, see [Options statement in z/OS Communications Server: IP Configuration Reference](#).

Results

You know you are done when CSSMTP can successfully deliver mail to a target server using secure connections. If SECURE YES is configured and CSSMTP is able to successfully negotiate and establish a TLS session, the following message is displayed:

```
EZD1821I csproc ABLE TO USE TARGET SERVER ipAddress
```

Restriction: To use the STARTTLS command with a target server, the target server must have a certificate that can be validated by the AT-TLS component of z/OS Communications Server as configured by Policy Agent. This certificate can be a self-signed certificate or a certificate that can be validated by a known certificate authority. If the certificate of the server cannot be validated, secure communication with the server fails and mail that requires security cannot be delivered to that server.

Steps for CSSMTP AUTH configuration

Use the following steps to configure CSSMTP AUTH.

Before you begin

There are four special considerations when configuring AUTH LOGIN/PLAIN:

1. The connection between CSSMTP and the mail server must be TLS-protected before it can authenticate with SMTP AUTH. This requires additional configuration on the client (CSSMTP) and server sides. The TargetServer statement in the CSSMTP configuration file must also contain ‘Secure Yes’.
2. Most mail servers will only indicate support for AUTH PLAIN or AUTH LOGIN on the EHLO response after a TLS handshake has been completed. To ensure that CSSMTP learns of this support, it is

recommended to set TLSEHLO YES in the CSSMTP configuration options statement. This is a global setting, not a TargetServer-specific setting.

3. Mail servers may support AUTH PLAIN, AUTH LOGIN, or both. If both methods are supported, CSSMTP will always select AUTH PLAIN. Before sending the username and password, CSSMTP will perform an extra check when using AUTH PLAIN. The hostname specified in the TargetServer statement must match the Subject Alternative Name (SAN) of the certificate that the server sent during the TLS handshake. If no SAN is present, CSSMTP will check that the hostname matches the Common Name (CN) of the certificate.

Note: For SMTP Auth support, the preferred specification of the target server is via the TargetName parameter. If the TargetIP parameter is used, a reverse lookup is done to determine the hostname.

4. If the AuthEntity is set to <MAILFROM> and Undeliverable option is set to ReturnToMailFrom Yes, make sure ReportMailFrom is configured. CSSMTP will use the email address in the ReportMailFrom for authenticating the undeliverable mail.
5. If the AuthEntity is set to <MAILFROM> (email level authentication), the mail skips the long retry and extended retry and goes to the deadletter action in case of SAF failure or Auth Failure.

Once the SAF entity is configured in the CSSMTP configuration file, the username and the password should be securely stored in SAF. CSSMTP is reusing the SAF LDAP BIND password storage for the password storage. However, CSSMTP has no dependency on LDAP, nor does it make use of it in any other way.

Procedure

1. Perform the following steps to activate the required classes:

- SETROPTS CLASSACT(LDAPBIND)
- SETROPTS CLASSACT(KEYSMSTR)
- SETROPTS RACLIST(KEYSMSTR)

2. The password is encrypted using a DES or AES key.

Note: If you already have LDAP.BINDPW.KEY profile, skip this step and go to step 3.

For AES, define the key in ICSF and give it a label. Define this profile to reference the AES key:

```
RDEFINE KEYSMSTR LDAP.BINDPW.KEY SSIGNON (KEYLABEL (mykey))
```

For DES, define this profile, using your own secret consisting of 16 hexadecimal characters:

```
RDEFINE KEYSMSTR LDAP.BINDPW.KEY SSIGNON (KEYENCRYPTED (0023528875DECFA))
```

```
SETROPTS RACLIST(KEYSMSTR) REFRESH
```

3. Value defined for AuthEntity is defined as a profile in the LDAPBIND class.

The username and password are defined in the PROXY segment of the profile in BINDDN and BINDPW fields.

```
RDEFINE LDAPBIND target.mail.server -  
  PROXY(BINDDN('username') BINDPW('password'))
```

For AuthEntity as <MailFrom>

If the AuthEntity is defined as <MAILFROM>, the email address used in the Mail From field must be defined as a profile in the LDAPBIND class (one profile per email address).

```
RDEFINE LDAPBIND test1@test.com  
  PROXY(BINDDN('username1')  
    BINDPW('password1'))  
RDEFINE LDAPBIND test2@test.com  
  PROXY(BINDDN('username2'))
```

```
BINDPW('password2'))
```

Note: The **BINDDN** and **BINDPW** fields should contain the credentials that will be sent to the mail server.

Code page considerations

Due to code page considerations, be cautious if a password contains the characters `!`, `[` or `]`. The password is stored as EBCDIC in RACF. CSSMTP retrieves it, converts it to ascii, then base64-encodes the result. A terminal emulator codepage may interpret `!`, `[` or `]` as a hexadecimal value that won't translate properly back to ascii. In these cases, a password can be input using these character substitutions to achieve the proper hex value. (The following applies if your emulator codepage is set to IBM1047 or IBM037) `|` (vertical bar) for `!` - should produce `x'4F'` ^ (often displays as the cent sign) for `[` - should produce `x'4A'` `!` for `]` - should produce `x'5A'`.

For example, an ascii password of `'pass!w[o]rd'` can be input into the SAF profile as `BINDPW('pass|w^o!rd')`.

For other codepages, the hex translation can be further checked in an ISPF session by turning 'hex on':

```
Command ==> hex on
000100 pass!w[o]rd  pass|w^o!rd
      98AA5AB9B9844498AA4A49598444
      7122A6A6B940007122F6A6A94000
```

4. Provide CSSMTP the authority to access the LDAPBIND profiles.

```
RDEFINE FACILITY BPX.SERVER UACC(NONE)
PERMIT BPX.SERVER CLASS(FACILITY) ID(CSSMTP) ACCESS(READ)
SETROPTS RACLIST(FACILITY) REFRESH
```

5. The user ID associated with the CSSMTP application must be given READ access to the *AuthEntity* in the LDAPBIND class.

```
PERMIT target.mail.server CLASS(LDAPBIND) ID(CSSMTP) ACCESS(READ)
```

Results

If the SAF profile is created correctly, CSSMTP is able to retrieve the username and the password from SAF to perform SMTP AUTH for the connection to the target server.

Otherwise, CSSMTP returns an error when retrieving the username and password and will not attempt the connection to the specified target server.

Steps for configuring SMF records for CSSMTP (optional)

You can use SMF to record CSSMTP events.

Before you begin

CSSMTP can write System Management Facilities (SMF) records for the following cases:

- When the configuration has been initialized or modified by a `MODIFY REFRESH` command, a `MODIFY LOG,LEVEL` command, or a `MODIFY USEREXIT` command. A CSSMTP application configuration record (CONFIG subtype 48) is written.
- At the end of a connection with a target server, a CSSMTP application connection record (CONNECT subtype 49) is written.
- At the end of the processing for each mail message, a CSSMTP application mail message record (MAIL subtype 50) is written.
- At the end of the processing of a spool file when all the mail messages have been completed, a CSSMTP application spool file record (SPOOL subtype 51) is written.

- When statistical information about the CSSMTP processing at the SMF intervals is required, a CSSMTP application statistical record (STATS subtype 52) is written.

Procedure

Perform the following steps to write SMF records to both the MVS SMF data sets and the real-time SMF NMI. Writing SMF records to the MVS SMF data sets and writing SMF records to the real-time SMF NMI are two independent functions and are controlled by different configuration parameters.

1. Add a SMF119 statement to the CSSMTP configuration file.

This configuration parameter controls which SMF record types are written to the MVS SMF data sets. For example:

```
SMF119
{
  CONFIG YES
  SPOOL YES
  MAIL NO
  CONNECT YES
  STATS YES
}
```

In this example, the CONFIG, SPOOL, CONNECT and STATS records will be written to MVS SMF data sets and not the MAIL record.

2. Restart the CSSMTP task or issue a MODIFY REFRESH command to dynamically update CSSMTP with the new SMF119 statement values.
3. Update the TCP/IP profile NETMONITOR statement to forward all of the CSSMTP SMF records that are associated with the CONFIG, SPOOL, CONNECT, and STATS types to an application using the real-time SMF NMI, SYSTCPSP.

These record types are both connection oriented and non-connection oriented (see “5” on page 1326). For more information about SYSTCPSP, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

```
NETMONITOR SMFSERVICE CSSMTP
```

For the descriptions of the SMF records see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

4. Update the TCPIP profile NETMONITOR statement to forward all the CSSMTP SMF records associated with the MAIL type to an application using the real-time SMF NMI, SYSTCPSP.

```
NETMONITOR SMFSERVICE CSMAil
```

For more information about SYSTCPSP, see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

5. Special considerations for CSSMTP application and NETMONITOR in a CINET environment:
 - The CSSMTP application can be started with the -p parameter to set stack affinity. All the SMF records are written to the real time SMF NMI associated with the stack whose name was specified on the -p parameter. This forces connection oriented SMF records (CONNECT) and non-connection oriented SMF records (CONFIG, SPOOL, MAIL and STATS) to go to the same stack. The CSSMTP and CSMAIL NETMONITOR parameters should be specified in the profile data sets of the stack name to match the name specified on the -p parameter.
 - If the CSSMTP application is started without the -p parameter and multiple stacks are active, then a network management application can not determine the stack that records will be written to. The CSSMTP and CSMAIL NETMONITOR parameters should be specified in the profile data sets of all stacks, so that network management applications can obtain all the records. The network management application will not get redundant records. In this case CSSMTP writes the records to the first stack with an active SMFService application and with the appropriate SMFSERVICE CSMAIL or CSSMTP parameter set.

Monitoring CSSMTP

You can use the following MODIFY commands to monitor CSSMTP:

- MODIFY DISPLAY,CONFig

Displays the current configuration values.

- MODIFY DISPLAY,IPList

Displays the current set of target servers to which mail can be sent that are configured or resolved from the TargetServer statement.

- MODIFY DISPLAY,SPoolstatus

Helps you determine how mail is being processed off the JES spool file.

- MODIFY DISPLAY,TARgets

Helps you monitor the mail that is being sent to target servers to determine whether mail is being delivered, is being placed in undeliverable states, or is being tried again through long retry queues. This command also helps you determine the list of target servers, their attributes, and the number of mail messages that a target server is accepting.

For information about the [MODIFY command: Communications Server SMTP application \(CSSMTP\)](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

sendmail to CSSMTP bridge

The sendmail to CSSMTP bridge (sendmail bridge) allows the user to send emails by using the facilities of z/OS UNIX. The sendmail bridge command parses input command switches, reads the mail message from the UNIX System Services file, and processes the mail message. The input mail message is updated by adding SMTP commands and SMTP headers, if no headers are specified in the input mail message. The updated mail message is transmitted to the JES spool data set that the Communications Server SMTP (CSSMTP) application can process. CSSMTP must be configured and running.

Restriction: The sendmail bridge is only a mail client function.

This topic provides information about how to configure the sendmail bridge.

For more configuration information, see [Sendmail to CSSMTP bridge](#) in [z/OS Communications Server: IP Configuration Reference](#) and for sendmail bridge command information, see [z/OS Communications Server: IP User's Guide and Commands](#).

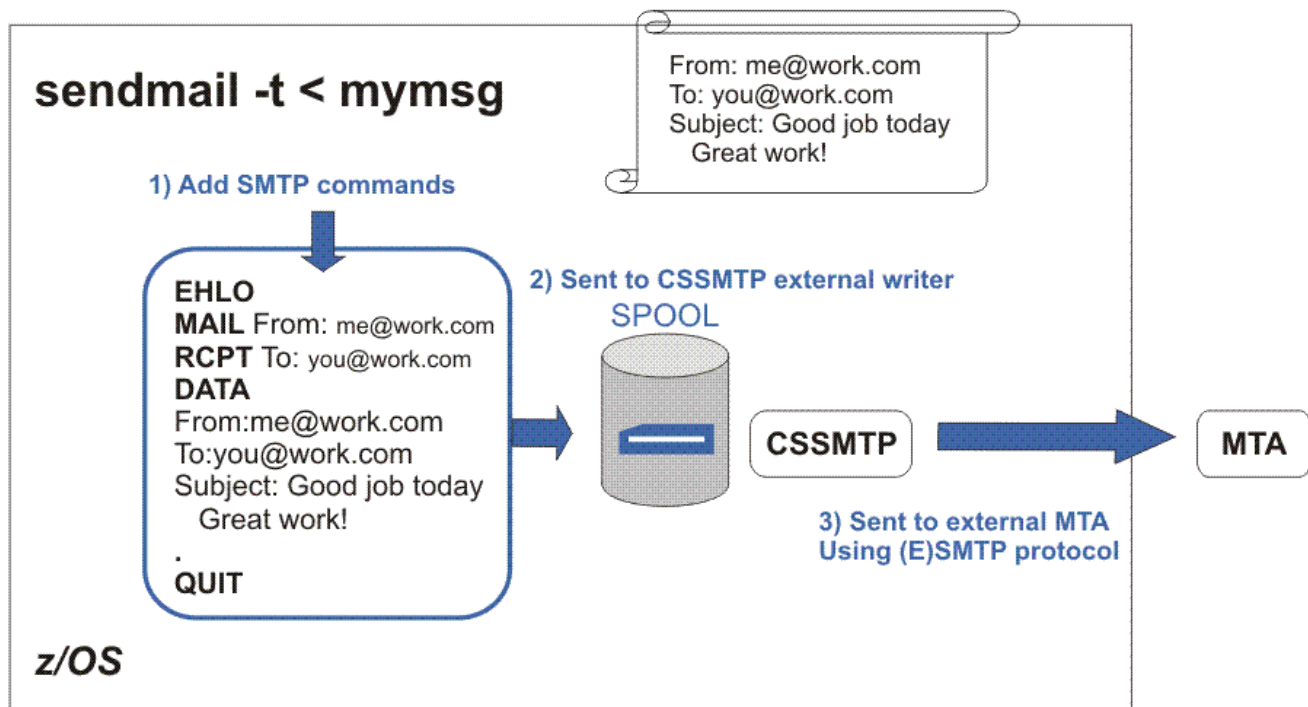

Figure 163. sendmail to CSSMTP bridge

Setting up the sendmail bridge

To set up the sendmail bridge to process and forward your mail, you must take the following actions:

1. Create and customize the configuration file.
See [“Steps for creating and customizing the configuration file” on page 1328.](#)
2. Configure and start CSSMTP.
 - Issue `F cssmtpproc,display,config` to check if CSSMTP is running
 - If you have not configured and started CSSMTP, see [Configuring the CSSMTP application.](#)
3. Consider security for the sendmail bridge.
See [“Security considerations for the sendmail bridge” on page 1329.](#)

Steps for creating and customizing the configuration file

You can take the following actions to create and customize the sendmail bridge configuration file:

- Copy the sample file `ezatmail.cf` from `/usr/lpp/tcpip/samples/` to `/etc/mail/ezatmail.cf`.

Guideline: If you used z/OS sendmail in previous releases, you can use your existing configuration files with the sendmail bridge: `/etc/mail/submit.cf` or `/etc/mail/sendmail.cf`. However, because many statements in those 2 files are not supported for the sendmail bridge, it is suggested that you use `ezatmail.cf` instead.

You can use the sendmail bridge command line switch `-C` to define the configuration file. For the search order of the sendmail bridge configuration file, see [z/OS Communications Server: IP Configuration Reference.](#)

- Customize the configuration file:

- If you plan to use an alias name for your mail recipients, you might need to provide an O statement with options AliasFile and MaxAliasRecursion.
- If you plan to limit the number of recipients in one mail message, you might need to provide an O statement with option MaxRecipientsPerMessage.
- If you plan to use a different CSSMTP external writer name from the default name "CSSMTP", you can configure a W statement with the CSSMTP external writer name that matches the name of your CSSMTP application. You can also use the environment variable EZATMAIL_CSSMTP_EXTWRTRNAME to define your CSSMTP external writer name. For the search order of the sendmail bridge CSSMTP external writer name, see [z/OS Communications Server: IP Configuration Reference](#).
- You can customize options for the sendmail bridge command. For additional information, see [z/OS Communications Server: IP User's Guide and Commands](#).

Security considerations for the sendmail bridge

- With the sendmail bridge command, the updated input mail message is transmitted to the JES spool data set that the Communications Server SMTP (CSSMTP) application processes. For more information about the protection of SYSOUT data sets, see [Security for CSSMTP](#). You can request Transport Layer Security (TLS) for messages sent by the sendmail bridge command through the configuration statement D{tls_version}. If D{tls_version} is specified, a STARTTLS SMTP command is added. When CSSMTP processes the JES spool data set, CSSMTP ensures a secured connection between CSSMTP and its target server is used to forward the mail message. The value that is defined by D{tls_version} is ignored. The secured connection is setup between CSSMTP and the target mail server based on configured AT-TLS policy.
- It is not required that D{tls_version} is set in the configuration file to ensure a secured connection is used. The user can ensure that a secured connection is used between CSSMTP and its target server by setting the Secure parameter to Yes on the CSSMTP TargetServer configuration statement. See [“Steps for using Transport Layer Security for CSSMTP” on page 1321](#).
- If you plan to invoke the sendmail bridge command by submitting a batch job that uses BPXBATCH, the sendmail bridge assumes user IDs are used when running the command, and these user IDs must be defined to execute sendmail correctly. The commands to define the sendmail user IDs are defined in SEZAINST(EZARACF). The commands are:

```
RDEFINE STARTED SENDMAIL.* STDATA(USER(SENDMAIL))
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

Configuring popper

POP3 uses port 110. You can define additional ports if there is a need for additional command-line options for popper. For information on the options that might be suitable for your site, see the [z/OS Communications Server: IP User's Guide and Commands](#).

z/OS UNIX popper will most likely be used by those whose local mailer requires a POP3 server. Typically their administrator will provide them with the address or name of the z/OS running the POP3 server, with instructions on where this information should be used.

The authentication method used in this implementation of popper is user ID and password.

The popper implementation can be divided into four steps:

- Update the /etc/services file.
- Update the /etc/inetd.conf file.
- Create the directory for the temporary maildrop file.
- Start inetd.

Update the /etc/services file

You need a port for the POP3 server defined in /etc/services. Add the following line to your /etc/services file. Note that the well-known port 110 is being used in this example:

```
pop3          110/tcp popper
```

Update the /etc/inetd.conf file

Because popper is invoked by INETD, add the following information to your /etc/inetd.conf file, where -d indicates to run popper in debugging mode:

```
pop3          stream tcp nowait bpxroot    /usr/sbin/popper popper -d
```

The debugging option is used to confirm correct installation, as shown in [“Correct connection” on page 1330](#).

Create the directory for the temporary maildrop file

When popper is invoked through a Mail User Agent (MUA) client request, such as GET NEW MESSAGES, popper starts to read the user's mail file system (/usr/mail/username) where the data has been stored, and puts this data (if there are messages) in a temporary maildrop file /usr/mail/popper/.username.pop. The contents of this file are transmitted to the remote client using the existing POP3 TCP connection.

Because the directory does not exist, create it as follows:

```
/usr/mail/popper/  
chmod 777 /usr/mail/popper
```

The popper uses this directory to create and fill the maildrop file. If this directory is not specified or if permissions are incorrect, you will get an error message similar to the following message:

```
EZZ7605I:Unable to open temporary maildrop '/usr/mail/popper/.username.pop'
```

Also, inside the POP3 session, you will get an error message similar to the following message:

```
-ERR System error, can't open temporary file, do you own it?
```

Restrictions:

- If the user maildrop file is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the popper.
- If the user maildrop file is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which the user maildrop file is stored cannot have write access to the directory.

Start inetd

After updating the inetd.conf file, start INETD. For more information on inetd, see [Appendix A, “Setting up the InetD configuration file,” on page 1357](#). Also see [z/OS Communications Server: IP Configuration Reference](#).

Correct connection

The following example shows a working connection to the popper server:

```
Debugging turned on  
(v2.3)Servicing request from "hostname.domainname" at xxx.xxx.xxx.xxx  
1  
+OK QPOP (version 2.3) at hostname.domainname starting.

Popper command - administering received mail

If the receiver MUA does not have direct access to the mail spool file, use Popper to access the mail spool on the local host. z/OS Popper is used when a POP3 server is needed.

Syntax

```

➔ popper - b <directory name>
          - d
          - n <message count>
          - s
          - t <file name>
          - T <timeout>
          - u

```

Parameters

The following command-line options can be used when you are invoking Popper.

-b <directory name>

Specifies the name of the directory in which bulletins are found. If not specified, /usr/mail/bulletins is used as the default.

Restrictions:

- If the bulletins file is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to Popper.
- If the bulletins file is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which the bulletins file is stored cannot have write access to the directory.

-d

Requests more debugging messages be turned on.

-n <message count>

Specifies the number of old bulletins to be delivered to new users. If not specified, no bulletins are delivered.

-s

Requests statistics logging be turned on.

-t <file name>

Specifies a trace file for all message logging. If not specified, messages are logged via the syslog facility.

-T <timeout>

Specifies the time, in seconds, before an idle POP3 connection is terminated. RFC 1939 specifies a minimum timeout of 600 seconds, but in practice such a long timeout does not work well. (When a connection gets aborted, the user is locked out of their mailbox for the timeout period.) If not specified, 120 seconds is used as the default timeout period.

-u

Requests that the user mailbox be updated on abort. RFC 1939 specifies that mailboxes should not be updated (that is, no messages should be deleted) if a connection is aborted abnormally. This option forces an update to occur despite the aborted connection. If not specified, no update occurs on aborted connections.

Chapter 27. TIMED daemon

TIMED is a daemon that is used to provide the time in response to UDP requests. TIMED gives the time in seconds since midnight January 1, 1900. You can start TIMED from the z/OS shell or as a started procedure. TCP/IP must be started prior to starting TIMED.

Note: TIMED is different from the TIME daemon available as an internal daemon of INETD. INETD cannot be used to start and perform as a listener for TIMED.

Starting TIMED from the z/OS shell

TIMED is installed in the /usr/lpp/tcpip/sbin/ directory.

To start the TIMED server from the command line, issue the **timed** command.

```
timed [-l] [-p port]
```

The following parameters are used for the **timed** command:

-l

Logs all the incoming requests and responses to the system log. Logged information includes the IP address of the requestor.

-p port

The TIMED server usually receives requests on well-known port 37. TIMED uses UDP only. You can specify the port in which requests are to be received.

Starting TIMED as a procedure

The following sample shows how to start TIMED as a procedure.

```
//TIMED    PROC
//*

//*
//TIMED    EXEC PGM=TIMED,REGION=0K,TIME=NOLIMIT,
//          PARM='POSIX(ON),ALL31(ON),TRAP(OFF)'/
//*STEPLIB DD DISP=SHR,DSN=TCP.SEZALOAD,
//*          VOL=SER=,UNIT=
//SYSPRINT DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//SYSIN    DD DUMMY
//SYSERR   DD SYSOUT=*
//SYSOUT   DD SYSOUT=*,DCB=(RECFM=F,LRECL=132,BLKSIZE=132)
//CEEDUMP  DD SYSOUT=*
//SYSABEND DD SYSOUT=*
//          PEND
```

Chapter 28. SNTP daemon

The SNTP daemon (SNTPD) is a TCP/IP daemon that is used to synchronize time between a client and a server. Simple Network Time Protocol (SNTP) is a protocol for synchronizing clocks across a WAN or LAN through a specific formatted message. An External Time Reference (ETR), named stratum 0, is chosen as the highest timer reference used for synchronization. A stratum 1 server is attached to and receives the time from the stratum 0 timer. For example, the z/OS sysplex timer could be a stratum 0 timer, and z/OS Communications Server would be a stratum 1 server. A client attached to the stratum 1 server can also be a stratum 2 server, receiving the time from the stratum 1 server, and so on. SNTP uses UDP packets for data transfer with the well-known port number 123. RFC 2030 (Mills 1996) describes SNTP. You can start SNTPD from the z/OS shell or as a started procedure. TCP/IP must be started prior to starting SNTPD.

Restrictions:

- The SNTP server only processes requests with a Mode value of 1 through 4. The SNTP server discards requests whose Mode value is 0, or is greater than 4.
- As per RFC 2030, the SNTP server discards requests whose length is less than the minimum required length of 48 bytes.

SNTPD is an SNTP server. If the server is configured for unicast mode only (that is, neither the multicast mode or the broadcast mode start parameters are specified), then the server just waits for requests from clients and then responds. If the server is also configured for multicast or broadcast mode, it sends unsolicited messages at the intervals that are specified on the multicast mode or the broadcast mode start parameters.

The `/etc/sntpd.pid` is a temporary SNTP daemon pid file that the SNTP daemon creates. This file contains the process ID of the current invocation of the SNTP daemon.

Restrictions:

- If `/etc/sntpd.pid` is a symbolic link, it must have an owning UID or GID that matches the EUID or EGID that is assigned to the SNTP daemon.
- If `/etc/sntpd.pid` is a hard link or the target of a hard link, users that are outside the owner or group of the directory in which `/etc/sntpd.pid` is stored cannot have write access to the directory. Additionally, write access to `/etc/sntpd.pid` must be limited to the owning UID or group, for example, `--w--w----` permissions.

Steps for starting SNTPD from the z/OS UNIX shell

You can start SNTPD from the z/OS UNIX shell.

Before you begin

Ensure the existence of the following files. The files used by z/OS UNIX SNTPD and their locations in the z/OS UNIX file system are as follows:

`/etc/services`

The ports for each application are defined here.

`/etc/syslog.conf`

The configuration parameters for usage of syslogd are defined in this file.

`/usr/sbin/sntpd`

This is a symbolic link to `/usr/lpp/tcpip/sbin/sntpd`, which is a sticky-bit file. The SNTPD member of SEZALOAD contains the executable code for the SNTP server.

`/usr/lib/nls/msg/C/sntpdmsg.cat`

The message catalog used by the z/OS UNIX SNTPD server.

When restricting low port usage, the port used by SNTPD (default value of 123) should either:

- Be reserved for the name of the SNTPD start procedure
- Use the SAF parameter on the PORT statement to restrict access to the SNTPD port

There is no configuration file specifically for SNTPD.

Procedure

Type `sntpd &` on the command line.

This command starts SNTPD and sends it to the background. The following optional parameters are used for the `sntpd` command:

-d

Enables debugging. Debug messages go to syslog daemon.

-df *pathname*

Enable debugging. Debug messages go to the specified file location.

-pf *pathname*

Path for pid file. For example:

```
-pf /var
```

-m *nnnnn*

Acts in multicast mode. Sends multicast updates (TTL=1) on all interfaces every *nnnnn* seconds. Listens to multicast requests and responds with unicast replies. The valid range for `-m` is 1 to 16284.

-b *nnnnn*

Acts in broadcast mode. This parameter sends local broadcasts on all interfaces every *nnnnn* seconds. It also specifies to listen to broadcast requests and respond with unicast replies. The valid range for `-b` is 1 to 16284.

-s *nn*

Use *nn* as the stratum level in all replies sent by the server. The valid range for *nn* is 1 to 15. If `-s` is not specified or a value is specified that is not valid, the default stratum level of 1 is used. The stratum level indicates the relative accuracy of the local clock compared to the clocks of other SNTP servers in the network. The value 1 is most accurate and 15 is least accurate.

-?

Display the syntax of the command usage and options.

Results

You know that SNTPD has started when the following message appears on the MVS console:

```
EZZ9600I SNTP SERVER READY.
```

Steps for starting SNTPD as a procedure

You can start SNTPD as an MVS started procedure.

Before you begin

Obtain a copy of this sample procedure from SEZAINST and store it in one of your PROCLIB concatenation data sets.

Procedure

Invoke the procedure using the system operator start command.

The following sample, SEZAINST(SNTPD), shows how to start SNTPD as a procedure:

```
//SNTPD    PROC
//*
```

```

/* Sample procedure for the Simple Network Time Protocol (SNTP)
/*

```

Results

You know that SNTPD has started when the following message appears on the console:

```
EZZ9600I SNTP SERVER READY.
```

Stack affinity

If you are running in a multiple stack environment and want SNTPD to use only a single stack, the environment variable `_BPXK_SETIBMOPT_TRANSPORT` can be used.

Chapter 29. Remote Execution

Guideline: It is suggested not enabling the TSO Remote Execution server. The RSH and REXEC protocols transfer user ID and password information in the clear (without encryption). There is also the potential of weak authentication for RSH clients using RHOSTS.DATA datasets. This authentication method allows remote command execution without requiring the RSH client to supply a password. IBM Health Checker for z/OS can be used to check whether the TSO Remote Execution server (called MVRSHD) is active and detect an RSH client attempting to use an RHOSTS.DATA dataset for authentication. For more details about IBM Health Checker, see [IBM Health Checker for z/OS User's Guide](#).

This topic describes how to configure and operate both the Remote Execution server and the UNIX Remote Execution server. z/OS Communications Server supports remote execution daemons in both the UNIX and TSO environments.

To execute commands under the UNIX shell, use the RSH command. To execute commands under TSO, use the REXEC command. These requests are serviced by the UNIX daemons, orshd and orexecd, and the TSO RXSERVE daemon.

The differences between the UNIX daemons and the TSO RXSERVE daemon are as follows:

- The UNIX daemons are initiated through the INETD server and can be configured to support a port other than their well-known port.
- The TSO daemon must be active and will service REXEC and RSH requests only on their well-known ports.

Only the UNIX daemons or the TSO daemon can be active at any one time.

UNIX REXEC

The UNIX Remote Execution Protocol Daemon (REXECD) is the server for the REXEC routine. REXECD allows execution of z/OS UNIX commands with authentication based on user names and passwords.

The Remote Shell Server (RSHD) is the server for the remote shell (RSH) client. The server provides remote execution facilities with authentication based on privileged port numbers, user IDs, and passwords.

See [“Configuring the z/OS UNIX Remote Execution servers” on page 1344](#) for more information about configuring this server.

TSO REXEC

The TSO Remote Execution server allows execution of a TSO command that has been received at a remote host. This server runs the Remote EXEcution Command Daemon (REXECD) which supports both the Remote Execution (RExec) and Remote Shell (RSH) protocols.

The TSO Remote Execution server has affinity for a specific transport in a CINET environment. Configure and execute a unique instance of the server for each TCP/IP stack requiring TSO remote execution services.

Configuring the TSO Remote Execution server

Procedure

Perform the following steps to configure the TSO Remote Execution server:

1. Update AUTOLOG and PORT statements in the PROFILE.TCPIP data set.
2. Determine whether the Remote Execution client will send a Remote Execution (RExec) command or Remote Shell (RSH) command.

3. Permit remote users to access MVS resources. (Required only if the client is not sending a password.)
4. Prevent potential wait state for special conditions.
5. Update the Remote Execution cataloged procedure.
6. Create a user exit routine (optional).
7. Permit access to JESSPOOL files.

Step 1: Configuring PROFILE.TCPIP for TSO Remote Execution server

If you want the Remote Execution server to start automatically when the TCPIP address space is started, include the name of the member containing the RXSERVE cataloged procedure in the AUTOLOG statement in the *hlq.PROFILE.TCPIP* data set.

```
AUTOLOG
RXSERVE
ENDAUTOLOG
```

To ensure that port 512 is reserved for the Remote Execution protocol and port 514 for the Remote Shell protocol, add the name of the member containing the Remote Execution cataloged procedure to the PORT statement in *hlq.PROFILE.TCPIP*:

```
PORT
512 TCP RXSERVE
514 TCP RXSERVE
```

See [z/OS Communications Server: IP Configuration Reference](#) for more information about the AUTOLOG and PORT statements.

Step 2: Determine whether Remote Execution client will send REXEC or RSH commands

The Remote Execution client can send commands to the TSO Remote Execution server by the following methods:

1. Sending the Remote Execution (REXEC) command
2. Sending the Remote Shell (RSH) command with a user ID and password separated by a slash (/) character with the -l option on the RSH command
3. Sending the Remote Shell (RSH) command without a password

With methods “1” on page 1340 and “2” on page 1340, the TSO Remote Execution server executes the request and passes the password to MVS for verification. (REXEC commands require a password.) When these methods are used, skip Step 3.

With method “3” on page 1340, to enable an RSH client to send RSH commands to the TSO Remote Execution server without specifying a password, Step 3 is required.

Step 3: Permit remote users to access MVS resources (optional)

This step is necessary only if your installation allows users to issue remote execution commands without the requirement of specifying a password on the remote execution client.

Procedure

Use the following steps to ensure that the server can correctly access necessary MVS resources. You can use z/OS Security Server (RACF) or an equivalent security program.

1. Verify that your system has been configured for allowing surrogate job submission as described in [z/OS Security Server RACF Security Administrator's Guide \(SC28-1915\)](#) or by using an equivalent security program.

2. Authorize the TSO Remote Execution server to submit jobs for the MVS user ID specified with the `-l` option of the RSH command. This can be done with the RACF facility as described in [z/OS Security Server RACF Security Administrator's Guide \(SC28-1915\)](#), or by using an equivalent security program.
3. Define an `mvs_userid.RHOSTS.DATA` data set and authorize the TSO Remote Execution server user ID permission to read this data set.

This can be done with the RACF facility as described in [z/OS Security Server RACF Security Administrator's Guide \(SC28-1915\)](#), or by using an equivalent security program.

Note: This is the user ID used to start the RXSERVE address space.

This data set identifies the Remote Execution clients that can execute MVS commands remotely by sending an RSH command.

When a Remote Execution client sends an RSH request to the TSO Remote Execution server, the request includes the local user ID of the client user (*local_userid*) and, if the client user specified the `-l` option of the RSH command, the request also contains the user ID to use on the remote host (*mvs_userid*). If the client does not specify the `-l` option, the user ID to be used on the remote host is assumed to be the same as the *local_userid*.

When the TSO Remote Execution server receives an RSH command without a password, the server looks for a data set called `mvs_userid.RHOSTS.DATA`. The `mvs_userid.RHOSTS.DATA` data set contains one or more entries. Each entry consists of two parts, a fully qualified name of the client user's host and a *local_userid* associated with that host. The *local_userid* is case sensitive. If the data set exists, the server reads it and looks for an entry with a host name that matches the client user's host. If the user ID specified on this entry in the `RHOSTS.DATA` data set matches the *local_userid* passed on the RSH command, the RSH command continues processing. If the entry does not exist, the server responds to the client with message EZA4386E `Permission denied`.

Tip: If the client connected to this host through a link-local address, the client's host name generated by the resolver can be in the format `hostname%scope`. Adding `%scope` information to the appropriate `RHOSTS.DATA` client host definitions results in a more efficient search for a matching client host name. For details on the [support for scope information on configured host names](#), see [z/OS Communications Server: IPv6 Network and Appl Design Guide](#).

In the following example of an `RHOSTS.DATA` data set, the MVS client user `mvsuser` is allowed to issue the RSH command without a password from host `rs60007` with a local AIX user ID of `aixuser`.

Example of `mvsuser.RHOSTS.DATA` data set:

```
rs60007.itso.ral.ibm.com aixuser
```

Guideline: It is suggested not enabling the MVRSHD server. The MVRSHD server supports the RSH and REXEC protocols which transfer user ID and password information in the clear. There is also the potential of weak authentication for RSH clients using `RHOSTS.DATA` datasets. This authentication method allows remote command execution without requiring the RSH client to supply a password. IBM Health Checker for z/OS can be used to check whether the MVRSHD server is active and detect an RSH client attempting to use an `RHOSTS.DATA` dataset for authentication. For more details about IBM Health Checker, see [IBM Health Checker for z/OS User's Guide](#).

4. Users may be authenticated using Kerberos or GSS. If the username in the Kerberos or GSS credentials matches the local user ID (*local_userid*) of the client supplied by the RSH client, then no password is required.

Step 4: Prevent potential wait state for special conditions

Under specific circumstances, the TSO Remote Execution server encounters a wait under certain conditions. Specifically, the RACF `SETROPTS(PASSWORD(REVOKE(nnn)))` option controls how many consecutive attempts to use incorrect passwords and password phrases RACF permits before it revokes the user ID on the next attempt, regardless of the z/OS program that is attempting to perform the logon. By default, users with the RACF `SPECIAL` attribute can be granted an additional logon attempt. In such a case, RACF issues message ICH302D ("ICH302D REPLY Y TO ALLOW ANOTHER ATTEMPT OR N TO REVOKE USERID userid.") and the operator replies "Y" to allow another attempt.

If the user ID with the SPECIAL attribute is attempting to log on through TSO Remote Execution server, the RACF write-to-operator-with-reply message forces the server into a wait until the operator replies. Until that reply is provided, the server cannot do any other work. To avoid this prompt (and the resulting wait) and thus have the user ID revoked without allowing an additional logon attempt when logging on through REXEC or RSH, define a profile in the XFACILIT class for the following resource:

```
IRR.DENY.SPECIAL.USER.ADDITIONAL.PASSWORD.ATTEMPTS.APPL.MVRSHD
```

Step 5: Update the TSO Remote Execution cataloged procedure

Update the TSO Remote Execution cataloged procedure by copying the sample provided in SEZAINST(RXPROC) to your system or recognized PROCLIB and modifying it to suit your local conditions. Specify the TSO Remote Execution server parameters and modify the JCL as required for your installation.

Rule: The PREFIX specification must be unique for every instance of RXSERVE that runs in a JESPLEX. The JESPLEX is a system that shares the same JES spool.

Tip: You can update the TSO Remote Execution server operating parameters during execution with the MODIFY command. All but MAXCONN, IPV6, and SECLABEL can be changed.

Step 6: Create a user exit routine (optional)

The TSO Remote Execution server enables you to provide an optional user exit routine. You can use this routine to alter the JOB and EXEC statement parameters. In addition, you can use this routine to provide JES control statements to meet installation-specific requirements, such as updating accounting information before the submission of the TSO batch job.

On entry to the exit, register 1 points to the following parameter list:

Offset

Description

+0

A pointer to an AF_INET or AF_INET6 address structure in the following format:

Offset

Description

+0

Address family AF_INET or AF_INET6 (2 bytes)

+2

Server port (2 bytes)

+4

Client AF_INET or AF_INET6 IP address (4 or 16 bytes)

+4

A pointer to a 1024-byte string terminated by the null character (0x00), which contains the JOB statement parameters. The exit routine can modify this string to meet installation-specific requirements. On entry, the string is set to the following string:

```
userid,USER=userid,[PASSWORD=passwd,]MSGCLASS=msgclass[,SECLABEL=seclabel]
```

The *userid* and *passwd* values are set to the user ID and password that the client provides, and the *msgclass* value is the message class of the Remote Execution server cataloged procedure. The PASSWORD parameter is present only when the client provides a password. The server passes the SECLABEL parameter only when the user ID is defined with a security label. The following example shows a modified string:

```
userid,USER=USER1,PASSWORD=USERXX1,MSGCLASS=E,LINES=999999,NOTIFY=SYSADM
```

+8

A pointer to a 256-byte string terminated by the null character (0x00), which contains the EXEC statement parameters. The exit routine can modify this string to meet installation-specific requirements. On entry, the string contains the EXEC statement for the procedure that is specified on the TSOPROC parameter of the Remote Execution server, or the default IKJACCNT procedure if the TSOPROC parameter is not specified. The following example shows a modified string:

```
IKJACCNT,REGION=4K,TIME=300
```

+12

A pointer to a 256-byte string terminated by the null character (0x00), which the exit can use to provide JES control statements. On entry, the string is set to 0x00. The following example shows a modified string:

```
/*JOBPARM  SYSAFF=SYS5
```

Exit return codes:

- 0

A return code of 0 indicates to the server to continue processing the request.

- Nonzero

A nonzero return code indicates to the server to send the job control buffer (offset +4) back to the client and close the connection.

Rules:

- Code the exit with the AMODE(31) and RMODE(ANY) attributes to ensure proper addressability of the input parameters.
- The exit must terminate all modified strings with the null character (0x00).
- If the server is IPv6 enabled and an IPv4 client connects, the IP address is the 4-byte IPv4 address and not the IPv4-mapped IPv6 address.
- If the exit provides JES control statements, the server inserts the control statements into the JCL stream following the JOB statement and before the EXEC statement without any parsing. If more than one control statement is present, the exit must ensure proper JCL line separation by including the NL character or CRLF character as necessary.
- The server inserts the EXEC parameters into the JCL stream without parsing. If the exit modifies the EXEC parameters, it must ensure proper JCL line separation by including the NL character or CRLF character as necessary.

Guidelines:

- For RSH commands without passwords, the PASSWORD parameter is not present.
- The userid in the first positional parameter of the JOB statement parameters can be processed by installation-written JES exits.
- The modified parameters are submitted as a TSO batch job.

Tip: The exit can have the server reject a connection by setting a nonzero return code. The exit can replace the JOB statement buffer contents with message text to be returned to the client. The first byte of the buffer can be set to 0x00 to reject the connection without sending a message to the client.

The user exit is shipped as a sample in the RXUEXIT member of the SEZAINST data set. For more information about this sample, see the REXEC topic in [z/OS Communications Server: IP Configuration Reference](#).

Step 7: Permit access to JESSPOOL files

If the SAF resource class JESSPOOL is defined, ALTER access is required to access output files. Alternatively, use a jobname of *prefix**, where *prefix* is defined in RXSERVE.

Configuring the z/OS UNIX Remote Execution servers

This topic describes the z/OS UNIX files used by z/OS UNIX REXECD and RSHD.

Files for z/OS UNIX REXECD

Note: The user ID associated with the daemon in `/etc/inetd.conf` requires superuser authority. See [z/OS UNIX System Services Planning](#) for a description of the kinds of authority defined for daemons.

The files used by z/OS UNIX REXECD and their locations in the z/OS UNIX file system are as follows:

`/etc/services`

The ports for each application are defined here.

`/etc/syslog.conf`

The configuration parameters for usage of syslogd are defined in this file.

`/etc/inetd.conf`

The configuration parameters for all applications started by inetd are defined in this file.

`/usr/sbin/orexecd`

The server.

If BPX.DAEMON is specified, then the sticky bit must be set on, and `/usr/sbin/orexecd`, and `orexecd` can be in an authorized MVS data set.

`/usr/lib/nls/msg/C/rexdmsg.cat`

The message catalog used by the z/OS UNIX REXECD server.

Note: This is not an actual member at this location, but it is a symbolic link to the part in `/usr/lpp/tcpip/nls/msg/C/*`.

Where the server looks for the message catalog (`rexmsg.cat`) depends on the value of `NLSPATH` and `LANG` environment variables. If you want to store the `msg.cats` elsewhere, you need to change the `NLSPATH` or the `LANG` environment variables. If `rexmsg.cat` does not exist, by default, the software uses the messages hard-coded within the software. These messages duplicate the English message catalog that is shipped with the product.

Files for z/OS UNIX RSHD

The files used by z/OS UNIX RSHD and their locations in the z/OS UNIX file system are as follows:

`/etc/services`

The ports for each application are defined here.

`/etc/syslog.conf`

The configuration parameters for usage of syslogd are defined in this file.

`/etc/inetd.conf`

The configuration parameters for all applications started by inetd are defined in this file.

`/usr/sbin/orshd`

The server.

If BPX.DAEMON is specified, the sticky bit must be set on, and `/usr/sbin/orshd`, and `orshd` can be in an authorized MVS data set.

`/usr/sbin/ruserok`

An optional user exit that will authenticate users logging into the z/OS UNIX RSHD server with a null password. See [“Setting up the z/OS UNIX RSHD installation exit” on page 1345](#) for more information.

Note: This exit is required to allow support for null passwords with RSH.

`/usr/lib/nls/msg/C/rshdmsg.cat`

The message catalog associated with the z/OS UNIX RSHD client is stored here. If this file does not exist, by default, the software uses the messages hard-coded within the software. These messages duplicate the English message catalog that is shipped with the product.

Note: The message catalog is not actually stored here. This is a symbolic link, and the actual member is in `/usr/lpp/tcpip/nls/msg/C/*`.

Considerations for Kerberos authentication

If you plan to use Kerberos authentication with z/OS UNIX RSHD, you need to ensure that the user ID under which `inetd` runs has permission to the ICSF callable services that Kerberos needs. Specifically, if the CSFSERV class is active, ensure that the user ID of `inetd` has read access to the following ICSF SAF resources:

CSF1TRC, CSF1SKE, CSF1SKD, CSF1TRD, and CSFOWH

On z/OS, Kerberos is implemented by Security Server. See [z/OS Integrated Security Services Network Authentication Service Administration](#) for more information.

Setting up the z/OS UNIX RSHD installation exit

When the `-x` option is enabled, if there is no password specified on the RSH command from the client, z/OS UNIX RSHD will drive the installation exit. When the installation exit is driven, RSHD looks for a program in `/usr/sbin` named `ruserok`. This is the only name that it will look for. If `/usr/sbin/ruserok` is not found, the request will fail.

When the z/OS UNIX RSHD server invokes `/usr/sbin/ruserok`, it will pass parameters in the following order:

1. Host name or the host IP address
2. Local user's UID
3. Remote user ID
4. Local user ID

If z/OS UNIX RSHD receives a return code of zero from the installation exit, z/OS UNIX RSHD continues. Any nonzero return code from the installation exit will cause RSHD to issue message EZYRS25E to the client and terminate all connections. The following code fragment can be used as an example to begin building a working `ruserok` installation exit:

```
int main(argc, argv)
    int argc;
    char *argv[];
    char *rhost1; /* "hostname" or "hostname.domain" of client
                   obtained by caller:
                   gethostbyaddr(getpeername()) or the host
                   ip address used by the gethostbyaddr if
                   it failed to return a "hostname" */
    int locuid; /* uid of the user name on local system */
    char *cliuname; /* user name on client's system */
    char *servuname; /* user name on this (server's) system */
    int rc = 4;

    rhost1 = argv[1];
    locuid = atoi(argv[2]);
    cliuname = argv[3];
    servuname = argv[4];
    .
    <authenticate user and set rc=0 if valid>
    .
    return(rc);
```

Configuring TSO and z/OS UNIX Remote Execution servers to use the same port

Because the remote execution servers are generic servers, they attempt to bind to `INADDR_ANY` when they are started. This allows them to listen on all defined IP addresses. However, this prevents both the TSO and z/OS UNIX Remote Execution servers from listening on the same port, and one of the servers would have to use a nonstandard port. Using the `BIND` parameter on the `PORT` reservation statement

in the TCPIP profile data set allows both the TSO and z/OS UNIX Remote Execution servers to bind to the same ports using different IP addresses. The following steps illustrate how this can be done. For more information on the PORT reservation statement, see [z/OS Communications Server: IP Configuration Reference](#).

1. Define a VIPA address to the TCPIP profile data set. This example shows a static VIPA address, but either a static or dynamic VIPA can be used.

```
DEVICE VIPAD1 VIRTUAL 0
LINK    VIPA1  VIRTUAL 0 VIPAD1

HOME
134.134.134.36      VIPA1
```

2. Add PORT statements to the TCP/IP profile for both the TSO and z/OS UNIX Remote Execution servers. One of the servers will bind to the VIPA address. The other can bind to INADDR_ANY by not specifying the BIND parameter. In this example, the z/OS UNIX Remote Execution servers will bind to the VIPA address. Also update the /etc/services file so that exec uses 512 and shell uses 514.

```
512 TCP OMVS BIND 134.134.134.36 ; z/OS Unix REXECD
514 TCP OMVS BIND 134.134.134.36 ; z/OS Unix RSHD
512 TCP RXSERVE                ; TSO REXECD
514 TCP RXSERVE                ; TSO RSHD
```

It is important that the server with the BIND parameter is listed before the one without the BIND parameter. This setup directs all requests to ports 512 or 514 with a destination IP address of 134.134.134.36 to the z/OS UNIX Remote Execution servers. Requests to ports 512 or 514 with a local destination IP address that is not 134.134.134.36 are directed to the TSO Remote Execution server.

To verify this setup:

1. Start the stack with the TCP/IP profile changes described above and start RXSERVE and INETD.

Note: INETD listens for the REXEC and RSH servers under z/OS UNIX.

2. Issue NETSTAT and it should show that both the REXEC servers are listening on port 512 and both RSH servers are listening on port 514. INETD, which listens for the z/OS UNIX Remote Execution servers, listens only on the VIPA address.

MVS User	TCP/IP Id	NETSTAT Conn	CS V1R2 Local Socket	TCPIP NAME: TCPCS Foreign Socket	21:34:41 State
INETDCS1	0000000D	134.134.134.36..514	0.0.0.0..0	Listen	
INETDCS1	0000000E	134.134.134.36..512	0.0.0.0..0	Listen	
RXSERVE	00000019	0.0.0.0..514	0.0.0.0..0	Listen	
RXSERVE	00000018	0.0.0.0..512	0.0.0.0..0	Listen	

Chapter 30. Express logon services with the Digital Certificate Access Server

The Digital Certificate Access Server (DCAS) is a z/OS TCP/IP server that you can use for enhanced logon solutions for z/OS applications. DCAS is part of several IBM express logon solutions, such as Express Logon Feature (ELF) and Web Express Logon (WEL), that work with IBM's host emulation products. DCAS provides a service for these solutions (with ELF, DCAS is needed only for the 3-tier solution) by providing them with z/OS user IDs and PassTickets for logon to host applications. A PassTicket is like a password. In addition, DCAS also provides an open interface and can be used by third-party express logon solutions to obtain user IDs and PassTickets for logon to z/OS applications. Note that DCAS does not support IBM Multi-Factor Authentication for z/OS.

Express Logon Feature

Express Logon Feature (ELF) is an enhanced logon solution that is provided by IBM host access products Host on Demand (HoD) and Personal Communications. ELF is also referred to as certificate-based logon. ELF enables you to log on to host applications using an X.509 certificate for authentication. For more information, see [“What DCAS provides” on page 1347](#) and [Appendix C, “Express Logon Feature,” on page 1365](#).

Web Express Logon

Web Express Logon (WEL) is a single-signon solution that is provided by IBM host access products Host on Demand (HoD) and Host Access Transformation Services (HATS). WEL enables users that are already authenticated, by Web-based logon for example, to log on to their host-based applications without having to reauthenticate by entering a user ID and password. In this case, the host access product communicates with the DCAS server to obtain a PassTicket. For more information about HoD, see <http://www.ibm.com/software/rational/products/hostondemand/>. For more information about HATS, see <http://www.ibm.com/software/awdtools/hats/>.

Using the DCAS server interface for your logon solutions

DCAS provides an open interface for clients to connect using TCP/IP to obtain information that can be used in providing enhanced host logon solutions. For details on [interfacing with DCAS](#), see [z/OS Communications Server: IP Programmer's Guide and Reference](#).

What DCAS provides

In general, DCAS provides a service for returning a PassTicket. A PassTicket is like a password and can be used to log on to z/OS applications. RACF provides PassTicket support using the PTKTDATA class. To understand PassTickets and using the [Using PassTickets](#), see [z/OS Security Server RACF Security Administrator's Guide](#). The type of information DCAS returns depends upon the type of information requested by the client. Also, DCAS configuration controls what type of information is allowed to be provided.

DCAS provides two types of information:

- Certificate-based

Given an x.509 certificate and an application ID, DCAS returns the user ID that has been mapped to the certificate in RACF and a PassTicket. This can be used by logon services that want to provide certificate-based logons. In this case, the certificate provided must be associated with a valid user ID in RACF. For information on [using RACDCERT to administer certificates](#), see [z/OS Security Server RACF](#)

[Security Administrator's Guide](#). This support is used by IBM's Express Logon Feature (ELF) for the 3-tier solution.

- User ID-based

Given a user ID and an application ID, DCAS returns a PassTicket. In this case, the end-user should already have been authenticated using a method such as Web-based sign on, and the logon solution provider must ensure this authentication prior to requesting the PassTicket. This support is used by IBM's Web Express Logon (WEL).

Requirements:

- You must configure the DCAS server. For details on [EXPRESS LOGON using DCAS](#), see [z/OS Communications Server: IP Configuration Reference](#). The DCAS server must be configured to support the IBM logon solution that you want, or when using it for a general or third-party solution, must be configured to return the information that the client requires. This requires that the system administrator that is configuring DCAS and the logon service provider using DCAS work together. The SERVERTYPE configuration statement in the DCAS server profile determines the type of information that DCAS can provide to connecting clients and services (certificate-based, user ID-based, or both).
- DCAS requires that all clients must connect by using TLS/SSL and that the client must be authenticated. DCAS uses AT-TLS for TLS/SSL. For more information, see [“Customizing DCAS for TLS/SSL” on page 1348](#). Review the CLIENTAUTH parameter in the DCAS configuration profile for determining the level of DCAS client authentication. To understand how to configure SSL key rings and certificates for DCAS, see [Appendix B, “TLS/SSL security,” on page 1359](#).
- For all supported configurations, DCAS provides a PassTicket for z/OS applications that are targets for express logon. For these applications, a PassTicket data profile must be defined. RACF provides PassTicket support using the PTKTDATA class.

Customizing DCAS for TLS/SSL

Customize DCAS to implement TLS security by using AT-TLS policies.

Before you begin

Ensure that you have the following setup or configuration:

- A valid DCAS configuration file must be available for DCAS to start. The following list shows the search order of DCAS configuration file:
 1. DCAS_CONFIG_FILE environment variable
 2. /etc/dcas.conf
 3. tsouserid.DCAS.CONF
 4. TCPIP.DCAS.CONF
- DCAS uses AT-TLS for its TLS/SSL support. For more information about setting up AT-TLS for DCAS, see [Steps for customizing DCAS for TLS/SSL](#) and [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#). For more information about configuring key rings and certificates for DCAS, see [Appendix B, “TLS/SSL security,” on page 1359](#).

Requirement: To use AT-TLS, you must configure the Policy Agent and enable the TCP/IP stack for AT-TLS. To configure AT-TLS, see [Chapter 20, “Application Transparent Transport Layer Security data protection,” on page 1149](#).

Procedure

Complete the following steps to customize DCAS to implement TLS security by using AT-TLS policies.

1. Decide the level of authentication that you use for TLS sessions:
 - Server authentication only
 - Client authentication level 1

- Client authentication level 2
- Client authentication level 3

For more information about server authentication and client authentication, see [“Secure Socket Layer overview” on page 1359](#).

2. Create the server key ring database and add the certificates that you need to the server key ring database. For more information about server authentication, see [“Server authentication ” on page 1359](#).
 - For server authentication, because every TLS session handshake includes server authentication, you must add a certificate for this server to the server key ring database. If a server certificate is self-signed, you must also export this certificate to the key ring databases of the clients that log in by using TLS. If a server certificate is signed by a certificate authority (CA), this CA certificate, instead of the server certificate, must be in the client key ring databases. For more information about server authentication, see [“Server authentication ” on page 1359](#).
 - For client authentication, if you use client authentication and self-signed certificates, you must import the client certificates into the server key ring database. If a client certificate is signed by a certificate authority (CA), this CA certificate, instead of the client certificate, must be in the server key ring database. For more information, see [“Client authentication” on page 1360](#).
3. You must configure the AT-TLS policies for DCAS. For more information about configuring AT-TLS, see [“Configuring the server system” on page 1154](#).
 - You must complete the following configuration for AT-TLS policies:
 - Code the TTLSEnvironmentAdvancedParms statement with the ApplicationControlled parameter ON in the policy configuration file. The ApplicationControlled parameter enables DCAS to start TLS security on a connection.
 - Set the HandshakeRole parameter to ServerWithClientAuth on the TTLSEnvironmentAction statement in the policy configuration file.
 - Code the same level of client authentication, the CLIENTAUTH parameter, in the DCAS configuration file and AT-TLS policies, the ClientAuthType parameter.
 - The TTLSRule statement with the LocalPortRange parameter and the LocalAddr parameter must include the DCAS configured values for PORT and IPADDR.
 - Configure TTLS cipherParms statement in the policy configuration file to use ciphers.
 - See [Digital Certificate access server \(DCAS\) configuration file keywords and parameters in z/OS Communications Server: IP Configuration Reference](#) for detailed information.

Table 74. Required AT-TLS policies when DCAS TLSMECHANISM is set to ATTLS

DCAS Configuration Value	AT-TLS Policy value (policy configuration file)
	Direction Inbound
	TTLSEnabled On
	ApplicationControlled ON
	HandshakeRole ServerWithClientAuth
CLIENTAUTH LOCAL2 (default)	ClientAuthType SAFCHECK
CLIENTAUTH LOCAL1	ClientAuthType Required (default)
PORT <portValue>	LocalPortRange <include portValue>
IPADDR <inaddrValue>	LocalAddr <include inaddrValue>

The following Policy Agent AT-TLS configuration sample shows the required policy configuration statements for AT-TLS:

```

TTLSGroupAction secure_DCAS_group
{
    TTLS-enabled On
}

TTLSEnvironmentAction secure_DCAS_env
{
    TTLSKeyringParms
    {
        Keyring DCAS/server-keyring-database
    }

    HandshakeRole ServerWithClientAuth

    TTLSEnvironmentAdvancedParms
    {
        ApplicationControlled On
        ClientAuthType SAFCHECK          # Used with CLIENTAUTH Local2
        TLSv1 Off
        TLSv1.1 On
        TLSv1.2 On
        TLSv1.3 On
    }

    TTLS-CipherParmsRef DCAS_ciphers    # Used to customize ciphersuites for DCAS
}

TTLS-CipherParms DCAS_ciphers
{
    # Sample ciphers. Should be customized!
    V3CipherSuites TLS_RSA_WITH_AES_256_CBC_SHA
    V3CipherSuites TLS_DHE_DSS_WITH_AES_256_CBC_SHA
    V3CipherSuites TLS_DHE_RSA_WITH_AES_256_CBC_SHA
    V3CipherSuites TLS_RSA_WITH_AES_128_CBC_SHA
    V3CipherSuites TLS_DHE_DSS_WITH_AES_128_CBC_SHA
    V3CipherSuites TLS_DHE_RSA_WITH_AES_128_CBC_SHA
    V3CipherSuites TLS_AES_128_GCM_SHA256
    V3CipherSuites TLS_AES_256_GCM_SHA384
}

TTLSRule secure_DCAS_rule
{
    LocalPortRange 8990          # This should be set to the port DCAS is
                                # listening on (PORT keyword in DCAS configuration file)
    Direction Inbound
    TTLSGroupActionRef secure_DCAS_group
    TTLSEnvironmentActionRef secure_DCAS_env
}

```

Tip:

- You can configure many other TLS settings in the AT-TLS policy.
- Default AT-TLS policies for DCAS are defined in the IBM Configuration Assistant for z/OS Communications Server.

When you define your AT-TLS policy rules for DCAS, you will need to decide on a variety of important TLS settings, such as the acceptable TLS protocol versions and the acceptable cipher suites. If need be, work with your network security administrator to determine the proper values for these settings.

4. Configure your security product for TLS. For more information, see [Appendix B, “TLS/SSL security,”](#) on page 1359.

Transport Layer Security (TLS) terms

The following terms apply to Transport Layer Security (TLS).

Partner authentication, server authentication, client authentication

Indicates an algorithm that is applied to verify the authenticity of the TLS/SSL partner. This is done by using X.509 digital certificates. Server authentication indicates that the server authenticates itself to the client. Client authentication indicates that the client authenticates itself to the server after the server authentication completes.

Data authentication protection, data authentication

Indicates that an algorithm is applied to the data that is being transferred. This algorithm modifies the data so that the receiving program can verify whether the data is originated from the expected sender.

Data integrity protection

Indicates that an algorithm is applied to the data that is being transferred. This algorithm modifies the data so that the receiving program can verify whether the data was not modified or changed by others during the transfer.

Privacy protection, encryption

Indicates that an algorithm is applied to the data that is being transferred. This algorithm encrypts or scrambles the data so that only the receiving program can use a special key to decrypt or unscramble the data to its original format.

The original data cannot be seen or interpreted when the data is being transferred.

Raw

Indicates that the data is transferred without being modified by any encryption, data authentication, or data integrity algorithms.

Cipher suite

A collection of partner authentication, data authentication, data integrity, and encryption algorithms, which are used in combination for a given TLS/SSL session.

Note: This term does not indicate the algorithms that are used and does not indicate that the data is encrypted.

Chapter 31. Miscellaneous server

The Miscellaneous (MISC) server is a server that can be used to test and debug applications.

The MISC server supports the 3 protocols described in RFCs 862, 863, and 864:

- Discard
- Echo
- Character Generator

Discard protocol

The MISC server throws away any data it receives. A TCP-based server listens for TCP connections on TCP port 9. If a connection is established, the data is discarded and no response is sent. A UDP-based server listens for UDP datagrams on UDP port 9. When a datagram is received, it is discarded and no response is sent.

Echo protocol

The MISC server returns to the originating application any data that it receives. A TCP-based server listens for TCP connections on TCP port 7. After a connection is established, any data that is received is sent back to the originating application. A UDP-based server listens for UDP datagrams on UDP port 7. When a datagram is received, the data it contained is sent back as an answering datagram.

Character generator protocol

The MISC server sends a repetitive stream of character data without regard to its content. A TCP-based server listens for TCP connections on TCP port 19. When a connection is established, a stream of data is sent to the connecting application. Any data that is received is thrown away. A UDP-based server listens for UDP datagrams on port 19. When a datagram is received, an answering datagram is sent that contains a random number (between 0 and 512) of characters. The data in the received datagram is ignored.

The data that is generated follows an ordered sequence. It repeats a pattern of 94 printable ASCII characters in a ring, so that character number 0 follows character number 94.

The following example shows the repeated pattern.

```
"!#$%&'()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefgh  
"#$%&'()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghi  
"#$%&'()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghij  
%$%&'()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijk  
%$%&'()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijkl  
&'()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklm  
'()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmn  
()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnop  
()*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnop  
*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopq  
*+,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqr  
,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrs  
,-./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrst  
./0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstu  
/0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuv  
0123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvw  
123456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwx  
23456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxy  
3456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz  
456789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{  
56789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{  
6789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{  
789:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{~  
89:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{~  
9:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{~!  
:;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{~!  
;=<=>?@ABCDEFGHIJKLMNopqrstuvwxyz[\]_`~ abcdefghijklmnopqrstuvwxyz{~!
```

Configuring the MISC server

Procedure

1. Specify AUTOLOG and PORT statements in *hlq.PROFILE.TCPIP*.
2. Update the MISC server cataloged procedure (MISCSERV).

Step 1: Configuring PROFILE.TCPIP for the MISC server

To allow the MISC server to start automatically when TCPIP is initialized, include the member name of the MISC server cataloged procedure in the AUTOLOG statement in the *hlq.PROFILE.TCPIP*.

```
AUTOLOG
  MISCSERV
ENDAUTOLOG
```

The AUTOLOG entry in *hlq.PROFILE.TCPIP* is optional. You can choose to start the MISC server manually, when it is needed, using the START command:

```
START MISCSERV
```

The MISC server requires ports 7, 9, and 19 for both TCP and UDP. To ensure that these ports are reserved for the MISC server, verify that they are assigned to the member containing the MISC server cataloged procedure in the PORT statement in *PROFILE.TCPIP*.

```
PORT
  7 UDP MISCSERV
  7 TCP MISCSERV
  9 UDP MISCSERV
  9 TCP MISCSERV
 19 UDP MISCSERV
 19 TCP MISCSERV
```

For more information on these statements, see the [z/OS Communications Server: IP Configuration Reference](#).

Step 2: Updating the MISC server cataloged procedure

Update the MISC server cataloged procedure by copying the sample in SEZAINST(MISCSERV) to your system or recognized PROCLIB and modifying the parameters and data set names to suit your local conditions.

MISC server cataloged procedure (MISCSERV)

```
//MISCSERV PROC MODULE=MISCSRV,PARMS=' '
//*
//* TCP/IP for MVS
//* SMP/E Distribution Name: SEZAINST(MISCSERV)
//*
//* Licensed Materials - Program Property of IBM.
//* "Restricted Materials of IBM"
//* 5694-A01 (C) COPYRIGHT IBM CORP. 1994, 2003
//* Status = CSV1R5
//* Distribution library SEZAINST(MISCSERV)
//*
//MISCSERV EXEC PGM=&MODULE,
//          REGION=4096K,TIME=1440,
//          PARM='&PARMS'
//*
//* The C runtime libraries should be in the system's link list
//* or add them to the STEPLIB definition here. If you add
//* them to STEPLIB, they must be APF authorized. Change
//* the name as appropriate for your installation.
//*
//STEPLIB DD DISP=SHR,
//          DSN=TCPIP.SEZATCP
```

```
//SYSPRINT DD SYSOUT=*
//SYSIN    DD DUMMY
//SYSMDUMP DD SYSOUT=*
//*
//*      MSMISCSR identifies an optional data set for NLS support.
//*      It specifies the MISC server message repository.
//*
//*MSMISCSR DD DISP=SHR,
//*      DSN=TCPIP.SEZAINST(MSMISCSR)
//*
//*      SYSTCPD explicitly identifies which data set is to be
//*      used to obtain the parameters defined by TCPIP.DATA
//*      when no GLOBALTCPIPDATA statement is configured.
//*      See the IP Configuration Guide for information on
//*      the TCPIP.DATA search order.
//*      The data set can be any sequential data set or a member of
//*      a partitioned data set (PDS).
//*
//SYSTCPD  DD DISP=SHR,
//      DSN=TCPIP.SEZAINST(TCPDATA)
```

Specifying the MISC server parameters

The MISC server generates periodic messages whenever a client sends data to ports 7, 9, or 19. If this server runs continually for a long period of time, considerable amounts of spool space can be consumed. Therefore, the MISC server has all tracing turned off by default.

You can enable the trace options for any of the three MISC server protocols using the `PARMS=` parameter on the PROC statement of the cataloged procedure. These options will be in effect when the server starts.

TRACE

Turns on tracing for any of the specified protocols and must be followed by one or more of these three keywords:

ECho

Specifies tracing for the echo protocol on port 7.

Discard

Specifies tracing for the discard protocol on port 9.

CHargen

Specifies tracing for the character generator protocol on port 19.

DEbug

Specifies tracing for problem determination.

For example, the following statement turns tracing on for the echo and discard protocols.

```
//MISCSERV PROC MODULE=MISCSRV,PARMS='TRACE ECHO DISCARD'
```

Appendix A. Setting up the InetD configuration file

The Internet Daemon (InetD) is a generic listener program that is used by such servers as the z/OS UNIX telnet server and the z/OS UNIX rexec server. Other servers such as the z/OS UNIX ftp server have their own listener program and do not use InetD. For more information about generic servers and sample InetD started procedure JCL, see [“Generic servers in a CINET environment”](#) on page 49.

The inetd.conf file is an example of the user configuration file. This file is stored in the /etc directory and is referenced as a start parameter in the InetD started procedure JCL. The inet.conf file can also be stored as an MVS data set. Ensure that you use configuration statements like those statements in the following example to enable the InetD services that are required on your system:

```
#=====
# service | socket | protocol | wait/ | user | server | server program
# name    | type   |          | nowait|      | program | arguments
#=====
#
shell      stream  tcp        nowait  OMVSKERN /usr/sbin/orshd orshd -l
exec       stream  tcp        nowait  OMVSKERN /usr/sbin/orexecd orexecd -lv
otelnets   stream  tcp        nowait  OMVSKERN /usr/sbin/otelnetsd otelnetsd
# Add the following line to enable Kerberos for orshd
kshell     stream  tcp        nowait  OMVSKERN /usr/sbin/orshd orshd -l -k KRB5
```

Figure 164. Adding applications to /etc/inetd.conf

If the rshd, rexecd, or otelnetsd service is to support IPv6 clients, then *tcp6* should be specified instead of *tcp*. Kerberos is not supported for IPv6-enabled services, such as z/OS UNIX Telnet, z/OS UNIX rsh, and z/OS UNIX rexec.

For IPv4 connection partners, the terminal ID passed from InetD to RACF (or an equivalent security program) is an 8-byte hexadecimal character string containing an IPv4 address. For example, the IP address 163.97.227.17 is translated to X'A361E311'. RACF interprets this as a terminal logon address and rejects it if it is not previously defined.

For IPv6 connection partners, only IPv4-mapped IPv6 addresses are handled in this way. The IPv4 address portion of the IPv6 address is placed in the terminal ID for RACF validation. No other IPv6 address format is supported through terminal ID RACF validation.

To establish a relationship between the servers defined in the /etc/inetd.conf file and specific port numbers in the z/OS UNIX environment, ensure that statements have been added to ETC.SERVICES for each of these servers. See the sample ETC.SERVICES installed in the /usr/lpp/tcpip/samples/services directory for how to specify ETC.SERVICES statements for these servers.

The traces for both the z/OS UNIX rexec and rsh servers are enabled through options in the InetD configuration file (/etc/inetd.conf):

```
#=====
# service | socket | protocol | wait/ | user | server | server program
# name    | type   |          | nowait|      | program | arguments
#=====
#
shell      stream  tcp        nowait  OMVSKERN /usr/sbin/orshd orshd -d 1
exec       stream  tcp        nowait  OMVSKERN /usr/sbin/orexecd orexecd -d 2
```

Figure 165. Setting traces in /etc/inetd.conf

The traces are turned on for both servers by passing a -d argument to the server programs. **1** is the RSHD server and **2** is the REXECD server. All commands executed after the debug flags have been turned on in the InetD configuration file and the InetD server has reread the file will produce trace output.

The trace is written in formatted form to the syslogd facility name daemon with a priority of debug. The trace data can be routed to a file in your Hierarchical File System by specifying the following definition in your syslogd configuration file (/etc/syslogd.conf):

```
#  
# All ftp, rexecd, rshd  
# debug messages (and above  
# priority messages) go  
# to server.debug.a  
#  
daemon.debug                /tmp/syslogd/server.debug.a
```

In this example, the trace data is written to /tmp/syslogd/server.debug.a in your Hierarchical File System. For more information on syslogd, see [“Logging of system messages” on page 30](#).

For more information about InetD, see [z/OS UNIX System Services Planning](#) or [z/OS UNIX System Services Command Reference](#).

Appendix B. TLS/SSL security

The Transport Layer Security (TLS) protocol is defined by the Internet Engineering Task Force (IETF) in RFCs 2246, 4346, 5246, and 8446. TLS is based on the Secure Socket Layer (SSL) protocol.

This appendix is a reference for z/OS Communications Server applications that use TLS/SSL.

More information about the concepts of cryptography and SSL can be found at the following websites:

- http://httpd.apache.org/docs/current/ssl/ssl_intro.html
- <http://www.verisign.com/ssl/ssl-information-center/how-ssl-security-works/index.html>

For examples of digital certificate implementation scenarios, see [z/OS Security Server RACF Security Administrator's Guide](#).

Secure Socket Layer overview

SSL provides data privacy and integrity as well as server and client authentication based upon a Public Key Infrastructure (PKI) method. PKI requires that the server organization generate a public key/private key pair that can be used during negotiations. PKI requires that data encrypted with the public key be decrypted by only the private key and that data encrypted with the private key be decrypted by only the public key. This is considered an asymmetric encryption method because different keys are used at each end of the secure connection. The Server sends its public key to the client when the client requests a connection.

The client and server encrypt SSL parameter negotiations using the PKI method of encryption. One of the most important items negotiated is the encryption algorithm to be used during data transmission. The algorithm chosen will be one that uses the same key at each end of the secure connection. This is known as a symmetric encryption method and is about 1000 times faster than the asymmetric PKI method used during SSL parameter negotiation. The encryption key used by the symmetric encryption method is created and exchanged during SSL negotiation protected by the PKI encryption method.

Some client-server connections support negotiations to determine if the client wants or supports SSL prior to beginning the SSL handshake. Most servers and clients can be configured to immediately start the SSL handshake process or to negotiate whether or not to perform the SSL handshake. See the security information for the appropriate server or client for information on whether negotiated TLS/SSL is supported and how it is implemented.

The SSL protocol begins with the handshake. During the handshake:

- Server authentication is done by the client.
- Optional client authentication is done by the server.
- An encryption algorithm and single encryption key are chosen to encrypt and decrypt session data between the client and server.

Server authentication

When using SSL to secure communications, the SSL authentication mechanism known as Server Authentication is used. This is the minimum amount of security provided by SSL and allows the client to validate that the Server is what it says it is.

To ensure that someone has not stolen the server's private and public keys and is pretending to be the server, the server sends additional information with the public key so the client can confirm the identity of the server. The complete package of information sent to the client is called a digital certificate which conforms to the X.509 standard.

This X.509 digital certificate includes, among other things, the Distinguished Name (DN) of the Server organization, the public key created by the server organization, the Distinguished Name of the

organization issuing the certificate, and the issuer's signature. The organization issuing the certificate may be a well-known Certificate Authority (CA) or you may issue (create) your own certificate, called a self-signed certificate.

To create a signature, the certificate issuer first generates a message digest from the owner's DN, the owner's public key, and the issuer's DN. The message digest is the result of hashing this information down to a small size, such as 128, 160, 256, or some other number of bits. The message digest result is unique for that information and is based on the hashing algorithm that is used. The message digest is encrypted with the issuer's private key to create the issuer's signature.

When the client receives the server certificate, the client must have the public key of the certificate signer. The public key is used to decrypt the message digest. The server certificate also contains the hashing algorithm used to create the message digest. The client uses the same algorithm to create another message digest using the Distinguished Names and public key information in the received server certificate. If this new message digest exactly matches the decrypted message digest (issuer's signature) created by the certificate issuer, the client can be assured that the certificate has not been altered. This method of authentication is dependent on the security of the private key that is used by the certificate issuer.

To conduct commercial business on the Internet, you should obtain a server certificate signed by a well-known Certificate Authority. Server certificates issued by a well-known CA gives the client high assurance that the server is authentic. Most client key rings have been primed with several well-known CA's certificates. That enables the client to authenticate a Server certificate signed by a well-known CA without having to first obtain the issuer's certificate which includes the public key. For relatively small, private networks within your own enterprise you can create your own self-signed server certificate. The only difference between a CA issued certificate and a self-signed certificate is the issuer's Distinguished Name and who's private key was used to encrypt the message digest. The client needs to use the correct public key to decrypt the message digest. The CA certificate containing the CA's public key is probably already in the client's key ring and it can be used to decrypt the CA signature (message digest). The self-signed certificate containing the organization's public key needs to be added to the client's list of signer certificates so the client can decrypt the signature (message digest) created when the self-signed certificate was created. Some client products allow the client to add the server certificate to its list of signer certificates when the server certificate is received during SSL negotiation. If the client is confident the certificate really came from the correct server, this is an easy way to add the certificate rather than getting a copy and adding it manually.

For server authentication to work, the server must have a private key and associated server certificate in the server key database file. The gskkyman utility or RACF Common Keyring support can be used to manage the keys and certificates needed for SSL support. If the gskkyman utility was used to create the key ring, a password stash file is also required.

SSL requires a server certificate as part of its server authentication process. The server certificate and the Certificate Authority certificates are stored in a key ring (also referred to as a key database). The server's key ring can be created using the gskkyman utility provided by the System Secure Socket Layer (System SSL) element of z/OS or by using RACF's certificate management support. The key ring is associated with a server or client using server or client specific statements.

Note: Global step-up type certificates are not supported by Telnet profile defined security if the client application sends the handshake complete message to the server before completing the second handshake. AT-TLS enabled Telnet does support global step-up type certificates.

Client authentication

Client authentication provides additional authentication and access control by checking client certificates at the server. This support prevents a client from obtaining a connection without an installation approved certificate.

The server authenticates the client by receiving the client's certificate during the SSL handshake and verifying the certificate is valid. Validation is done by the server the same way the client validates the server's certificate. The client sends a signed certificate to the server. System SSL at the server decrypts the signature (message digest) using the public key of the client certificate issuer found in the server key

database file. The server then creates a new message digest using the certificate's Distinguished Names and public key and compares the new message digest with the decrypted one. If they match, the server can be assured the client is authentic. Depending on where the client certificate is stored, up to three different levels of client authentication are available. See the security information for the appropriate server or client for setup details.

Level 1 authentication is performed by System SSL. The client passes an X.509 certificate to the Server as part of the SSL Handshake. To pass authentication, the Certificate Authority (CA) that signed the client certificate must be considered trusted by the server. That is, the certificate for the CA must be in the key ring used by the Server and designated as trusted. Note that the value of this option alone is based on which CAs are considered trusted. If the CA is a public CA and the certificate is in an easily obtained class, anyone can obtain such a certificate. In this case passing level 1 SSL Client Authentication does not provide much additional security unless coupled with the level 2 RACF support. If the CA is controlled by the enterprise, some level of access control is provided because the client that possesses such a certificate is at least known to the organization.

In addition to the checking done with the first level of client authentication support, *level 2* authentication requires that the client certificate is registered with RACF or another SAF-compliant security product and is mapped to a valid z/OS user ID. The client certificate that is received during the SSL handshake is used to query the security product to verify that the certificate maps to a user ID known to the system before connection negotiation. This level of support provides extra access control at the server and ensures that the user is known to have a valid user ID on the server host. Each server uses the returned user ID in a different way. To see how the user ID is used for a particular server, see the security information for the appropriate server or client. Level 1 authentication occurs before level 2 authentication.

Level 3 authentication provides, in addition to level 1 and level 2 support, the capability to restrict access to the server based on the user ID returned from RACF. In some cases a certificate may be valid and mapped to a user ID but should be valid for only one of several servers. The third level of control uses the SERVAUTH RACF class to restrict access to the server based on client user ID. If the SERVAUTH class is not active or the SERVAUTH profile for the server is not defined, it is assumed level 3 authentication is not requested. If the SERVAUTH class is active and the server profile is defined, a connection is accepted only if the requester's user ID associated with the client certificate is in the profile. Otherwise, the connection is dropped.

To enable Client Authentication for each server, use the following server-specific statements:

AUTHENTICATION LEVEL	FTP	Telnet	DCAS
	SECURE_LOGIN statement	AT-TLS ClientAuthType setting	CLIENTAUTH statement
AUTH LEVEL 1	REQUIRED	Required	LOCAL 1
AUTH LEVEL 2	VERIFY_USER	SAFCheck	LOCAL 2
AUTH LEVEL 3	VERIFY_USER	SAFCheck	LOCAL 2

Note: See [Achieving the basic level of security](#) for more information on the ClientAuthType parameter settings.

Level 1 client authentication is done by SSL using a gskkyman key ring or a RACF key ring. If the client certificate was issued by a well-known Certificate Authority, it is likely the CA certificate is already primed in the gskkyman key ring. The CA certificate is probably also in RACF. However, all CA certificates in RACF initially have a status of NOTRUST. The CA certificate must be set to TRUST and connected to the appropriate RACF key ring. If the certificate issuer (a CA or self-signed) is not part of the list of well-known CAs, the key ring must be primed with the signer certificate of the CA or the self-signed client certificate.

After Level 1 authentication is performed by SSL using either key ring, the certificate is passed to the server which accesses the RACF database for Level 2 and Level 3 authentication.

Encryption algorithms

After authentication occurs, the client and server must agree on a symmetric encryption method and generate a single encryption key to use for data encryption. The chosen key is exchanged by using the PKI method of encryption. After the symmetric encryption algorithm (such as AES) and a single encryption key are chosen, all data exchanges use this algorithm and key instead of the PKI method of encryption.

In an SSL-encrypted session, all data is encrypted with the symmetric encryption algorithm immediately before it is sent to the client. Data from the client is decrypted immediately after it is received. The encryption algorithm that is used for the connection depends on a combination of the following factors:

- The encryption algorithm list that the SSL subsystem supports
- The list that the server wants to use
- The encryption algorithms that the client requests

During the SSL handshake, the client sends a list of encryption algorithms it is able to use. The server submits its list and the SSL subsystem picks an algorithm that all parties support, giving preference to the order that the server specifies. If the server does not support any of the encryption algorithms that the client requests, the connection is closed. AT-TLS and a small number of z/OS Communications Server applications use the TLS/SSL support that is provided by the System SSL component of the z/OS Cryptographic Services element of z/OS. The strength of cryptographic algorithms available through System SSL depends on the level of System SSL that is installed.

The System SSL base FMID provides cryptographic support up to 56-bit in strength. In order to use cryptographic support greater than 56-bit (for example, Triple DES, AES, ChaCha-Poly1305, etc.), either the System SSL Security Level 3 FMID must be ordered and installed or the CP Assist for Cryptographic Functions (CPACF) DES/TDES Enablement Feature 3863 must be installed. For more information about installing the Security Level 3 FMID, see *z/OS Program Directory*. The encryption algorithm list can be customized for the servers and client to a subset of the System SSL list. For specific server and client statements that are used to create the encryption list, see the security information for the appropriate server or client.

Encryption is provided by either hardware, if available, or software algorithms within System SSL or Integrated Cryptographic Services Facility (ICSF). There is no TCP profile definition to control whether the cryptographic hardware is used for secure connections. For information about cryptographic hardware usage within System SSL, see [z/OS Cryptographic Services System SSL Programming](#). To use FIPS 140 mode, ICSF must be started and available to System SSL.

If hardware encryption is to be used, be sure that the RACF user ID associated with the server has read access to the RACF CSFSERV class resources. If ICSF is available but the server has not been given access to these resources, the SSL initialization may fail. The reason code is likely to be 4 (bad password) because System SSL will attempt to use the hardware encryption during processing of the key ring.

Enable CSFSERV resources

If hardware encryption and Integrated Cryptographic Services Facility (ICSF) are installed, system SSL verifies that the user ID that is associated with the server is permitted to use CSFSERV resources. The RACF administrator can permit the RACF user ID to use the CSFSERV resources:

```
PERMIT service-name CLASS(CSFSERV) ID(serverid) ACCESS(READ)
```

For information about the [CSFSERV resources](#) (service-names) that are accessed by System SSL, see [z/OS Cryptographic Services System SSL Programming](#).

z/OS FTP users can either permit every FTP client user ID to these general resource profiles, or they can mark these profiles as delegated and permit only the FTP daemon user ID to the profiles.

In the following example, resource CSFENC in class CSFSERV is delegated, and only the FTP daemon user ID (FTPD for this example) needs to be permitted. Make these changes before you start FTPD.

Permit the FTP daemon to the resource:

```
PERMIT CSFENC CLASS(CSFSESV) ID(FTPD) ACCESS(READ)
```

Mark the resource profile as delegated:

```
RALTER CSFSESV CSFENC APPLDATA('RACF-DELEGATED')
```

Refresh the CSFSESV class:

```
SETROPTS RACLIST(CSFSESV) REFRESH
```

For more examples, see the EZARACF sample in SEZAINST. For more information about [Defining delegated resources](#), see [z/OS Security Server RACF Security Administrator's Guide](#).

The MAXLEN installation option for hardware cryptography determines the maximum length that can be used to encrypt and decrypt data by using ICSF. Set this option to 65527 or greater, which is the maximum TCP/IP packet size.

The System SSL GSKSRVR server provides the capability to determine whether cryptographic hardware is being used through its DISPLAY CRYPTO operator command (for example, f gsksrvr,d crypto). The System SSL GSKSRVR server is not automatically started. For more information about the SSL started task and setting up and using the GSKSRVR server, see [z/OS Cryptographic Services System SSL Programming](#).

For more information about controlling who can use cryptographic keys and services, see [z/OS Cryptographic Services ICSF Administrator's Guide](#).

Appendix C. Express Logon Feature

Users accessing SNA applications using Telnet clients such as Host On Demand are generally required to know the user ID and password for the application they want to access. The ID-and-password authentication process creates several potential problems. For example, users may forget their IDs and passwords. If they do forget, the passwords must be reset by a system administrator, a time-consuming process. On the other hand, writing down the IDs and passwords or sharing them with someone else creates a security risk, especially because passwords are usually valid for relatively long periods of time.

IBM's solution to these problems is the Express Logon Feature (ELF), a process which allows a user on a workstation with a Telnet client and an X.509 certificate to log on to an SNA application without entering an ID or password. The Express Logon Feature is supported on two-tier and three-tier network designs. The two-tier design uses the z/OS TN3270E Telnet server. The three-tier design uses a middle-tier Telnet server and a Digital Certificate Access Server (DCAS).

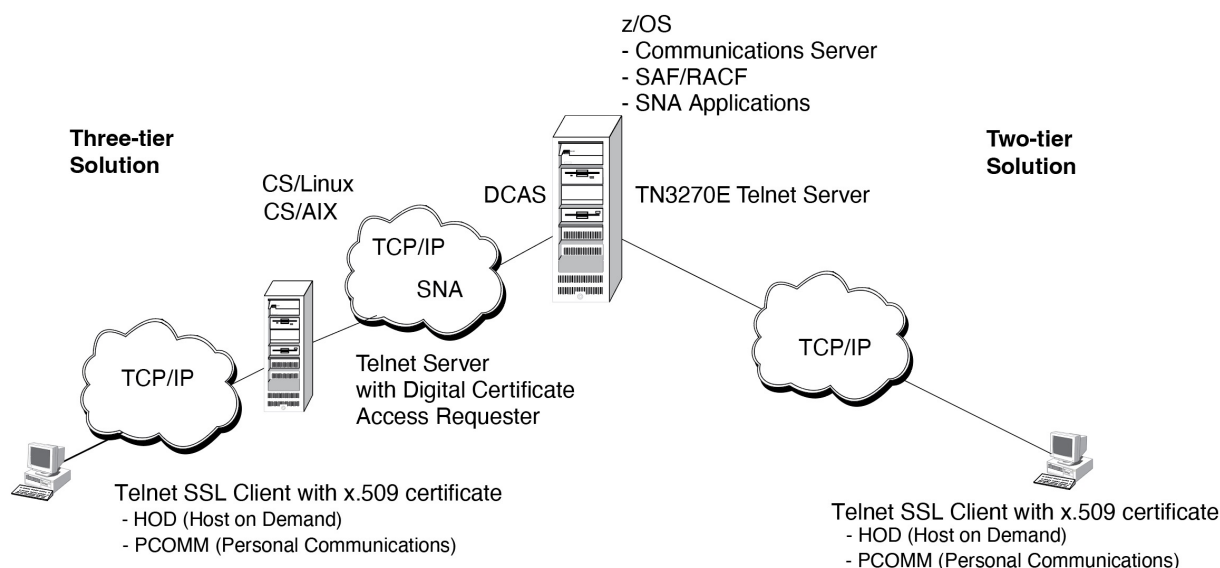

Figure 166. Express Logon network

Both network designs require a Telnet client emulator that supports:

- Transport Layer Security (TLS) or Secure Sockets Layer (SSL) connections with client authentication and an X.509 certificate. Using RACF services in z/OS, the client certificate must be associated with a valid user ID.
- The Express Logon Feature (ELF).

The two-tier design requires the z/OS TN3270E Telnet server with TLS/SSL, client authentication, and Express Logon functions turned on. See [“Express Logon Feature”](#) on page 666 for server setup information.

The three-tier design requires a middle-tier Telnet server that includes a Digital Certificate Access Requester (DCAR) and the z/OS Digital Certificate Access Server (DCAS). A middle-tier Telnet server, so called because it is not on the host, but rather between the Telnet client emulator and the host.

Note: The term *DCAR* is used to describe the part of the Telnet middle-tier server that supports the Express Logon Feature and communicates as a client with the DCAS. It is not separate from the Telnet middle-tier server. The term *DCAR* might not be used in other information that describes ELF but has been used here to simplify the description of this function.

A Digital Certificate Access Server (DCAS) exists on the host. DCAS uses RACF services to obtain a user ID that has been mapped to a digital certificate.

The host also provides RACF Secured Signon services, which the DCAS or the z/OS host TN3270E Telnet server uses to generate a PassTicket. A PassTicket is a RACF token similar to a password except that it is valid only for ten minutes. Additionally, the z/OS TN3270E Telnet server might use a Multi-Factor Authentication (MFA) token that was generated by IBM MFA for z/OS.

In a typical scenario, an ELF-enabled client wants to log on to a TSO application on the host.

- In the two-tier design, the user starts a secure connection with level 2 client authentication, which passes the client certificate to the TN3270E Telnet server. The TN3270E Telnet server uses either RACF MFA services to retrieve a user ID and an MFA token or uses RACF Secured Signon services to obtain a user ID and PassTicket.
- In the three-tier design, the user starts the Telnet connection to the middle-tier Telnet server. The client of the DCAS is the middle-tier Telnet server or DCAR, which attempts to log on to an SNA application for the client emulator. The DCAS receives a digital certificate from the DCAR and returns a user ID and PassTicket. Secure communication is used between the DCAS and the DCAR. The server recognizes that the client wants the Express Logon function and invokes the DCAR, which opens a secure connection with client authentication and passes the client's certificate and application name to the DCAS on the host. The DCAS uses RACF Secured Signon services to obtain a user ID and PassTicket, which the DCAS returns to the DCAR. The DCAR passes this information back to the middle-tier Telnet server.

In both cases the ELF-enabled client and server now have enough information to complete the logon to TSO. This occurs without the user ever having to enter a user ID or password.

Note: You can use RACF or any other SAF-compliant security product that supports MFA (for the two-tier design) or PassTickets with Express Logon.

Configuring RACF services for Express Logon

At a minimum, you must register all client certificates with RACF or create a RACF certificate name filter for the client certificates by using the RACDCERT command. This associates the certificates with the IDs of users who are attempting to log on. In the two-tier solution, the certificate is passed from the client to the TN3270E Telnet server. In the three-tier solution, the certificate is passed from the client to the middle-tier Telnet server, then to the DCAR, and then to the DCAS.

Configuring RACF and IBM Multi-Factor Authentication for z/OS (two-tier solution only)

To use IBM Multi-Factor Authentication (MFA) for z/OS, you must set up and configure the IBM MFA for z/OS product and also add appropriate MFA parameters to the RACF user profile for the users that need to log in with MFA tokens. For more information about IBM MFA for z/OS setup and configuration, see the following documentation:

- *IBM MFA V1R1: TouchToken, PassTicket, and Application Bypass Support* ([An IBM Redpaper publication: IBM Form #: REDP-5386](#))
- [z/OS Security Server RACF Security Administrator's Guide](#)
- [IBM Z Multi-Factor Authentication Installation and Customization](#)

Configuring RACF for PassTickets

You must also create a RACF PTKTDATA profile for each application ID the user is attempting to access. The PTKTDATA profile allows the DCAS or z/OS TN3270E Telnet server to obtain a PassTicket and user ID for the application. In the three-tier solution, the DCAS must pass the PassTicket and user ID back to the DCAR. For Host On Demand, the application ID part of the profile name must be the same as that configured in the Host On Demand Express Logon Application ID popup window. In most cases, the application name with which the user logs on will match the application ID portion of the RACF PTKTDATA class profile. However, for TSO and some other applications, the names and IDs may not match:

- If VTAM generic resources are used for TSO, define the application name portion on the RACF profile using the TCASGNAM defined in the TSOKEYxx, SYS1.PARMLIB member.

- If VTAM generic resources are not used, define the application name on the RACF profile as TSO.
- When configuring for TSO application logon, use the format TSO<SID> in the PassTicket profile, where SID is the SMF system ID defined in the SMFPRMxx member of SYS1.PARMLIB. (For example, if the SID is 3390, you would type TSO3390 in the profile.) For details, see [z/OS Security Server RACF Security Administrator's Guide](#).

For applications that allow shared user IDs (multiple users request access to the application simultaneously with the same user ID), you must specify the APPLDATA('NO REPLAY PROTECTION') option on the RDEFINE command in the PTKTDATA profile. This bypasses the default RACF protection against replay of PassTickets.

An example of configuring the Express Logon components

The following example describes, in general terms, how to set up and configure Express Logon by using the following products and components:

- IBM Host On Demand Telnet client
- z/OS TN3270E Telnet server (for two-tier solution)
- IBM Communications Server for Windows (middle-tier Telnet server for three-tier solution)
- DCAS - see [Chapter 30, “Express logon services with the Digital Certificate Access Server,”](#) on page 1347

For details on configuring each product, see the appropriate documentation for that product.

Configuring the Host On Demand Telnet client

To setup and configure the Host On Demand client, follow these steps:

1. For each application to which the user will log on, create a macro to record the logon screen of the application.

The user plays this macro when displaying the logon screen on the client.

2. Enter the application ID in the application ID popup window.

The application ID must be the same name specified on the z/OS for the application ID portion of the PTKTDATA profile. The ID in the profile in most cases must be the same as the application name.

3. Use the Host On Demand key-management utility to:
 - a. Create a key database (key ring).
 - b. Create a certificate request or generate a self-signed certificate and associate the certificate with the key ring.
 - c. Use FTP to transmit the middle-tier Telnet certificate to the client workstation and store the server certificate in the key database of the client.
 - d. Use FTP to transmit the Host On Demand Telnet client certificate to the middle-tier server and store in the SSL key database of the server.
4. Use FTP to transmit the client certificate to an MVS data set on the z/OS host. Use the RACF Certificate Services RACDCERT command to associate the certificate with a valid user ID.

Configuring the z/OS TN3270E Telnet server (two-tier solution)

Express Logon Feature requires TLS/SSL with level 2 client authentication functionality at the server. After that level of security is working, specify the EXPRESSLOGONMFA (to use Multi-Factor Authentication tokens) or EXPRESSLOGON (to use PassTickets) parameter statement to enable ELF in the z/OS TN3270E Telnet server.

Configuring the middle-tier Telnet server (IBM Communications Server for Windows example)

The middle-tier server is a Telnet server such as IBM Communications Server for Windows, that communicates with the Host On Demand client using a TLS/SSL connection with client authentication. The middle-tier server DCAR also communicates with the DCAS on the host. The DCAS and DCAR communicate over a TCP/IP connection using TLS/SSL with client authentication.

To configure the Telnet server, follow these steps:

1. Use the Communications Server for Windows SNA Node Configuration panels to enable the Express Logon Feature and configure the DCAS server address and port.
2. Use the local key management utility to store the client certificate and the DCAS certificate in the local key ring:
 - a. Create a key database file.
 - b. Create a certificate request or generate a self-signed certificate and associate the certificate with the key ring.
 - c. Store the client certificate and the DCAS certificate in the key ring of the server.
3. Use FTP to transmit the DCAR certificate to the z/OS host and use gskkyman or RACF Certificate Services to store the DCAR certificate in the DCAS key ring.

Appendix D. Using HCD

This information includes examples of panels that are used to define IQD channels and devices for z/OS Communications Server using HCD.

1. Select processors

Figure 167. Select processors

2. Select 'S' Work with attached channel paths

Figure 168. Work with attached channel paths

3. On the Channel Path List enter the Add command (or press F11) to initiate the Define Channel Path dialog.

Figure 169. Initiate the Define Channel Path dialog

4. Fill in the Add Channel Path panel, then press Enter (Select SHR for Operation mode to share IQD Chpids across LPARs).

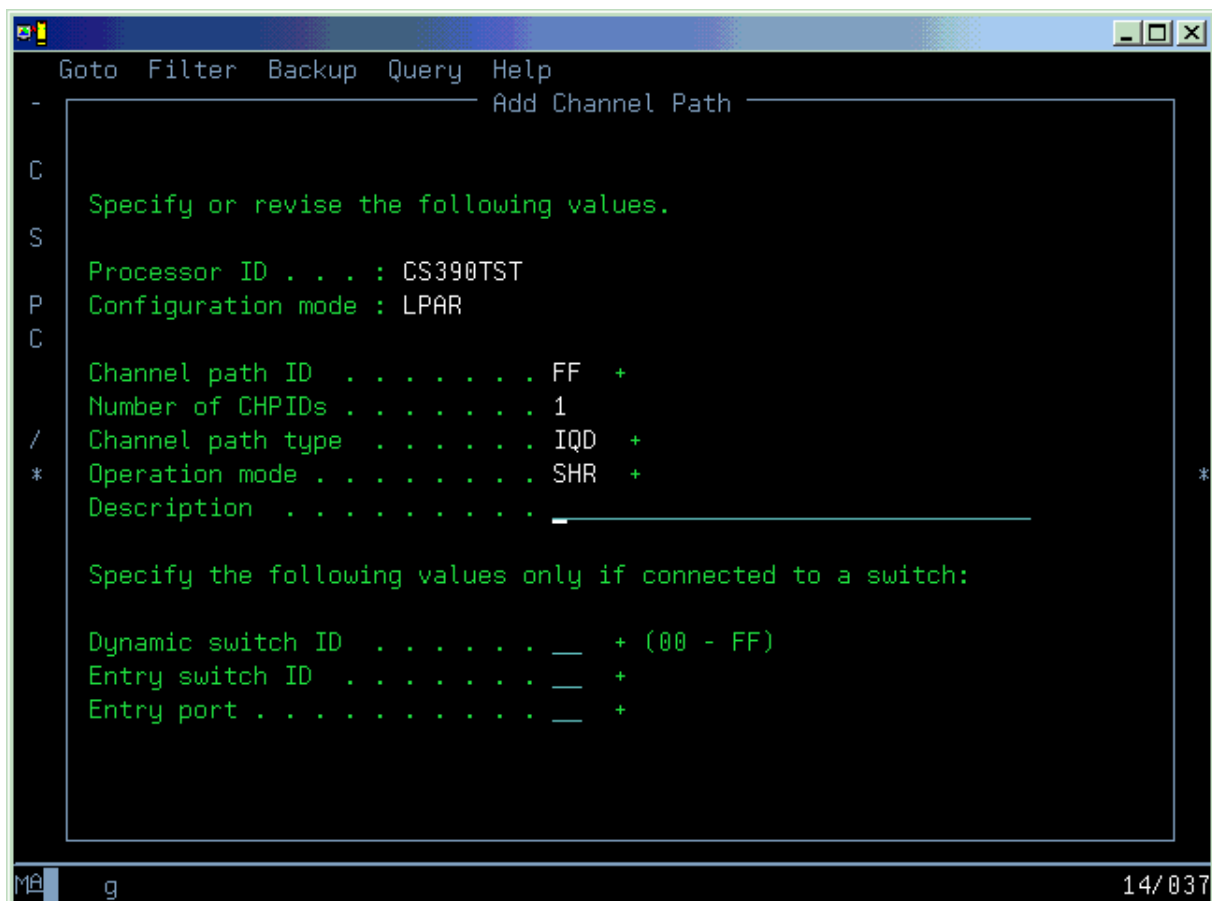

Figure 170. Add channel path

5. For an IQD channel path, the Specify Maximum Frame Size panel pops up with the default value of 16 KB.

Figure 171. Specify Maximum Frame Size

Or change the frame size to wanted size:

Table 75. Frame size specification	
Maximum Frame Size	TCP/IP MTU size
16K	8K
24K	16K
40K	32K
64K	56K

- Define the channel path access list that each LPAR should have access to.

Figure 172. Define the channel path access list

7. Having pressed Enter, the Channel Path List is redisplayed with channel path number FF defined.

```

Goto  Filter  Backup  Query  Help
-----
                                Channel Path List          Row 1 of 1 More:  >
Command ==> _____ Scroll ==> PAGE

Select one or more channel paths, then press Enter. To add use F11.

Processor ID . . . : CS390TST
Configuration mode : LPAR

                                Dyn +  --Entry +--
/ CHPID Type + Mode + Switch Switch Port Con. Description
_ FF   IQD   SHR   _   _   _
***** Bottom of data *****

```

Figure 173. Channel path number FF defined

8. As the next step, add the control unit(s) to the IQD channel path. Select the defined channel path with action "Work with attached control units" (action code 'S').

```

Goto  Filter  Backup  Query  Help
-----
                                Channel Path List          Row 1 of 1 More:  >
Command ==> _____ Scroll ==> PAGE

Select one or more channel paths, then press Enter. To add use F11.

Processor ID . . . : CS390TST

Appendix E. Steps for preparing to run IP security

To run IP security, you need to configure the IKE daemon. Each step is described in detail in the corresponding subtopic.

Procedure

Perform the following steps to prepare to run the IKE daemon:

1. Set the appropriate UNIX System Services parameters.
2. Ensure the IKE daemon's user ID has enough system resources.
3. Authorize the IKE daemon to the external security manager.
4. Authorize the **ipsec** command to the external security manager.
5. Authorize IP security to ICSF (optional).
6. Set up the IKE daemon for RSA signature mode authentication (optional).

Step 1: Setting appropriate UNIX System Services parameters

Verify that AF_UNIX and AF_INET are defined in the BPXPRMxx member of SYS1.PARMLIB. If the domains are not defined, see [z/OS UNIX System Services Planning for the Customizing the BPXPRMxx member of SYS1.PARMLIB](#).

Step 2: Ensure the IKE daemon's user ID has enough system resources

The user ID under which the IKE daemon runs requires sufficient system resources when all the z/OS system's IKE peers attempt to negotiate or renegotiate IPsec tunnels with z/OS at the same time. If thousands of IKE peers attempt to negotiate or renegotiate, you might need to adjust certain system parameters upwards to ensure that IKED does not run out of critical resources. Ensure that IKED does not run out of the following critical resources:

- Virtual storage
- System message queue space
- UDP queue capacity

Follow the instructions in this section to ensure that the IKE daemon's user ID has sufficient resources.

Virtual storage capacity

Take the following steps to ensure the user ID has enough virtual storage:

- Adjust the REGION parameter to ensure that the TSO/E region size (REGION) for the IKE daemon user ID is at least 1 GB.
- Set the BPXPRMxx parmlib member by using the MAXASSIZE parameter to ensure that ASSIZEMAX in the OMVS segment for your user profile is at least 1 GB.
- Set the MEMLIMIT value in your OMVS segment, or set the BPXPRMxx or the SMFPRMxx parmlib members to ensure that the MEMLIMIT value for the user ID is at least 1 GB. The default value is 2 GB.

You can see the format of the **RACF ALTUSER** command when the command is issued to assign the storage allocations for a user. The MEMLIMIT value is set in the OMVS segment for the user.

```
ALU user-name TSO(SIZE(1048576)) OMVS(ASSIZEMAX(1073741824) MEMLIMIT(1G))
```

For more information about the MEMLIMIT system parameter, see [z/OS MVS Programming: Extended Addressability Guide](#). For information about the **ulimit** command, see [z/OS UNIX System Services Command Reference](#).

System message queue capacity

The IKE daemon uses internal OMVS message queues to route work to various threads in the process. In environments with a large number of IKE peers, the number of messages on these queues might grow significantly, to the point where the default maximum number of messages allowed on a message queue is exceeded. In such environments, set the IPCMSGQMNUM parameter of the SETOMVS command to a high value to accommodate scenarios where large numbers of SAs are being negotiated simultaneously. For more information about the IPCMSGQMNUM parameter, see [z/OS MVS System Commands](#).

UDP queue capacity

If UDPQUEUELIMIT is configured or defaulted in the TCPIP profile, a UDP queue limit is in effect for the TCP/IP stack. When large numbers of IKE peers are negotiating SAs with z/OS, the limit can be exceeded. Thus, some remote IKE peers retransmit messages to z/OS and the duration of the SA negotiations increases. In such cases, you can use the UDP Traffic Regulation function of z/OS Communications Server's Intrusion Detection Services (IDS) to increase the UDP queue limit for the IKE daemon's UDP queues. Specifically, define a UDP traffic regulation rule for ports 500 and 4500 with the queue limit value set to VERY_LONG. For more information about UDP Traffic Regulation, see [Traffic regulation policies for UDP ports](#).

Step 3: Authorizing the IKE daemon to the external security manager

You need to authorize the IKE daemon to the external security manager.

To authorize the IKE daemon to RACF, perform the steps in [“Steps for authorizing the IKE daemon to RACF”](#) on page 1392.

Steps for authorizing the IKE daemon to RACF

The commands used to authorize the IKE daemon to RACF are in EZARACF in the SEZAINST data set.

Procedure

Perform the following steps to authorize the IKE daemon to RACF:

1. Add user ID IKED, and add IKED to the STARTED class.

- If IKED is defined using UID 0:

```
ADDUSER  IKED      DFLTGRP(OMVSGRP) NOPASSWORD OMVS(UID(0)) HOME('/')
RDEFINE  STARTED  IKED.*              STDATA(USER(IKED))
PERMIT   BPX.DAEMON CLASS(FACILITY) ID(IKED)      ACCESS(READ)
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

- If IKED is defined using a nonzero UID (for example, 300) and IKE GID (for example, 931), then IKED needs the following access:

```
ADDGROUP IKE OMVS(GID(931))
ADDUSER  IKED DFLTGRP(IKE) OMVS(UID(300)) HOME('/var/ike/') NOPASSWORD
CONNECT  IKED GROUP(IKE) UACC(READ)
RDEFINE  STARTED IKED.*              STDATA(USER(IKED))
PERMIT   BPX.DAEMON CLASS(FACILITY) ID(IKED)      ACCESS(READ)
SETROPTS RACLIST(STARTED) REFRESH
SETROPTS GENERIC(STARTED) REFRESH
```

- a. Set the /var directory access to all using the following command:

```
chmod 777 /var
```

- b. If the /var/ike directory does not already exist, use a superuser ID to create it and modify this directory using the following commands:

```
mkdir /var/ike/  
chown IKED /var/ike  
chgrp IKE /var/ike  
chmod 770 /var/ike
```

- c. If the /var/sock/ directory does not already exist, use a superuser ID to create it and set the access to all using the following commands:

```
mkdir /var/sock/  
chown 0 /var/sock  
chmod 777 /var/sock
```

- d. Define RACF definitions for IKED to retrieve IP security policies from Policy Agent:

```
RDEFINE SERVAUTH EZB.PAGENT.sysname.*.IPSEC UACC(NONE)  
PERMIT EZB.PAGENT.sysname.*.IPSEC CLASS(SERVAUTH) ID(IKED) ACCESS(READ)  
SETROPTS RACLIST(SERVAUTH) REFRESH  
SETROPTS GENERIC(STARTED) REFRESH
```

- e. Permit IKED to issue console messages directly without the BPXM023I message prefix:

```
RDEFINE FACILITY BPX.CONSOLE UACC(NONE)  
PERMIT BPX.CONSOLE CLASS(FACILITY) ID(IKED) ACCESS(READ)  
SETROPTS RACLIST(FACILITY) REFRESH
```

2. Allow the IKED to access SYS1.PARMLIB as follows:

```
PERMIT    SYS1.PARMLIB  ID(IKED)          ACCESS(READ)
```

3. Enable the IKED to run as nonswappable.

If you have defined the BPX.STOR.SWAP resource to RACF, you can enable the IKED using the following commands:

```
PERMIT BPX.STOR.SWAP CLASS(FACILITY) ID(IKED) ACCESS(READ)  
SETROPTS RACLIST(FACILITY) REFRESH
```

Step 4: Authorizing the ipsec command to the external security manager

You need to authorize the **ipsec** command to the external security manager.

To authorize the **ipsec** command to RACF, perform the steps in [“Steps for authorizing the ipsec command to RACF”](#) on page 1393.

For more information about [ipsec command](#), see [z/OS Communications Server: IP System Administrator's Commands](#).

Steps for authorizing the ipsec command to RACF

The commands used to authorize the **ipsec** command are in EZARACF in the SEZAINST data set.

Procedure

Perform the following steps to authorize the **ipsec** command to RACF:

1. Define access control for the **ipsec** command.

The **ipsec** command uses both display and control features. You can control access to each feature independently.

- To control access to both the display and control capabilities of the **ipsec** command, issue the following commands:

```
SETROPTS GENERIC(SERVAUTH)
RDEFINE SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.* UACC(NONE)
PERMIT EZB.IPSECCMD.sysname.tcpprocname.* CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
SETROPTS GENERIC(SERVAUTH) REFRESH
```

- To control access specifically to the display capabilities of the **ipsec** command for a stack, issue the following commands:

```
RDEFINE SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.DISPLAY UACC(NONE)
PERMIT EZB.IPSECCMD.sysname.tcpprocname.DISPLAY CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
```

- To control access specifically to the display capabilities of the **ipsec** command for global defensive filters, issue the following commands:

```
RDEFINE SERVAUTH EZB.IPSECCMD.sysname.DMD_GLOBAL.DISPLAY UACC(NONE)
PERMIT EZB.IPSECCMD.sysname.DMD_GLOBAL.DISPLAY CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
```

- To control access specifically to the control capabilities of the **ipsec** command for a stack, issue the following commands:

```
RDEFINE SERVAUTH EZB.IPSECCMD.sysname.tcpprocname.CONTROL UACC(NONE)
PERMIT EZB.IPSECCMD.sysname.tcpprocname.CONTROL CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
```

- To control access specifically to the control capabilities of the **ipsec** command for global defensive filters, issue the following commands:

```
RDEFINE SERVAUTH EZB.IPSECCMD.sysname.DMD_GLOBAL.CONTROL UACC(NONE)
PERMIT EZB.IPSECCMD.sysname.DMD_GLOBAL.CONTROL CLASS(SERVAUTH) ID(userid)
ACCESS(READ)
```

Tip: These SERVAUTH profiles provide **ipsec** command access to only the local stack. For information about SERVAUTH profiles for controlling **ipsec** command access for the network security services (NSS) server, see [“Network security services for the IPsec discipline” on page 207](#).

2. To refresh the in-storage RACF profiles in the SERVAUTH class, issue the following command:

```
SETROPTS RACLIST(SERVAUTH) REFRESH
```

Step 5: Authorizing IP security to ICSF (optional)

IP security can take advantage of the encryption and decryption functions that are available on System z hardware in the following ways:

- Encrypting and decrypting TCP/IP packet data in an IPSec tunnel.
- Encrypting signature data included as part of IKE message flows. This encryption is performed only when digital signature authentication is requested.

This encryption support is provided by the combination of the Integrated Cryptographic Feature (ICRF) on the processor and the Integrated Cryptographic Service Facility/MVS (ICSF) software product. ICSF provides cryptography support through various cryptographic hardware features. The cryptographic features that are available to your applications depends on your processor or server model. For information about which features are available on your hardware, see the information about callable service support by hardware configuration in [z/OS Cryptographic Services ICSF Overview](#).

To use this support, ICSF must be started and running. Preferably, start ICSF prior to starting TCP/IP. However, it can also be started when TCP/IP is active. For details on configuring ICSF, see [z/OS Cryptographic Services ICSF Administrator's Guide](#). ICSF provides SAF controls that you can optionally

use to restrict access to these cryptographic services. To view a sample procedure for generating the corresponding SAF profiles for various CSFSERV services, see the Cryptographic Services Authorization section of the EZARACF sample in the SEZAINST data set.

Requirement: If you plan to control access to the ICSF cryptographic support, TCP/IP must be permitted to access the ICSF cryptographic services (CSFSERV).

Guideline: If you do not have any reason to restrict access to the ICSF cryptographic support, you should not activate the CSFSERV resource class, define any of the profiles listed below, or permit users to these profiles. If you do need to set up controls in the CSFSERV resource class, complete the steps below to enable use of ICSF for IP security.

Steps for setting up profiles in the CSFSERV resource class

Use these steps to control access to the ICSF cryptographic support.

Procedure

Perform the following steps to set up profiles in the CSFSERV resource class:

1. Determine the SAF profiles that you will use within the CSFSERV resource class:
 - a) You must permit the IKED and the NSSD to the CSFIQF profile.
 - b) If you have CP Assist for Cryptographic Function (CPACF) enabled on your processors and you want to take advantage of it, you must have ICSF started but you do not need to grant permission to any SAF profiles.
 - c) If you do not have CPACF enabled, but you do have a cryptographic coprocessor, to take advantage of it you must perform the following steps:
 - i) Permit TCP/IP to the following profiles:
 - CSFCKI
 - CSFCKM (used only for Triple DES)
 - CSFDEC1
 - CSFENC1
 - CSFOWH1
 - ii) Permit the IKED and the NSSD to the following profiles:
 - CSFDSG
 - CSFDSV
 - CSFPKI
 - d) If you are using AES encryption in TCP/IP for manual or dynamic tunnels, you must permit TCP/IP to the following profiles:
 - CSFDEC1
 - CSFENC1
 - e) If you are using AES encryption in the IKED for dynamic tunnels, you must permit the IKED to the following profiles:
 - CSFDEC
 - CSFENC
 - f) If you are using SHA2 or AES-XCBC authentication in TCP/IP, you must permit TCP/IP to the following profiles:
 - CSF1HMG
 - CSF1TRC
 - CSF1TRD

- CSFMGN1
- g) If you are using SHA2 or AES-XCBC authentication in the IKED, you must permit the IKED to the following profiles:
- CSF1HMG
 - CSF1TRC
 - CSF1TRD
 - CSFOWH
- h) If you are using Diffie-Hellman groups 19, 20, or 21 in the IKED, you must permit the IKED to the following profiles:
- CSF1DVK
 - CSF1GAV
 - CSF1GKP
 - CSF1TRC
 - CSF1TRD
- i) If you are using digital signature authentication in the IKED, you must permit the IKED to the following profiles:
- CSFDSG
 - CSFDSV
 - CSFPKI
- j) If you are using digital signature authentication in the NSSD, you must permit the NSSD to the following profiles:
- CSF1HMG
 - CSF1TRC
 - CSF1TRD
 - CSFDSG
 - CSFDSV
 - CSFMGN
 - CSFOWH
 - CSFPKI
- k) If you are using elliptic curve signature authentication in the NSSD, you must permit the NSSD to the following profiles:
- CSF1GAV
 - CSF1PKS
 - CSF1PKV
- l) If you have enabled FIPS 140 support in TCP/IP, you must permit TCP/IP to the following profiles:
- CSF1HMG
 - CSF1SKD
 - CSF1SKE
 - CSF1TRC
 - CSF1TRD
 - CSFRNG
- m) If you have enabled FIPS 140 support in TCP/IP and you are using manual tunnels, the z/OS Communications Server Policy Agent must be permitted to the CSF1TRC profile.

- n) If you have enabled FIPS 140 support in the IKED, you must permit the IKED to the following profiles:
 - CSF1DMK
 - CSF1DVK
 - CSF1HMG
 - CSF1SKD
 - CSF1SKE
 - CSF1TRC
 - CSF1TRD
 - CSFOWH
2. Define the appropriate profiles in the CSFSERV class:

```
RDEFINE CSFSERV profile-name UACC(NONE)
```
3. Give TCP/IP access to the appropriate profiles:

```
PERMIT profile-name CLASS(CSFSERV) ID(stackname) ACCESS(READ)
```
4. Give the userids associated with IKED, NSSD, and Policy Agent access to the appropriate resource profile in the CSFSERV class:

```
PERMIT profile-name CLASS(CSFSERV) ID (userid)
```
5. Activate the CSFSERV class and refresh the in-storage RACF profiles:

```
SETROPTS CLASSACT(CSFSERV)
SETROPTS RACLIST(CSFSERV) REFRESH
```
6. Set the MAXLEN ICSF installation option to 65535 or greater because this is the maximum TCP/IP packet size. The MAXLEN installation option for hardware cryptography determines the maximum length that can be used to encrypt and decrypt data using ICSF.

Step 6: Setting up the IKE daemon for digital signature authentication (optional)

You can configure the IKE daemon to use its own certificate service or to use the certificate service from a network security services (NSS) server. You can control whether to use the native certificate service or the NSS certificate service at the stack level. A single stack can use either the native certificate service or the NSS certificate service, but it cannot use both. If the IKED is to use an IKEv2 signature-based authentication method on behalf of a stack, that stack must be defined as a network security services (NSS) client.

By default, the IKE daemon uses the native certificate service for all stacks. Certificates for stacks configured to use the native certificate service must be on the key ring specified by the KeyRing parameter of the IkeConfig statement.

The IKE daemon native certificate service does not consult certificate revocation information when it authenticates a digital signature. If you want revocation checking, then direct the IKED to use the IPsec certificate service of an NSS server and enable revocation checking for the remote security endpoint. For information about enabling revocation checking for a remote security endpoint using the KeyExchangeAction statement, see [z/OS Communications Server: IP Configuration Reference](#).

The IKE daemon can be directed to use an NSS server's certificate service for an individual stack by specifying the Cert option on the ServiceType parameter of an NssStackConfig statement for that stack. The NssStackConfig statement is specified in the IKE daemon configuration file. The NSS server does not have to be on the same system as the IKE daemon. The location of the NSS server is specified by the NetworkSecurityServer parameter and optionally the NetworkSecurityServerBackup parameter of the

IkeConfig statement. For more information about the [IkeConfig statement](#), see [z/OS Communications Server: IP Configuration Reference](#).

Certificates for stacks configured to use an NSS server for certificate service must be on the key ring specified on the KeyRing parameter of the NssConfig statement in the NSS server configuration file. For more information about the NssConfig, see [z/OS Communications Server: IP Configuration Reference](#).

Figure 188 on page 1398 shows a partial configuration for the IKE daemon on system SYSTEMA and an NSS server. The NetworkSecurityServer parameter on the IkeConfig statement specifies that the IKE daemon is configured to use network security services from an NSS server that is listening on IP address 9.1.1.1. Two NssStackConfig statements are shown. The ClientName parameters associate a local TCP/IP stack with an NSS client name. This is the name by which the NSS server knows this stack. The UserId parameter associates the client name with a user ID defined on the NSS server's system. Both the client name and user ID are used by the NSS server to verify that an NSS client is authorized to request certificate service, and to determine what certificates the client is authorized to use (For additional details, see [“Steps for authorizing resources for NSS” on page 1114](#)). The KeyRing parameter on the IkeConfig statement identifies the location of certificates for all stacks for which there are no NssStackConfig statements. The KeyRing parameter on the NssConfig statement identifies the location of certificates for all NSS client stacks that use the NSS server certificate service.

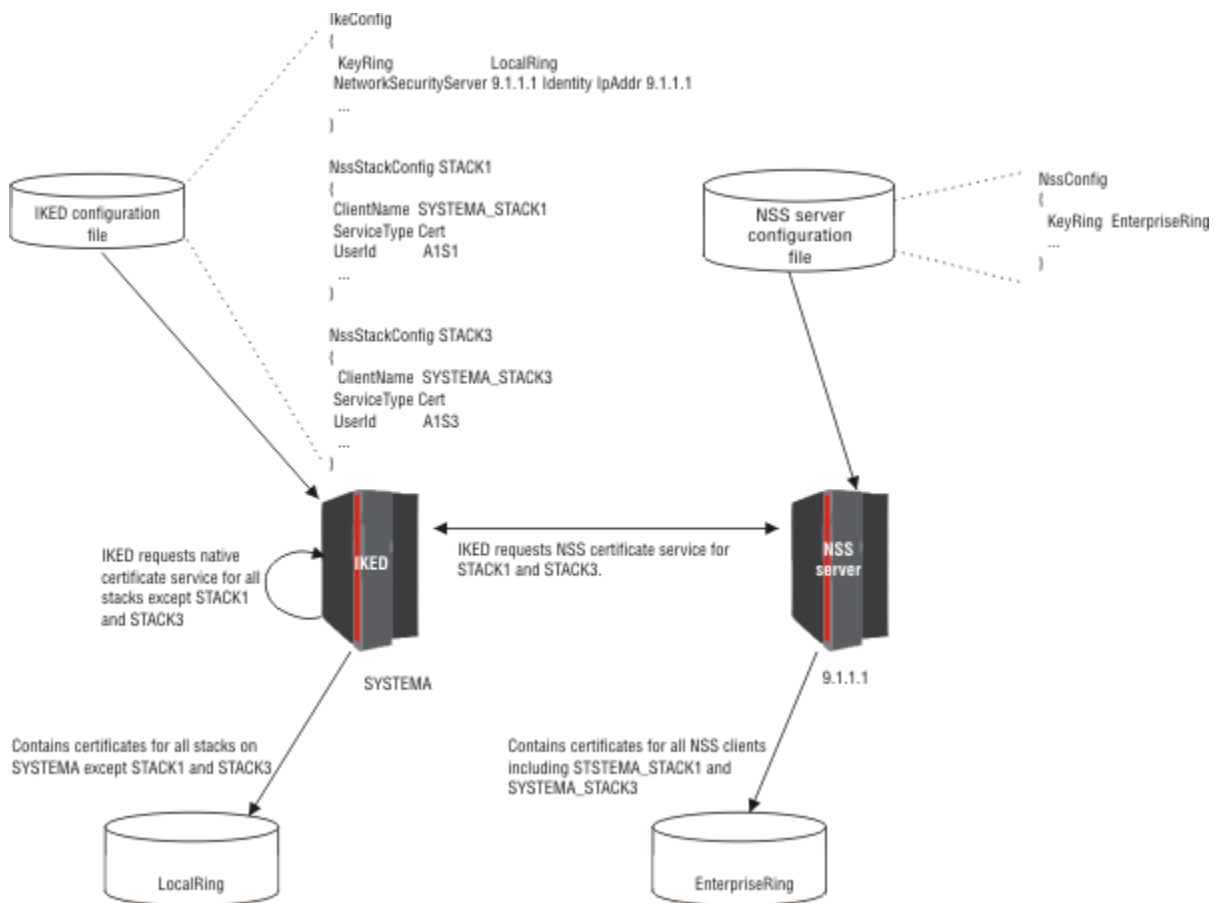

Figure 188. Partial configuration for the IKE daemon and an NSS server

The following subtopics provide steps for setting up the IKE daemon for RSA signature mode authentication:

- When the native certificate service is used
- When the certificate service of an NSS server is used

Tip: Use the following references to understand the concepts that are involved in using digital certificates with RACF:

- For more information about RACF key rings and digital certificates, see [z/OS Security Server RACF Security Administrator's Guide](#).
- For more information about [controlling the use of the RACDCERT command](#), see [z/OS Security Server RACF Security Administrator's Guide](#).
- For a complete description of the facilities and authorizations that are needed to create and modify digital certificates and key rings, see [z/OS Security Server RACF Command Language Reference](#).

Steps for setting up the IKE daemon for digital signature authentication when the native certificate service is used

You can configure the IKE daemon to use its own certificate service and to use RSA signature mode authentication. Details for each step are in the corresponding subtopics.

Procedure

Perform the following steps to set up the IKE daemon for digital signature authentication when the native certificate service is being used:

1. Define RACF facilities and access controls.
2. Define profiles to control access to the RACDCERT command.
3. Create a RACF key ring for the user ID under which the IKED is to run.
4. Install an X509 digital certificate to be used by the native IKE certificate service.

Step 1: Define RACF facilities and access controls

Procedure

To support RSA signature mode authentication in phase 1 negotiations, perform the following steps to give the IKE daemon the required access to a RACF key ring using the RDATA LIB or FACILITY class. The RDATA LIB class is preferred as it allows for granular authorization to a specified key ring. The FACILITY class allows global authorization to all key rings and certificates. See [z/OS Security Server RACF Callable Services](#) for additional information.

To provide access using the RDATA LIB class:

1. If it is not already defined, create the RDATA LIB definitions required to allow certificates to be stored and accessed from the RACF database by issuing the following TSO commands:

```
SETROPTS CLASSACT(RDATA LIB) RACLST(RDATA LIB)
RDEFINE RDATA LIB IKED.<keyRingName>.LST UACC(NONE)
```

2. To permit the IKED to the RDATA LIB resource, issue the following TSO command:

```
PERMIT IKED.<keyRingName>.LST CLASS(RDATA LIB) ID(IKED) ACCESS(READ)
```

3. Refresh the RDATA LIB class:

```
SETROPTS RACLST(RDATA LIB) REFRESH
```

To provide access using the FACILITY class:

1. If they are not already defined, create the definitions that are required to allow certificates to be stored and accessed from the RACF database by issuing the following TSO commands:

```
RDEFINE FACILITY IRR.DIGTCERT.LISTRING UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.LIST UACC(NONE)
```

2. To permit the IKED to the facilities, issue the following TSO commands:

```
PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(IKED) ACC(READ)
PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(IKED) ACC(READ)
```

3. Refresh the FACILITY class:

```
SETROPTS RACLIST(FACILITY) REFRESH
```

Step 2: Define profiles to control access to the RACDCERT command

Before you begin

The RACF database provides digital certificate and key ring support through the RACDCERT command. The administrator who is responsible for managing the RACF key ring for the IKED needs appropriate access to this command.

Procedure

Perform the following steps to define profiles to control access to this command:

1. If they are not already defined, create the definitions that are required to control access to the basic RACDCERT actions by issuing the following TSO commands:

```
RDEFINE FACILITY IRR.DIGTCERT.ADD UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.ADDRING UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.CONNECT UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.GENCERT UACC(NONE)
RDEFINE FACILITY IRR.DIGTCERT.GENREQ UACC(NONE)
```

2. Issue the following TSO commands (where *userid* is the ID of the person who will be executing the RACDCERT command to manage digital certificates):

```
PERMIT IRR.DIGTCERT.ADD CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.ADDRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
PERMIT IRR.DIGTCERT.CONNECT CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.GENCERT CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.GENREQ CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.LIST CLASS(FACILITY) ID(userid) ACC(CONTROL)
PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID(userid) ACC(UPDATE)
```

3. Refresh the FACILITY class:

```
SETROPTS RACLIST(FACILITY) REFRESH
```

4. If the RDATALIB class was used to control list access to the IKED key ring in Step 1 (Define RACF facilities and access controls), the administrator's ID should also be permitted to the RDATALIB profile.

```
PERMIT IKED.keyringname.LST CLASS(RDATALIB) ID(userid) ACC(UPDATE)
SETROPTS CLASSACT(RDATALIB) REFRESH
```

Step 3: Create a RACF key ring for the user ID under which the IKED is to run

Digital certificates are made available to the IKE daemon by connecting them to a key ring that is owned by the IKE daemon. To create a key ring for the IKE daemon, issue the following TSO command:

```
RACDCERT ID(IKED) ADDRING(ikeyring)
```

The value used for *ikeyring* is case sensitive.

Step 4: Install an X509 digital certificate to be used by the native certificate service

The procedure for installing a digital certificate on a SAF key ring for the native certificate service to use is similar to the procedure for installing a digital certificate on a SAF key ring for the NSS certificate service to use. For details, see [“IPSec certificate management” on page 1402](#).

Steps for setting up the IKE daemon for digital signature authentication using the certificate service of an NSS server

You can configure the IKE daemon to use the certificate service of an NSS server and to use RSA signature mode authentication. Details for each step are in the corresponding subtopics.

Procedure

Perform the following steps to set up the IKE daemon for digital signature authentication when the certificate service of an NSS server is being used:

1. Update the IKE daemon configuration file to define NSS clients.
2. Install X509 digital certificates for NSS clients on the NSS server's key ring.
3. Authorize the NSS clients.
4. Enable HTTP Certificate Lookup (optional)

Step 1: Update the IKE daemon configuration file to define NSS clients

The IKE daemon configuration file must be updated to include the `NetworkSecurityServer` parameter and optionally the `NetworkSecurityServerBackup` parameter on the `IkeConfig` statement. These parameters identify the location of the NSS server. In addition, an `NssStackConfig` statement with a `ServiceType` value `Cert` must be added for each stack that will use the NSS certificate service. For additional details about configuring the [IKE daemon](#), see [z/OS Communications Server: IP Configuration Reference](#).

Step 2: Install X509 digital certificates for NSS clients on the NSS server's key ring

This step must be performed on the system where the NSS server will run.

The procedure for installing a digital certificates on a SAF key ring to be used by the NSS server is similar to the procedure used for installing a digital certificate on a SAF key ring for use by the native certificate service. For details, see [“IPSec certificate management” on page 1402](#).

Step 3: Authorize the NSS clients

This step must be performed on the system where the NSS server will run.

NSS clients defined in the IKE daemon configuration file must be authorized to use the NSS server's certificate service. For authorization details, see [step “8” on page 1116](#).

Step 4: Enable HTTP Certificate Lookup (optional)

The following actions occur during a phase 1 IKE exchange:

- Peers exchange encoded certificate information in certificate payloads
- The NSS server provides the IKED with certificate information to send
- The IKED forwards the encoded certificate information that it received from the NSS server

IKEv2 defines two new encoding types that require the use of an HTTP server:

- Hash and URL of a certificate
- Hash and URL of a certificate bundle

The NSS server supports these new encoding types; however, by default the IKED does not support sending or receiving them.

Use the `CertificateURLLookupPreference` parameter on the `KeyExchangePolicy` and `KeyExchangeAction` statements in the IP security policy configuration file to enable the IKED to use the hash and URL encoding types. Code the appropriate value on the `CertificateURLLookupPreference` parameter:

- Disallow, which is the default value, indicates that the IKED will not send the new encoding type and will ignore the new encoding type when received.
- Tolerate indicates that the IKED will not send the new encoding type, but it will accept the new encoding type when received.
- Allow indicates that the IKED may send the new encoding type and it will accept the new encoding type when received.

Rule: You must configure the NSS server appropriately before the IKED can send the new encoding types.

Enabling this capability might result in smaller messages being exchanged between the IKED and its remote security endpoint as well as the IKED and the NSS server; however, it may also result in increased latency during an IKEv2 negotiation.

For more details about the CertificateURLLookupPreference parameter on the KeyExchangePolicy and KeyExchangeAction statements, see [z/OS Communications Server: IP Configuration Reference](#). For more details about configuring the NSS server to use the new certificate encoding types, see [“Using hash and URL certificate encoding types”](#) on page 1127.

IPSec certificate management

The IKE daemon and NSS server require the ability to retrieve digital certificates from a RACF key ring, each associated with a particular identity, and also to perform operations with the associated private key. The IKED can own multiple certificates on its RACF key ring. The NSS server can own multiple certificates for multiple NSS clients (that is, stacks). You can install an X509 digital certificate in the following ways:

- Generate an X509 digital certificate and have it signed by a certificate authority.
- Generate a self-signed X509 digital certificate.
- Migrate an existing key database to a RACF key ring.

Steps for generating an X509 digital certificate and having it signed by a certificate authority

The IKE daemon and NSS server require the ability to retrieve digital certificates associated with a particular identity from a RACF key ring, and to perform operations with the associated private key.

Before you begin

Assume that you have an X509 digital certificate that has the X500 distinguished name CN=SYSTEMA STACK1, OU=Inventory, O=IBM, C=US and the domain name `ibm.com`. The certificate identifies the local IKE daemon that executes on z/OS with the user ID IKED.

Tip: If you are creating a certificate for a stack configured to use the certificate service from an NSS server, issue these commands against the RACF database for the system on which the NSS server runs. Modify the user ID in the examples to be the user ID that is running the NSS server and modify the key ring to be the key ring that is configured in the NSS server's configuration file.

Procedure

Perform the following steps to install the X509 digital certificate:

1. Generate a self-signed certificate for the server:

```
RACDCERT ID(IKED) GENCERT SUBJECTSDN(CN('SYSTEMA STACK1') OU('Inventory') O('IBM') C('US'))
WITHLABEL('SYSTEMA STACK1') ALTNAME(DOMAIN('ibm.com'))
```

2. Take one of the following actions:

- RACF supplies certificates for many commercial certificate authorities. If you are using one of these supplied certificate authority certificates, follow the steps for supplied digital certificates in [z/OS Security Server RACF Security Administrator's Guide](#).

- If the certificate authority you are using is not one of the supplied certificate authorities, obtain the root certificate of the certificate authority that is to sign the certificate of the IKED, and place it in an MVS data set (for example, USER1.EXTCA1.CERT). Add it to the RACF database as follows:

```
RACDCERT ID(IKED) ADD('USER1.EXTCA1.CERT') WITHLABEL('External CA') CERTAUTH
```

3. Create a certificate request to send to the chosen certificate authority.

The certificate request that you create is based on the certificate that was created in step 1. Place this certificate into a data set called USER1.SYSTEMA.STACK1.GENREQ as follows:

```
RACDCERT ID(IKED) GENREQ(LABEL('SYSTEMA STACK1'))
DSN('USER1.SYSTEMA.STACK1.GENREQ')
```

4. Send the certificate request to the certificate authority.

The certificate request is in base 64-encoded text. Typically, the request is sent to the certificate authority by cutting and pasting the certificate request into an email that is sent to the certificate authority.

The certificate authority validates the certificate. If the certificate is approved by the certificate authority, it is signed by the certificate authority and returned to the requester.

5. Receive the returned certificate into a data set (for example, USER1.SYSTEMA.STACK1.CERT).

The returned certificate is in base 64-encoded text. This can be done by cutting and pasting, with FTP, or with another technique.

6. Replace the self-signed certificate with the certificate that is signed by the certificate authority.

The certificate is replaced only if the user ID that is specified as the ID value on the RACDCERT ADD command is the same user ID that was specified when the certificate was created. Ensure that the user ID is the same. Otherwise, the certificate is added, rather than replacing the self-signed certificate, and does not contain the certificate's private key.

```
RACDCERT ID(IKED) ADD('USER1.SYSTEMA.STACK1.CERT') WITHLABEL('SYSTEMA STACK1')
```

7. Connect the certificate to an existing key ring:

```
RACDCERT ID(IKED) CONNECT(LABEL('SYSTEMA STACK1') RING(ikeyring) USAGE(PERSONAL))
```

8. Connect the certificate authority's certificate to the key ring:

```
RACDCERT ID(IKED) CONNECT(CERTAUTH LABEL('External CA') RING(ikeyring)
USAGE(CERTAUTH))
```

This completes the certificate hierarchy from root to SYSTEMA STACK1.

9. Add the following statement to the IKE daemon configuration file, iked.conf, or the NSS server configuration file, nssd.conf:

```
Keyring    IKED/ikeyring
```

Results

You know you are done when the X509 digital certificate is available, and is mapped to the X500DN identity CN=SYSTEMA STACK1,OU=Inventory,O=IBM,C=US from the certificate's subject name, and the FQDN identity *ibm.com* from the certificate's alternate subject name.

You can verify that the certificates that you have created are connected to the key ring associated with user ID IKED by using the RACDCERT command and examining the output of the Ring Associations field. Verify that the certificate authority was created and added to the IKED/*ikeyring* as follows:

```
RACDCERT CERTAUTH LIST(LABEL('External CA'))
```

Verify that the personal certificate for the IKE daemon was created and added to the IKED/*ikeyring* as follows:

```
RACDCERT ID(IKED) LIST(LABEL('SYSTEMA STACK1'))
```

Requirement: If the certificates connected to the key ring are for an NSS client, you must create a SERVAUTH profile for each certificate. You must give the user ID associated with the NSS client access to this profile. Create this profile in the RACF database for the system on which the NSS server runs. For details about these profiles, see [“Steps for authorizing resources for NSS” on page 1114](#).

Steps for generating a self-signed X509 digital certificate

The IKE daemon and NSS server require the ability to retrieve digital certificates associated with a particular identity from a RACF key ring, and to perform operations with the associated private key.

Before you begin

The certificate that is assigned to the secure server is a locally-signed certificate rather than one signed by a certificate authority. Assume that the local certificate authority has the distinguished name of OU='Local Certificate Authority',O=IBM,C=US.

Requirement: If you are creating a certificate for a stack configured to use the certificate service from an NSS server, issue these commands against the RACF database for the system on which the NSS server runs. The user ID in the examples must be the user ID running the NSS server and the key ring must be the key ring configured in the NSS server's configuration file.

Procedure

Perform the following steps to implement a locally signed server certificate:

1. Generate a self-signed certificate to represent the local certificate authority:

```
RACDCERT CERTAUTH GENCERT SUBJECTSDN(OU('Local Certificate Authority') O('IBM') C('US'))  
KEYUSAGE(CERTSIGN) WITHLABEL('IBM Local Certificate Authority')
```

This certificate is used as the certificate authority certificate.

2. Export the certificate to a data set (in this case, USER1.LOCCERTA.CERT):

```
RACDCERT CERTAUTH EXPORT(LABEL('IBM Local Certificate Authority')) DSN('USER1.LOCCERTA.CERT')
```

3. Create a certificate for the server that is signed with the certificate authority certificate that was created in step 1:

```
RACDCERT ID(IKED) GENCERT SUBJECTSDN(CN('SYSTEMA STACK1') OU('Inventory') O('IBM') C('US'))  
WITHLABEL('SYSTEMA STACK1') ALTNAME(DOMAIN('ibm.com'))  
SIGNWITH(CERTAUTH LABEL('IBM Local Certificate Authority'))
```

4. Connect the certificate to an existing key ring:

```
RACDCERT ID(IKED) CONNECT(LABEL('SYSTEMA STACK1') RING(ikeyring) USAGE(PERSONAL))
```

5. Connect the local certificate authority certificate to the key ring:

```
RACDCERT ID(IKED) CONNECT(CERTAUTH LABEL('IBM Local Certificate Authority') RING(ikeyring)  
USAGE(CERTAUTH))
```

This completes the certificate hierarchy from root to SYSTEMA STACK1.

6. Add the following statement to the IKE daemon configuration file, iked.conf, or the NSS server configuration file, nssd.conf:

```
Keyring    IKED/ikeyring
```

Results

You know you are done when the X509 digital certificate is available, and is mapped to the X500DN identity CN=SYSTEMA STACK1, OU=Inventory, O=IBM, C=US from the certificate's subject name, and the FQDN identity `ibm.com` from the certificate's alternate subject name.

You can verify that the certificates that you have created are connected to the key ring associated with user ID IKED by using the RACDCERT command and examining the output of the Ring Associations field. Verify that the certificate authority was created and added to the IKED/*ikeying* as follows:

```
RACDCERT CERTAUTH LIST(LABEL('IBM Local Certificate Authority'))
```

Verify that the personal certificate for the IKE daemon was created and added to the IKED/*ikeying* as follows:

```
RACDCERT ID(IKED) LIST(LABEL('SYSTEMA STACK1'))
```

Requirement: If the certificates connected to the key ring are for an NSS client, you must create a SERVAUTH profile for each certificate. You must give the user ID associated with the NSS client access to this profile. Create this profile in the RACF database for the system on which the NSS server runs. For details about these profiles, see [“Steps for authorizing resources for NSS” on page 1114](#).

Steps for migrating an existing key database to a RACF key ring

The IKE daemon and NSS server require the ability to retrieve digital certificates associated with a particular identity from a RACF key ring, and to perform operations with the associated private key.

Before you begin

To migrate an existing key database file to a RACF key ring, see the information on migrating key database files to RACF key rings in [z/OS Cryptographic Services System SSL Programming](#).

Procedure

Perform the following steps to migrate keys and certificates that are stored in an existing z/OS key database into a RACF key ring:

1. Using gskkyman, export the certificate and private key to a password-protected PKCS#12 file. For details on copying a certificate with its private key, see [z/OS Cryptographic Services System SSL Programming](#).
2. Copy the newly created PKCS#12 file to an MVS data set.
3. Use the RACDCERT command with the ADD operand to define a certificate and private key. The data set name that was created in step 2 contains the certificate.
4. Use the RACDCERT command with the ADDRING operand to create a new key ring in RACF.
5. Use the RACDCERT command with the CONNECT operand to add the certificate and private key to one or more existing RACF key rings.

Appendix F. Using an LDAP server for policy definitions

Lightweight Directory Access Protocol (LDAP) is a fast-growing technology for accessing common directory information. LDAP has been embraced and implemented in most network-oriented middleware. As an open, vendor-neutral standard, LDAP provides an extendable architecture for centralized storage and management of information that needs to be available for today's distributed systems and services.

Note: If the z/OS LDAP server is used, a Db2 backend is required.

Policy object model overview

Policies consist of several related objects. The main object is the *policy rule*. A policy rule object refers to one or more *policy condition*, *policy action*, or *policy time period condition* objects, and also contains information on how these objects are to be used. Policy time period objects are used to determine when a given policy rule is active. Active policy objects are related in a way that is analogous to an 'IF' statement in a program. For example:

```
IF condition THEN action
```

In other words, when the set of conditions referred to by a policy rule are TRUE, then the policy actions associated with the policy rule are executed.

Figure 189. Basic policy objects

Policy rules can refer to one or more policy conditions. A policy rule with a single policy condition is known as a *simple* rule, and one with more conditions is known as a *complex* rule. Complex policy rules can have their conditions evaluated according to one of two different methods. The first is Disjunctive Normal Form (DNF), which means an ORed set of ANDed conditions. The second is Conjunctive Normal Form (CNF), which means an ANDed set of ORed conditions. In order to accomplish these evaluations, individual policy conditions are assigned an arbitrary group number, and also an indication of whether or not the condition is negated. For example, consider the following set of conditions for a policy rule:

```
C1: Group Number = 1, Condition Negated = FALSE
C2: Group Number = 1, Condition Negated = TRUE
C3: Group Number = 1, Condition Negated = FALSE
```

C4: Group Number = 2, Condition Negated = FALSE
C5: Group Number = 2, Condition Negated = FALSE

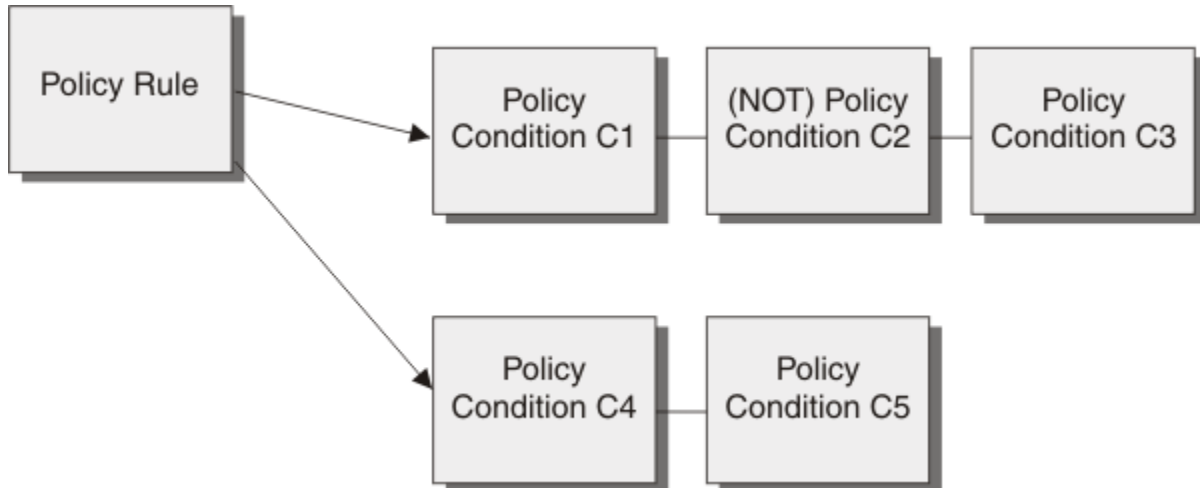

Figure 190. Complex policy conditions

If the conditions are to be evaluated using DNF, then the overall condition for the policy rule is:

$(C1 \text{ AND } (\text{NOT } C2) \text{ AND } C3) \text{ OR } (C4 \text{ AND } C5)$

On the other hand, if CNF is used to evaluate the conditions, then the overall condition for the policy rule is:

$(C1 \text{ OR } (\text{NOT } C2) \text{ OR } C3) \text{ AND } (C4 \text{ OR } C5)$

Complex rules can be split into multiple simple rules. Negated conditions are not allowed in a rule if explosion is to be performed. Consider the following set of conditions for a policy rule:

C1: Group Number = 1, Condition Negated = FALSE
C2: Group Number = 1, Condition Negated = FALSE
C3: Group Number = 1, Condition Negated = FALSE
C4: Group Number = 2, Condition Negated = FALSE
C5: Group Number = 2, Condition Negated = FALSE

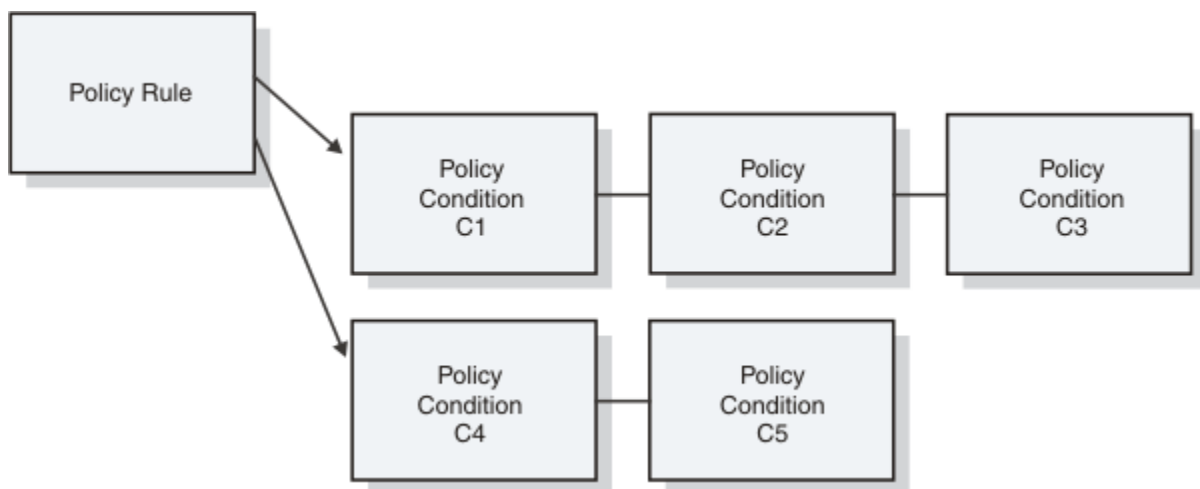

Figure 191. Complex policy conditions before explosion

If DNF is used to evaluate the conditions, splitting the complex rule produces the following simple rules:

Simple Rule 1: C1 AND C2 AND C3
Simple Rule 2: C4 AND C5

If CNF is used to evaluate the conditions, splitting the complex rule produces the following simple rules:

```
Simple Rule 1:  C1 AND C4
Simple Rule 2:  C1 AND C5
Simple Rule 3:  C2 AND C4
Simple Rule 4:  C2 AND C5
Simple Rule 5:  C3 AND C4
Simple Rule 6:  C3 AND C5
```

Policy actions specify actions to take when the set of conditions for a policy rule evaluate to TRUE. The policy model allows multiple actions for a policy rule. Many policy rules typically use only a single action, but multiple actions make sense for some policy types.

Policy conditions and actions can either be specific to a single rule, or be reusable among several policy rules. To allow either type of conditions and actions, and to specify related information such as condition group number and negation indicator, several other policy objects are required. First are *policy condition association* and *policy action association* objects. These objects contain condition and action related attributes, respectively, and may directly contain policy conditions and actions (rule-specific).

Figure 192. Rule-specific conditions and actions

The policy association objects alternatively may refer to conditions and actions (reusable). *Policy condition instance* and *policy action instance* objects are used to represent reusable policy conditions and actions, respectively.

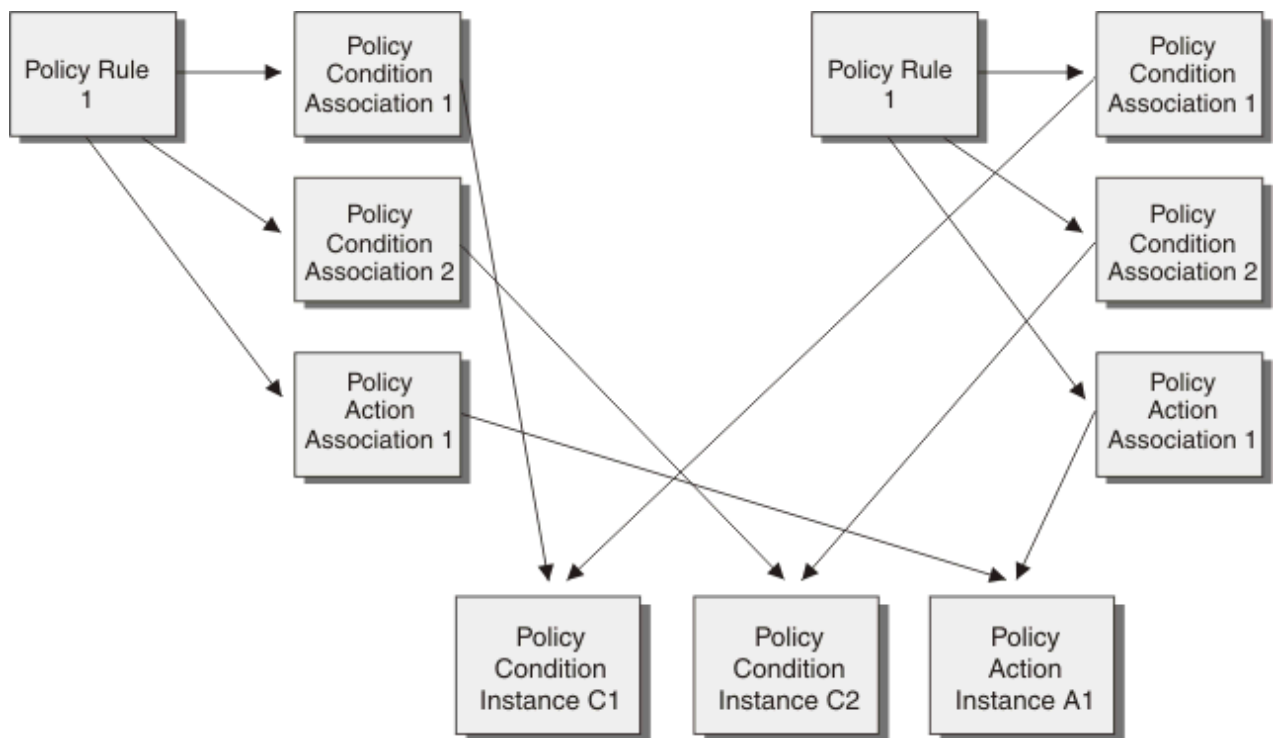

Figure 193. Reusable conditions and actions

Primarily for administrative grouping of policy rules, the *policy group* object is used. Policy groups can refer either to policy rules or to policy groups. This allows related policy rules to be grouped together, and also allows policy groups to be grouped to any needed level of nesting.

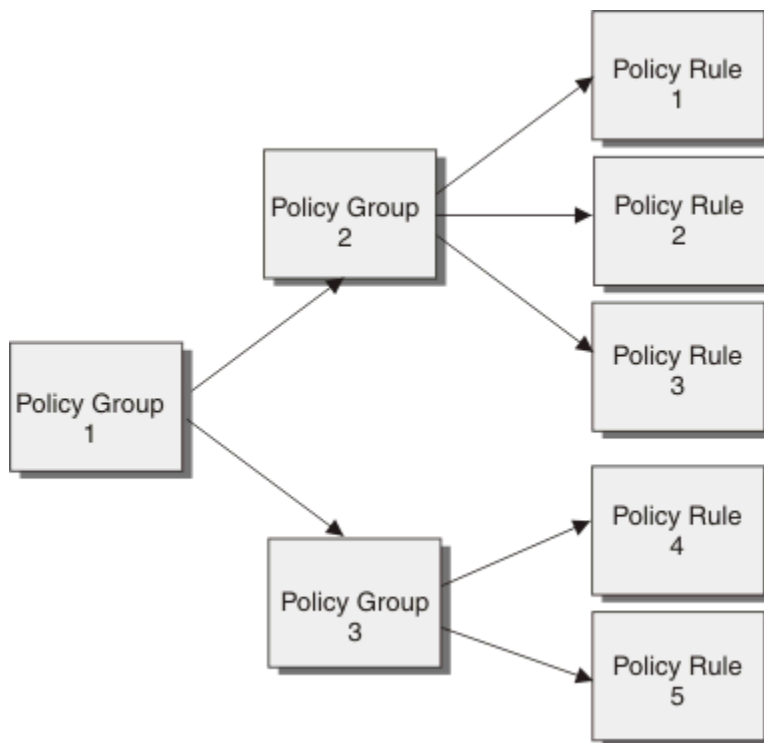

Figure 194. Policy groups

Overview of the object classes

Policies defined on an LDAP server are comprised of one or more objects, each with a defined object class, and a unique name. Object names are in the form of LDAP Distinguished Names (DNs), which are text strings composed of individual parts known as Relative Distinguished Names (RDNs). The structure of the naming defines a hierarchical tree, in a manner similar to directories in a hierarchical file system. For example, consider the following set of objects:

```
Object 1, DN: o=IBM, c=US
Object 2, DN: cn=group_1, o=IBM, c=US
Object 3, DN: cn=group_5, o=IBM, c=US
Object 4, DN: cn=group_1_sub_A, cn=group_1, o=IBM, c=US
```

This set of objects can be viewed as a tree, with Object 1 as the root. Objects 2 and 3 are branches under the root, with Object 4 a branch under Object 2. The names used are attributes of the objects they define. For example, Object 2, whose name starts with "cn=group_1" contains a cn attribute with the value group_1. See [z/OS IBM Tivoli Directory Server Administration and Use for z/OS](#) for more information on LDAP naming.

Object class names define the type of each LDAP object. The *top* object class is predefined and is the root of all other object classes.

There are three types of object classes.

Abstract object classes

Used to define broad concepts, such as policy and to define basic attributes that apply to all subclasses.

Structural object classes

Basic building blocks, and are the only type of object class that can be instantiated as real objects on an LDAP server.

Auxiliary object classes

Used to define attributes that are shared among different structural object classes, or are used to extend the basic set of objects.

Attributes from auxiliary classes are *attached* to structural objects by including them in the structural objects, and also by including the auxiliary object class as one of the values of the objectClass attribute in the structural object.

The following object classes are recognized by the Policy Agent. The indentation defines subclasses. For example, ibm-policyGroup is a subclass of ibm-policy, and therefore inherits all of the attributes defined for ibm-policy.

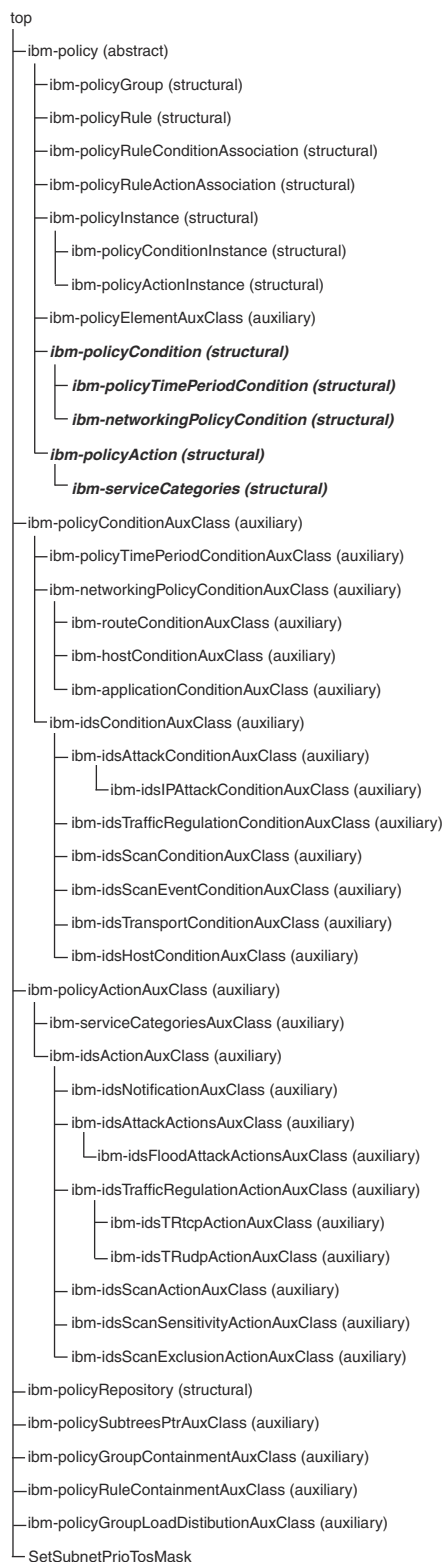

Figure 195. LDAP schema object class hierarchy

Note: The classes identified in bold italics in Figure 195 on page 1412 are for schema version 2 and are mutually exclusive with the schema version 3 classes with similar names.

Object class name	Purpose of object
Top	Used to anchor the LDAP hierarchical tree root.

Object class name	Purpose of object
ibm-policy	Used as the root for all policy objects.
ibm-policyGroup	Defines a policy group object.
ibm-policyRule	Defines a policy rule object.
ibm-policyRuleConditionAssociation	Defines an association between a policy rule object and a policy condition.
ibm-policyRuleActionAssociation	Defines an association between a policy rule object and a policy action.
ibm-PolicyInstance	Defines an instance of a reusable policy object.
ibm-PolicyConditionInstance	Defines an instance of a reusable policy condition object.
ibm-PolicyActionInstance	Defines an instance of a reusable policy action object.
ibm-PolicyElementAuxClass	Defines an auxiliary class that can be used to tag non-policy objects as though they were policy objects.
ibm-policyCondition	Defines a policy condition object. (schema version 2 — supported for migration)
ibm-policyTimePeriodCondition	Defines an auxiliary class to represent time periods during which a policy rule is considered to be active. (schema version 2 — supported for migration)
ibm-networkingpolicyCondition	Defines a subclass of ibm-PolicyCondition used to define networking policy conditions. (schema version 2 — supported for migration)
ibm-policyAction	Defines a policy action object. (schema version 2 — supported for migration)
ibm-serviceCategories	Defines an auxiliary class to represent a set of QoS attributes for a policy action. (schema version 2 — supported for migration)
ibm-policyConditionAuxClass	Defines an auxiliary class for generic policy conditions.
ibm-policyTimePeriodConditionAuxClass	Defines an auxiliary class to represent time periods during which a policy rule is considered to be active.
ibm-networkingPolicyConditionAuxClass	Defines an auxiliary class used to define networking policy conditions.
ibm-routeConditionAuxClass	Defines an auxiliary class to represent QoS routing conditions for a policy rule.
ibm-hostConditionAuxClass	Defines an auxiliary class to represent QoS host (end-point) conditions for a policy rule.
ibm-applicationConditionAuxClass	Defines an auxiliary class to represent QoS application and transport conditions for a policy rule.

Object class name	Purpose of object
ibm-idsConditionAuxClass	Defines an auxiliary class to represent generic IDS conditions.
ibm-idsAttackConditionAuxClass	Defines an auxiliary class to represent IDS attack conditions.
ibm-idsIPAttackConditionAuxClass	Defines an auxiliary class to represent IDS IP attack conditions.
ibm-idsTrafficRegulationConditionAuxClass	Defines an auxiliary class to represent IDS Traffic Regulation conditions.
ibm-idsScanConditionAuxClass	Defines an auxiliary class to represent IDS global scan conditions.
ibm-idsScanEventConditionAuxClass	Defines an auxiliary class to represent IDS scan event conditions.
ibm-idsTransportConditionAuxClass	Defines an auxiliary class to represent IDS transport conditions.
ibm-idsHostConditionAuxClass	Defines an auxiliary class to represent IDS host conditions.
ibm-policyActionAuxClass	Defines an auxiliary class for generic policy actions.
ibm-serviceCategoriesAuxClass	Defines an auxiliary class to represent a set of QoS attributes for a policy action.
ibm-idsActionAuxClass	Defines an auxiliary class to represent generic IDS actions.
ibm-idsNotificationAuxClass	Defines an auxiliary class to represent notification options for IDS actions.
ibm-idsAttackActionsAuxClass	Defines an auxiliary class to represent attack attributes for IDS actions.
ibm-idsFloodAttackActionsAuxClass	Defines an auxiliary class to represent flood-specific attack attributes for IDS actions.
ibm-idsTrafficRegulationActionAuxClass	Defines an auxiliary class to represent generic Traffic Regulation attributes for IDS actions.
ibm-idsTRtcpActionAuxClass	Defines an auxiliary class to represent Traffic Regulation TCP attributes for IDS actions.
ibm-idsTRudpActionAuxClass	Defines an auxiliary class to represent Traffic Regulation UDP attributes for IDS actions.
ibm-idsScanActionAuxClass	Defines an auxiliary class to represent global scan attributes for IDS actions.
ibm-idsScanSensitivityActionAuxClass	Defines an auxiliary class to represent scan sensitivity attributes for IDS actions.
ibm-idsScanExclusionActionAuxClass	Defines an auxiliary class to define scan exclusion lists for IDS actions.
ibm-policyRepository	Defines a repository for generic reusable policy objects.

Object class name	Purpose of object
ibm-policySubtreesPtrAuxClass	Defines an auxiliary class to represent pointers to subtrees in the LDAP directory tree to be retrieved by the Policy Agent. This allows entire subtrees to be retrieved at once, improving retrieval performance in some situations.
ibm-policyGroupContainmentAuxClass	Defines an auxiliary class for binding a policy group object to another policy group.
ibm-policyRuleContainmentAuxClass	Defines an auxiliary class for binding a policy rule object to another policy group.
ibm-policyGroupLoadDistributionAuxClass	Defines an auxiliary class to represent load distribution attributes for policy groups. The load distribution attributes are applied to all policy rules that are pointed to by groups to which this auxiliary class has been attached.
SetSubnetPrioTosMask	Defines a mapping of outbound IPv4 packet Type of Service (ToS) byte or IPv6 packet Traffic Class values to QDIO device priorities and Virtual LAN (VLAN) user priorities.

Policy objects are used to accomplish the following objectives:

- Group related objects together. Policy groups can contain related policy rules, and can also contain other policy groups. This allows objects to be grouped in various administrative ways. If the resulting objects will be retrieved by any Policy Agent prior to z/OS Communications Server V1R2, then the object should not include the values ibm-policyGroupContainmentAuxClass, ibm-policyRuleContainmentAuxClass or ibm-policyGroupLoadDistributionAuxClass for the objectClass attribute.
- Specify conditions for a policy rule. The conditions are used to filter traffic packets, and can specify attributes such as source and destination port, application name, protocol, and so on. Policy rules can be either simple or complex, depending on the nature of the specified conditions. When a single condition is specified, the rule is a simple rule. This single condition can be composed of any of the condition attributes, but only one instance of each. For example, only a single destination port range can be specified in a simple rule. Complex rules specify more than one condition. The specified conditions are organized into one or more levels, and each level is composed of one or more conditions. Each condition can be composed of one instance of any of the condition attributes. The conditions can thus be thought of as a two-dimensional array. Any individual condition can be negated. Two types of processing are applied to the conditions, depending on the specified condition list type:
 - Disjunctive Normal Form (DNF). DNF conditions are logically ANDed at each level, and ORed between levels.
 - Conjunctive Normal Form (CNF). CNF conditions are logically ORed at each level, and ANDed between levels.

For example, suppose five conditions are specified, two at one level and three at another:

```
Level 1: C1, NOT C2
Level 2: C3, C4, C5
```

If DNF is specified, the conditions are evaluated as:

```
(C1 AND NOT C2) OR (C3 AND C4 AND C5)
```

CNF evaluation of the same conditions is:

(C1 OR NOT C2) AND (C3 OR C4 OR C5)

This allows a wide variety of conditional logic to be defined for policy rules.

- Specify time periods during which policy rules are active. Active policy rules are those that are installed in a TCP/IP stack by the Policy Agent. A wide variety of attributes are available to specify time periods, and up to 25 time periods can be specified for any policy rule. The policy rule is active if any of the specified time intervals include the current time.
- Specify actions to take on behalf of traffic that maps to active policy rules, based on the evaluation of its conditions. QoS Actions contain a scope attribute that indicates the type of policy being defined, namely Differentiated Services, RSVP, or both Differentiated Services and RSVP. Up to four actions can be specified for each rule, but only one action per scope can be active at a time. IDS actions contain an action type that indicates the type of policy being defined, namely Attack, TR, Scan Global, or Scan Event. Only one IDS action can be specified for each rule. QoS and IDS actions (or conditions) can't be mixed within a single policy rule.

Considerations for defining LDAP objects

LDAP objects can refer to other objects, using the DN of the referenced object. For example, a policy rule can be separated from its conditions and time periods, with those objects being referenced by the rule object.

Each LDAP object is composed of a number of attributes. Some of the attributes are generic LDAP attributes that apply to all LDAP objects. Other attributes are used only for Version 1 policy definitions. All other Version 2 and later policy attributes must begin with a unique prefix:

ibm-

When defining complex policy rules (those with more than one condition or action), two mutually exclusive methods can be used to associate the conditions or actions with the rule:

- The `ibm-policyConditionListDN` and `ibm-policyActionListDN` attributes can be omitted from the rule. In this case, the condition and action association objects **MUST** be created as subordinate objects to the policy rule, in other words, under the rule in the directory subtree. This is known as Directory Information Tree (DIT)-containment.
- The `ibm-policyConditionListDN` and `ibm-policyActionListDN` attributes can be specified in the rule. In this case, the condition and action association objects **SHOULD** be created as subordinate objects to the policy rule, in other words, under the rule in the directory subtree. However, this is not a requirement, only a recommendation. The objects can actually exist anywhere in the DIT.

Policy Agent retrieval of LDAP objects

The design of the LDAP object tree should be carefully thought out. The Policy Agent uses a variety of mechanisms to search for and retrieve objects from an LDAP server:

- An initial search is done for a subtree of objects based on the `SearchBaseDN` parameter on the `ReadFromDirectory` statement.
- If any objects retrieved by this initial search contain subtree pointer references (using the `ibm-policySubtreesAuxContainedSet` attribute) then a search is done for all such subtrees. This is a recursive search: additional objects retrieved might also contain subtree pointer references.
- The above searches use a filter to retrieve only certain object classes. For LDAP protocol version 3, the default is to scan only for the `ibm-policy` object class. This is an abstract object class from which all other policy object classes are derived. Most LDAPv3 servers implement abstract and auxiliary classes such that this search will properly retrieve policy, and only policy, object classes. However, some LDAPv3 servers do not honor abstract/auxiliary object classes as a search filter. For these servers, specify `LDAP_AbstractPolicy NO` on the `ReadFromDirectory` statement. This causes the searches to use a filter that retrieves ALL object classes.

- All of the above searches may be scoped, or filtered, using keywords specified on the ReadFromDirectory statement parameters SearchPolicyKeyword, SearchPolicyGroupKeyword, or SearchPolicyRuleKeyword. The LDAP server returns only objects with any matching keywords.
- Some objects retrieved using the above searches may contain DN pointer references to additional objects. These objects are individually retrieved. If the object to be retrieved is a policy rule, then a subtree search is performed, using the keywords specified on the ReadFromDirectory statement. All other objects are retrieved as single objects, using the DN pointers (no keywords are used on the search).
- All policy rule objects retrieved using the above searches are further filtered using the PolicyRole parameter on the ReadFromDirectory statement. Any rules that do not match policy roles specified on the ReadFromDirectory statement are discarded.

Therefore, it is possible to design an LDAP tree such that a minimal set of objects is initially retrieved, followed by many additional individual LDAP retrievals. If the total set of objects is large, there is a performance impact to retrieving objects in this manner. If possible, try to design the tree and the ReadFromDirectory parameters to retrieve the largest set of objects initially, to achieve the best performance, or to use subtree pointer references to retrieve larger sets of objects in one operation.

LDAP sample files

The following set of sample files provides an example of policy definitions in LDAP. For more information on using these sample files, see [“Using the sample LDAP objects”](#) on page 1418.

/usr/lpp/tcpip/samples/pagent.ldif

This file contains the top level directory structure for the set of sample quality of service (QoS) and intrusion detection services (IDS) policies.

/usr/lpp/tcpip/samples/pagent_starter_QOS.ldif

This file contains the starter set sample of LDAP definitions of QoS objects. This file requires the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_starter_IDS.ldif

This file contains the starter set sample of LDAP definitions of IDS objects. This file requires the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_advanced_QOS.ldif

This file contains the advanced set sample of LDAP definitions of QoS objects. This file requires the objects defined in the QoS starter set sample file pagent_starter_QOS.ldif and the directory structure defined in sample file pagent.ldif.

/usr/lpp/tcpip/samples/pagent_advanced_IDS.ldif

This file contains the advanced set sample of LDAP definitions of IDS objects. This file requires the objects defined in the IDS starter set sample file pagent_starter_IDS.ldif and the directory structure defined in sample file pagent.ldif.

The next set of samples is the definition of the schemas in LDAP protocol version 3 format. They must be installed on the LDAPv3 server in the correct order as an object in the server's database, rather than as configuration information. This process is known as schema publication. See RFCs 1804 and 2251. The files need to be specified on ldapmodify commands to modify the cn:schema entry in the server's database. See [“Installing the schema definition on the LDAP server”](#) on page 1418 for more information.

/usr/lpp/tcpip/samples/pagent_r8qosschema.ldif

This file contains the schema version 3 QoS schema definitions.

/usr/lpp/tcpip/samples/pagent_r5idsschema.ldif

This file contains the schema version 3 IDS schema definitions.

The next set of samples contain the text of draft documents used to develop the Version 3 schema.

/usr/lpp/tcpip/samples/pagent_pcm.txt

This file contains the draft version of the proposed Policy Core Information Model (PCIM) used as the basis for the support in this release. PCIM is described by RFC 3060 but this file is an earlier draft level.

/usr/lpp/tcpip/samples/pagent_core.txt

This file contains the draft version of the proposed Policy Core LDAP Schema Internet Draft used in z/OS V1R2 and later releases.

Note: This file is provided as-is and there are some differences between the draft and the implementation. The intent of this file is to provide background information on the level of the supported schema.

/usr/lpp/tcpip/samples/pagent_cond.txt

This file contains the draft version of the proposed Policy Conditions Internet Draft used in z/OS V1R2 and later releases.

Note: This file is provided as-is and there are some differences between the draft and the implementation. The intent of this file is to provide background information on the level of the supported schema.

Installing the schema definition on the LDAP server

The files that define the schema supported by the Policy Agent are shipped as a set of sample files. You need to modify the configuration of the LDAP server to include these schema definition files.

For LDAP protocol version 3, the schema definition is shipped in *ldif* format and installed on the LDAP server as a modification to the generic schema entry, known as a subschema. You must modify the existing schema entry to include the supported schema as a subschema by using the **ldapmodify** command. The schema definition files that you must install are located in the `/usr/lpp/tcpip/samples` directory. You must install the files in the following order:

1. `pagent_r8qosschema.ldif`
2. `pagent_r5idsschema.ldif`

This process is supported for the z/OS LDAP server.

To install the schema definitions, use commands like those shown in the following examples:

```
ldapmodify -h <server address> -p <server port> -D <administrator userid>  
-w <password> -f /usr/lpp/tcpip/samples/pagent_r8qosschema.ldif
```

```
ldapmodify -h <server address> -p <server port> -D <administrator userid>  
-w <password> -f /usr/lpp/tcpip/samples/pagent_r5idsschema.ldif
```

See the TDBM backend information in [z/OS IBM Tivoli Directory Server Administration and Use for z/OS](#) for more details.

Using the sample LDAP objects

There are 5 sample files that provide examples of policy definitions in LDAP:

- `pagent.ldif`
- `pagent_starter_IDS.ldif`
- `pagent_starter_QOS.ldif`
- `pagent_advanced_IDS.ldif`
- `pagent_advanced_QOS.ldif`

For brief descriptions of these files, see [“Policy sample files” on page 826](#). You can either use some or all of these predefined policies in the starter and advanced sets, or modify them as needed.

The recommended way to create customized policies is to copy the sample policies you want to change to the custom portion of the `pagent.ldif` file (under the appropriate `cn=custom root`, `QoS` or `IDS`), modify them as needed, and then point to the custom set as the search base on the `ReadFromDirectory` statement.

For example, the pagent.ldif file has the following hierarchical structure [this shows the relevant parts of the Distinguished Name (DN) for each object]:

```
o=IBM, c=US (root object)
  cn=repository (root of all reusable policy conditions and actions)
    ou=policy (root of all policy groups and rules)
      cn=groups (root of sample groups)
        cn=starter (root of simple starter set of policies)
          cn=IDS (IDS starter set - actually defined in file
pagent_starter_IDS.ldif)
          cn=QoS (QoS starter set - actually defined in file
pagent_starter_QoS.ldif)
          cn=advanced (root of advanced set of policies)
            cn=IDS (IDS advanced set - actually defined in file
pagent_advanced_IDS.ldif)
            cn=QoS (QoS advanced set - actually defined in file
pagent_advanced_QoS.ldif)
            cn=custom (root of customer-defined set of policies)
              cn=IDS (root of customer-defined IDS policies (empty))
              cn=QoS (root of customer-defined QoS policies (empty))
```

To obtain only the customized policies, specify the top custom policy group object as the search base on the ReadFromDirectory statement as follows:

```
ReadFromDirectory {
...
SearchPolicyBaseDN    dn:cn=custom, ou=policy, o=IBM, c=US
...
}
```

Note: If your LDAP server has a root structure other than "o=IBM, c=US", be sure to change the root structure in all the files you want to use by replacing every instance of "o=IBM, c=US" with the appropriate root used on your LDAP server.

Defining QoS policies using LDAP

This topic contains examples for defining QoS policies using LDAP.

Differentiated Services policy example

The goal of this Differentiated Services policy is to map a subset of the traffic outbound from an FTP server.

This policy is identified as a Differentiated Services policy by the ibm-PolicyScope:DataTraffic attribute in the ibm-PolicyActionInstance object.

The following statements apply to the example in this topic:

- The policy rule selects traffic originated by ports in the range 20-21 (FTP outbound data connection uses port 20) from the source address 200.50.23.11 or 200.50.33.14 or 202::B055:1.
- The policy rule is active on weekdays between 6 a.m. and 10 p.m. local time, between the dates 7/1/2000 and 7/1/2005.
- The policy action specifies that the ToS byte be set to '10000000' for traffic that conforms to this policy.
- The action establishes a *token bucket* traffic conditioner with a mean rate of 256 kilobits per second, a peak rate of 512 kilobits per second, and a burst size of 64 kilobytes. Any traffic that exceeds these specifications will be sent as *best effort*, with an accompanying ToS byte of '00000000'.

The goal of this policy is to ensure that outgoing data that match the specified attributes will be assigned a QoS service level defined in action "interactive1".

The following statements apply to the example in this topic:

- This rule will match only traffic on TCP connections (protocol 6) with a source port of 80 (i.e. HTTP server) and application defined data beginning with the string "/catalog".
- Because we are dealing with HTTP traffic, this rule is basically indicating that all outgoing traffic associated with a URI that begins with "/catalog" should be managed using the DS characteristics specified in the "interactive1" policy action.

RSVP policy example

The goal of this RSVP policy is to establish limits on resource reservations requested by RSVP applications using the RSVP API (RAPI) interface. The policy is identified as an RSVP policy by the `ibm-PolicyScope:RSVP` attribute in the `ibm-PolicyActionInstance` object.

The following statements apply to the example in this topic:

- The policy rule selects traffic from source ports in the range 8000 to 8001, with a protocol ID of 6 (TCP).
- One policy action specifies that the ToS byte be set to 01100000 for traffic that conforms to this policy.
- The RSVP policy action limits the type of RSVP service requested by RSVP applications to Controlled Load. Applications requesting Guaranteed service are downgraded to using Controlled Load service. In addition, the action limits the mean rate and token bucket size to 50000 bytes per second and 6000 bytes, respectively. These values are requested by RSVP applications in the traffic specification, or Tspec.
- The action also limits the number of active RSVP flows that map to this policy to 10.

Sysplex distributor routing policy example

The goal of this sysplex distributor policy is to limit the number of SD target servers for inbound Telnet traffic. The policies are identified as SD policies by the `ibm-policyGroupForLoadDistribution:TRUE` attribute in the `ibm-PolicyGroup` object.

The following statements apply to the example in this topic:

- Separate policies are defined on the sysplex distributor distributing and target servers.
- The policy rules select incoming Telnet connection requests.
- The selected target server will be based on WLM information and QoS information if activated at the target servers.
- The rule (`disttelnet`) is coded on the distributing stack to select inbound traffic destined to the Telnet server.
- The rule (`targettelnet`) is coded on the target server to select outbound data from the Telnet server.
- If none of the specified target servers are available to service incoming requests (either the node is down or the Telnet server is not active), then sysplex distributor will distribute the requests to any available target server.

Note: If the `ibm-Interface:1-0.0.0.0` attribute were not present, and none of the defined target servers were available, sysplex distributor would reject the request.

Appendix G. Related protocol specifications

This appendix lists the related protocol specifications (RFCs) for TCP/IP. The Internet Protocol suite is still evolving through requests for comments (RFC). New protocols are being designed and implemented by researchers and are brought to the attention of the Internet community in the form of RFCs. Some of these protocols are so useful that they become recommended protocols. That is, all future implementations for TCP/IP are recommended to implement these particular functions or protocols. These become the *de facto* standards, on which the TCP/IP protocol suite is built.

RFCs are available at <http://www.rfc-editor.org/rfc.html>.

Draft RFCs that have been implemented in this and previous Communications Server releases are listed at the end of this topic.

Many features of TCP/IP Services are based on the following RFCs:

RFC

Title and Author

RFC 652

Telnet output carriage-return disposition option D. Crocker

RFC 653

Telnet output horizontal tabstops option D. Crocker

RFC 654

Telnet output horizontal tab disposition option D. Crocker

RFC 655

Telnet output formfeed disposition option D. Crocker

RFC 657

Telnet output vertical tab disposition option D. Crocker

RFC 658

Telnet output linefeed disposition D. Crocker

RFC 698

Telnet extended ASCII option T. Mock

RFC 726

Remote Controlled Transmission and Echoing Telnet option J. Postel, D. Crocker

RFC 727

Telnet logout option M.R. Crispin

RFC 732

Telnet Data Entry Terminal option J.D. Day

RFC 733

Standard for the format of ARPA network text messages D. Crocker, J. Vittal, K.T. Pogran, D.A. Henderson

RFC 734

SUPDUP Protocol M.R. Crispin

RFC 735

Revised Telnet byte macro option D. Crocker, R.H. Gumpertz

RFC 736

Telnet SUPDUP option M.R. Crispin

RFC 749

Telnet SUPDUP—Output option B. Greenberg

RFC 765

File Transfer Protocol specification J. Postel

- RFC 768**
User Datagram Protocol J. Postel
- RFC 779**
Telnet send-location option E. Killian
- RFC 791**
Internet Protocol J. Postel
- RFC 792**
Internet Control Message Protocol J. Postel
- RFC 793**
Transmission Control Protocol J. Postel
- RFC 820**
Assigned numbers J. Postel
- RFC 823**
DARPA Internet gateway R. Hinden, A. Sheltzer
- RFC 826**
Ethernet Address Resolution Protocol: Or converting network protocol addresses to 48.bit Ethernet address for transmission on Ethernet hardware D. Plummer
- RFC 854**
Telnet Protocol Specification J. Postel, J. Reynolds
- RFC 855**
Telnet Option Specification J. Postel, J. Reynolds
- RFC 856**
Telnet Binary Transmission J. Postel, J. Reynolds
- RFC 857**
Telnet Echo Option J. Postel, J. Reynolds
- RFC 858**
Telnet Suppress Go Ahead Option J. Postel, J. Reynolds
- RFC 859**
Telnet Status Option J. Postel, J. Reynolds
- RFC 860**
Telnet Timing Mark Option J. Postel, J. Reynolds
- RFC 861**
Telnet Extended Options: List Option J. Postel, J. Reynolds
- RFC 862**
Echo Protocol J. Postel
- RFC 863**
Discard Protocol J. Postel
- RFC 864**
Character Generator Protocol J. Postel
- RFC 865**
Quote of the Day Protocol J. Postel
- RFC 868**
Time Protocol J. Postel, K. Harrenstien
- RFC 877**
Standard for the transmission of IP datagrams over public data networks J.T. Korb
- RFC 883**
Domain names: Implementation specification P.V. Mockapetris
- RFC 884**
Telnet terminal type option M. Solomon, E. Wimmers

RFC 885

Telnet end of record option J. Postel

RFC 894

Standard for the transmission of IP datagrams over Ethernet networks C. Hornig

RFC 896

Congestion control in IP/TCP internetworks J. Nagle

RFC 903

Reverse Address Resolution Protocol R. Finlayson, T. Mann, J. Mogul, M. Theimer

RFC 904

Exterior Gateway Protocol formal specification D. Mills

RFC 919

Broadcasting Internet Datagrams J. Mogul

RFC 922

Broadcasting Internet datagrams in the presence of subnets J. Mogul

RFC 927

TACACS user identification Telnet option B.A. Anderson

RFC 933

Output marking Telnet option S. Silverman

RFC 946

Telnet terminal location number option R. Nedved

RFC 950

Internet Standard Subnetting Procedure J. Mogul, J. Postel

RFC 952

DoD Internet host table specification K. Harrenstien, M. Stahl, E. Feinler

RFC 959

File Transfer Protocol J. Postel, J.K. Reynolds

RFC 961

Official ARPA-Internet protocols J.K. Reynolds, J. Postel

RFC 974

Mail routing and the domain system C. Partridge

RFC 1001

Protocol standard for a NetBIOS service on a TCP/UDP transport: Concepts and methods NetBios Working Group in the Defense Advanced Research Projects Agency, Internet Activities Board, End-to-End Services Task Force

RFC 1002

Protocol Standard for a NetBIOS service on a TCP/UDP transport: Detailed specifications NetBios Working Group in the Defense Advanced Research Projects Agency, Internet Activities Board, End-to-End Services Task Force

RFC 1006

ISO transport services on top of the TCP: Version 3 M.T. Rose, D.E. Cass

RFC 1009

Requirements for Internet gateways R. Braden, J. Postel

RFC 1011

Official Internet protocols J. Reynolds, J. Postel

RFC 1013

X Window System Protocol, version 11: Alpha update April 1987 R. Scheifler

RFC 1014

XDR: External Data Representation standard Sun Microsystems

RFC 1027

Using ARP to implement transparent subnet gateways S. Carl-Mitchell, J. Quarterman

SMTP Service Extensions for Transmission of Large and Binary MIME Messages G. Vaudreuil
- RFC 1831**
RPC: Remote Procedure Call Protocol Specification Version 2 R. Srinivasan
- RFC 1832**
XDR: External Data Representation Standard R. Srinivasan
- RFC 1833**
Binding Protocols for ONC RPC Version 2 R. Srinivasan

RFC 1850

OSPF Version 2 Management Information Base F. Baker, R. Coltun

RFC 1854

SMTP Service Extension for Command Pipelining N. Freed

RFC 1869

SMTP Service Extensions J. Klensin, N. Freed, M. Rose, E. Stefferud, D. Crocker

RFC 1870

SMTP Service Extension for Message Size Declaration J. Klensin, N. Freed, K. Moore

RFC 1876

A Means for Expressing Location Information in the Domain Name System C. Davis, P. Vixie, T. Goodwin, I. Dickinson

RFC 1883

Internet Protocol, Version 6 (IPv6) Specification S. Deering, R. Hinden

RFC 1884

IP Version 6 Addressing Architecture R. Hinden, S. Deering, Eds.

RFC 1886

DNS Extensions to support IP version 6 S. Thomson, C. Huitema

RFC 1888

OSI NSAPs and IPv6 J. Bound, B. Carpenter, D. Harrington, J. Houldsworth, A. Lloyd

RFC 1891

SMTP Service Extension for Delivery Status Notifications K. Moore

RFC 1892

The Multipart/Report Content Type for the Reporting of Mail System Administrative Messages G. Vaudreuil

RFC 1894

An Extensible Message Format for Delivery Status Notifications K. Moore, G. Vaudreuil

RFC 1901

Introduction to Community-based SNMPv2 J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1902

Structure of Management Information for Version 2 of the Simple Network Management Protocol (SNMPv2) J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1903

Textual Conventions for Version 2 of the Simple Network Management Protocol (SNMPv2) J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1904

Conformance Statements for Version 2 of the Simple Network Management Protocol (SNMPv2) J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1905

Protocol Operations for Version 2 of the Simple Network Management Protocol (SNMPv2) J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1906

Transport Mappings for Version 2 of the Simple Network Management Protocol (SNMPv2) J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1907

Management Information Base for Version 2 of the Simple Network Management Protocol (SNMPv2) J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1908

Coexistence between Version 1 and Version 2 of the Internet-standard Network Management Framework J. Case, K. McCloghrie, M. Rose, S. Waldbusser

RFC 1912

Common DNS Operational and Configuration Errors D. Barr

- RFC 1918**
Address Allocation for Private Internets Y. Rekhter, B. Moskowitz, D. Karrenberg, G.J. de Groot, E. Lear
- RFC 1928**
SOCKS Protocol Version 5 M. Leech, M. Ganis, Y. Lee, R. Kuris, D. Koblas, L. Jones

The Transport Layer Security (TLS) Protocol Version 1.3 E. Rescorla

Internet drafts

Internet drafts are working documents of the Internet Engineering Task Force (IETF), its areas, and its working groups. Other groups can also distribute working documents as Internet drafts. You can see Internet drafts at <http://www.ietf.org/ID.html>.

Appendix H. Accessibility

Accessible publications for this product are offered through [IBM Documentation for z/OS](#).

If you experience difficulty with the accessibility of any z/OS documentation see [How to Send Feedback to IBM](#) to leave documentation feedback.

Notices

This information was developed for products and services that are offered in the USA or elsewhere.

IBM may not offer the products, services, or features discussed in this document in other countries. Consult your local IBM representative for information on the products and services currently available in your area. Any reference to an IBM product, program, or service is not intended to state or imply that only that IBM product, program, or service may be used. Any functionally equivalent product, program, or service that does not infringe any IBM intellectual property right may be used instead. However, it is the user's responsibility to evaluate and verify the operation of any non-IBM product, program, or service.

IBM may have patents or pending patent applications covering subject matter described in this document. The furnishing of this document does not grant you any license to these patents. You can send license inquiries, in writing, to:

IBM Director of Licensing IBM Corporation North Castle Drive, MD-NC119 Armonk, NY 10504-1785 United States of America

For license inquiries regarding double-byte character set (DBCS) information, contact the IBM Intellectual Property Department in your country or send inquiries, in writing, to:

Intellectual Property Licensing Legal and Intellectual Property Law IBM Japan Ltd. 19-21, Nihonbashi-Hakozakicho, Chuo-ku Tokyo 103-8510, Japan

The following paragraph does not apply to the United Kingdom or any other country where such provisions are inconsistent with local law: INTERNATIONAL BUSINESS MACHINES CORPORATION PROVIDES THIS PUBLICATION "AS IS" WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESS OR IMPLIED, INCLUDING, BUT NOT LIMITED TO, THE IMPLIED WARRANTIES OF NON-INFRINGEMENT, MERCHANTABILITY OR FITNESS FOR A PARTICULAR PURPOSE. Some states do not allow disclaimer of express or implied warranties in certain transactions, therefore, this statement may not apply to you.

This information could include technical inaccuracies or typographical errors. Changes are periodically made to the information herein; these changes will be incorporated in new editions of the publication. IBM may make improvements and/or changes in the product(s) and/or the program(s) described in this publication at any time without notice.

This information could include missing, incorrect, or broken hyperlinks. Hyperlinks are maintained in only the HTML plug-in output for the IBM Documentation. Use of hyperlinks in other output formats of this information is at your own risk.

Any references in this information to non-IBM websites are provided for convenience only and do not in any manner serve as an endorsement of those websites. The materials at those websites are not part of the materials for this IBM product and use of those websites is at your own risk.

IBM may use or distribute any of the information you supply in any way it believes appropriate without incurring any obligation to you.

Licensees of this program who wish to have information about it for the purpose of enabling: (i) the exchange of information between independently created programs and other programs (including this one) and (ii) the mutual use of the information which has been exchanged, should contact:

IBM Corporation Site Counsel 2455 South Road Poughkeepsie, NY 12601-5400 USA

Such information may be available, subject to appropriate terms and conditions, including in some cases, payment of a fee.

The licensed program described in this document and all licensed material available for it are provided by IBM under terms of the IBM Customer Agreement, IBM International Program License Agreement or any equivalent agreement between us.

Any performance data contained herein was determined in a controlled environment. Therefore, the results obtained in other operating environments may vary significantly. Some measurements may have been made on development-level systems and there is no guarantee that these measurements will be the same on generally available systems. Furthermore, some measurements may have been estimated through extrapolation. Actual results may vary. Users of this document should verify the applicable data for their specific environment.

Information concerning non-IBM products was obtained from the suppliers of those products, their published announcements or other publicly available sources. IBM has not tested those products and cannot confirm the accuracy of performance, compatibility or any other claims related to non-IBM products. Questions on the capabilities of non-IBM products should be addressed to the suppliers of those products.

All statements regarding IBM's future direction or intent are subject to change or withdrawal without notice, and represent goals and objectives only.

This information contains examples of data and reports used in daily business operations. To illustrate them as completely as possible, the examples include the names of individuals, companies, brands, and products. All of these names are fictitious and any similarity to the names and addresses used by an actual business enterprise is entirely coincidental.

COPYRIGHT LICENSE:

This information contains sample application programs in source language, which illustrate programming techniques on various operating platforms. You may copy, modify, and distribute these sample programs in any form without payment to IBM, for the purposes of developing, using, marketing or distributing application programs conforming to the application programming interface for the operating platform for which the sample programs are written. These examples have not been thoroughly tested under all conditions. IBM, therefore, cannot guarantee or imply reliability, serviceability, or function of these programs. The sample programs are provided "AS IS", without warranty of any kind. IBM shall not be liable for any damages arising out of your use of the sample programs.

Terms and conditions for product documentation

Permissions for the use of these publications are granted subject to the following terms and conditions.

Applicability

These terms and conditions are in addition to any terms of use for the IBM website.

Personal use

You may reproduce these publications for your personal, noncommercial use provided that all proprietary notices are preserved. You may not distribute, display or make derivative work of these publications, or any portion thereof, without the express consent of IBM.

Commercial use

You may reproduce, distribute and display these publications solely within your enterprise provided that all proprietary notices are preserved. You may not make derivative works of these publications, or reproduce, distribute or display these publications or any portion thereof outside your enterprise, without the express consent of IBM.

Rights

Except as expressly granted in this permission, no other permissions, licenses or rights are granted, either express or implied, to the publications or any information, data, software or other intellectual property contained therein.

IBM reserves the right to withdraw the permissions granted herein whenever, in its discretion, the use of the publications is detrimental to its interest or, as determined by IBM, the above instructions are not being properly followed.

IBM Online Privacy Statement

IBM Software products, including software as a service solutions, ("Software Offerings") may use cookies or other technologies to collect product usage information, to help improve the end user experience, to tailor interactions with the end user, or for other purposes. In many cases no personally identifiable information is collected by the Software Offerings. Some of our Software Offerings can help enable you to collect personally identifiable information. If this Software Offering uses cookies to collect personally identifiable information, specific information about this offering's use of cookies is set forth below.

Depending upon the configurations deployed, this Software Offering may use session cookies that collect each user's name, email address, phone number, or other personally identifiable information for purposes of enhanced user usability and single sign-on configuration. These cookies can be disabled, but disabling them will also eliminate the functionality they enable.

If the configurations deployed for this Software Offering provide you as customer the ability to collect personally identifiable information from end users via cookies and other technologies, you should seek your own legal advice about any laws applicable to such data collection, including any requirements for notice and consent.

For more information about the use of various technologies, including cookies, for these purposes, see IBM's Privacy Policy at ibm.com/privacy and IBM's Online Privacy Statement at ibm.com/privacy/details in the section entitled "Cookies, Web Beacons and Other Technologies," and the "IBM Software Products and Software-as-a-Service Privacy Statement" at ibm.com/software/info/product-privacy.

Policy for unsupported hardware

Various z/OS elements, such as DFSMS, JES2, JES3, and MVS, contain code that supports specific hardware servers or devices. In some cases, this device-related element support remains in the product even after the hardware devices pass their announced End of Service date. z/OS may continue to service element code; however, it will not provide service related to unsupported hardware devices. Software problems related to these devices will not be accepted for service, and current service activity will cease if a problem is determined to be associated with out-of-support devices. In such cases, fixes will not be issued.

Minimum supported hardware

The minimum supported hardware for z/OS releases identified in z/OS announcements can subsequently change when service for particular servers or devices is withdrawn. Likewise, the levels of other software products supported on a particular release of z/OS are subject to the service support lifecycle of those products. Therefore, z/OS and its product publications (for example, panels, samples, messages, and product documentation) can include references to hardware and software that is no longer supported.

- For information about software support lifecycle, see: [IBM Lifecycle Support for z/OS \(www.ibm.com/software/support/systemsz/lifecycle\)](http://www.ibm.com/software/support/systemsz/lifecycle)
- For information about currently-supported IBM hardware, contact your IBM representative.

Policy for unsupported hardware

Various z/OS elements, such as DFSMS, HCD, JES2, JES3, and MVS, contain code that supports specific hardware servers or devices. In some cases, this device-related element support remains in the product even after the hardware devices pass their announced End of Service date. z/OS may continue to service element code; however, it will not provide service related to unsupported hardware devices. Software problems related to these devices will not be accepted for service, and current service activity will cease if a problem is determined to be associated with out-of-support devices. In such cases, fixes will not be issued.

Trademarks

IBM, the IBM logo, and ibm.com are trademarks or registered trademarks of International Business Machines Corp., registered in many jurisdictions worldwide. Other product and service names might be trademarks of IBM or other companies. A current list of IBM trademarks is available on the web at [Copyright and trademark information at www.ibm.com/legal/copytrade.shtml](http://www.ibm.com/legal/copytrade.shtml).

Bibliography

This bibliography contains descriptions of the documents in the z/OS Communications Server library.

z/OS Communications Server documentation is available online at the z/OS Internet Library web page at <http://www.ibm.com/systems/z/os/zos/library/bkserv/>.

z/OS Communications Server library updates

Updates to documents are also available on RETAIN and in information APARs (info APARs). Go to <https://www.ibm.com/mysupport> to view information APARs.

z/OS Communications Server information

z/OS Communications Server product information is grouped by task in the following tables.

Planning

Title	Number	Description
z/OS Communications Server: New Function Summary	GC27-3664	This document is intended to help you plan for new IP or SNA functions, whether you are migrating from a previous version or installing z/OS for the first time. It summarizes what is new in the release and identifies the suggested and required modifications needed to use the enhanced functions.
z/OS Communications Server: IPv6 Network and Appl Design Guide	SC27-3663	This document is a high-level introduction to IPv6. It describes concepts of z/OS Communications Server's support of IPv6, coexistence with IPv4, and migration issues.

Resource definition, configuration, and tuning

Title	Number	Description
z/OS Communications Server: IP Configuration Guide	SC27-3650	This document describes the major concepts involved in understanding and configuring an IP network. Familiarity with the z/OS operating system, IP protocols, z/OS UNIX System Services, and IBM Time Sharing Option (TSO) is recommended. Use this document with the z/OS Communications Server: IP Configuration Reference .

Title	Number	Description
z/OS Communications Server: IP Configuration Reference	SC27-3651	This document presents information for people who want to administer and maintain IP. Use this document with the z/OS Communications Server: IP Configuration Guide . The information in this document includes: <ul style="list-style-type: none"> • TCP/IP configuration data sets • Configuration statements • Translation tables • Protocol number and port assignments
z/OS Communications Server: SNA Network Implementation Guide	SC27-3672	This document presents the major concepts involved in implementing an SNA network. Use this document with the z/OS Communications Server: SNA Resource Definition Reference .
z/OS Communications Server: SNA Resource Definition Reference	SC27-3675	This document describes each SNA definition statement, start option, and macroinstruction for user tables. It also describes NCP definition statements that affect SNA. Use this document with the z/OS Communications Server: SNA Network Implementation Guide .
z/OS Communications Server: SNA Resource Definition Samples	SC27-3676	This document contains sample definitions to help you implement SNA functions in your networks, and includes sample major node definitions.
z/OS Communications Server: IP Network Print Facility	SC27-3658	This document is for systems programmers and network administrators who need to prepare their network to route SNA, JES2, or JES3 printer output to remote printers using TCP/IP Services.

Operation

Title	Number	Description
z/OS Communications Server: IP User's Guide and Commands	SC27-3662	This document describes how to use TCP/IP applications. It contains requests with which a user can log on to a remote host using Telnet, transfer data sets using FTP, send electronic mail, print on remote printers, and authenticate network users.
z/OS Communications Server: IP System Administrator's Commands	SC27-3661	This document describes the functions and commands helpful in configuring or monitoring your system. It contains system administrator's commands, such as TSO NETSTAT, PING, TRACERTE and their UNIX counterparts. It also includes TSO and MVS commands commonly used during the IP configuration process.
z/OS Communications Server: SNA Operation	SC27-3673	This document serves as a reference for programmers and operators requiring detailed information about specific operator commands.
z/OS Communications Server: Quick Reference	SC27-3665	This document contains essential information about SNA and IP commands.

Customization

Title	Number	Description
z/OS Communications Server: SNA Customization	SC27-3666	<p>This document enables you to customize SNA, and includes the following information:</p> <ul style="list-style-type: none"> • Communication network management (CNM) routing table • Logon-interpret routine requirements • Logon manager installation-wide exit routine for the CLU search exit • TSO/SNA installation-wide exit routines • SNA installation-wide exit routines

Writing application programs

Title	Number	Description
z/OS Communications Server: IP Sockets Application Programming Interface Guide and Reference	SC27-3660	This document describes the syntax and semantics of program source code necessary to write your own application programming interface (API) into TCP/IP. You can use this interface as the communication base for writing your own client or server application. You can also use this document to adapt your existing applications to communicate with each other using sockets over TCP/IP.
z/OS Communications Server: IP CICS Sockets Guide	SC27-3649	This document is for programmers who want to set up, write application programs for, and diagnose problems with the socket interface for CICS using z/OS TCP/IP.
z/OS Communications Server: IP IMS Sockets Guide	SC27-3653	This document is for programmers who want application programs that use the IMS TCP/IP application development services provided by the TCP/IP Services of IBM.
z/OS Communications Server: IP Programmer's Guide and Reference	SC27-3659	This document describes the syntax and semantics of a set of high-level application functions that you can use to program your own applications in a TCP/IP environment. These functions provide support for application facilities, such as user authentication, distributed databases, distributed processing, network management, and device sharing. Familiarity with the z/OS operating system, TCP/IP protocols, and IBM Time Sharing Option (TSO) is recommended.
z/OS Communications Server: SNA Programming	SC27-3674	This document describes how to use SNA macroinstructions to send data to and receive data from (1) a terminal in either the same or a different domain, or (2) another application program in either the same or a different domain.
z/OS Communications Server: SNA Programmer's LU 6.2 Guide	SC27-3669	This document describes how to use the SNA LU 6.2 application programming interface for host application programs. This document applies to programs that use only LU 6.2 sessions or that use LU 6.2 sessions along with other session types. (Only LU 6.2 sessions are covered in this document.)
z/OS Communications Server: SNA Programmer's LU 6.2 Reference	SC27-3670	This document provides reference material for the SNA LU 6.2 programming interface for host application programs.

Title	Number	Description
z/OS Communications Server: CSM Guide	SC27-3647	This document describes how applications use the communications storage manager.

Diagnosis

Title	Number	Description
z/OS Communications Server: IP Diagnosis Guide	GC27-3652	This document explains how to diagnose TCP/IP problems and how to determine whether a specific problem is in the TCP/IP product code. It explains how to gather information for and describe problems to the IBM Software Support Center.
z/OS Communications Server: ACF/TAP Trace Analysis Handbook	GC27-3645	This document explains how to gather the trace data that is collected and stored in the host processor. It also explains how to use the Advanced Communications Function/Trace Analysis Program (ACF/TAP) service aid to produce reports for analyzing the trace data information.
z/OS Communications Server: SNA Diagnosis Vol 1, Techniques and Procedures and z/OS Communications Server: SNA Diagnosis Vol 2, FFST Dumps and the VIT	GC27-3667 GC27-3668	These documents help you identify an SNA problem, classify it, and collect information about it before you call the IBM Support Center. The information collected includes traces, dumps, and other problem documentation.
z/OS Communications Server: SNA Data Areas Volume 1 and z/OS Communications Server: SNA Data Areas Volume 2	GC31-6852 GC31-6853	These documents describe SNA data areas and can be used to read an SNA dump. They are intended for IBM programming service representatives and customer personnel who are diagnosing problems with SNA.

Messages and codes

Title	Number	Description
z/OS Communications Server: SNA Messages	SC27-3671	This document describes the ELM, IKT, IST, IUT, IVT, and USS messages. Other information in this document includes: <ul style="list-style-type: none"> • Command and RU types in SNA messages • Node and ID types in SNA messages • Supplemental message-related information
z/OS Communications Server: IP Messages Volume 1 (EZA)	SC27-3654	This volume contains TCP/IP messages beginning with EZA.
z/OS Communications Server: IP Messages Volume 2 (EZB, EZD)	SC27-3655	This volume contains TCP/IP messages beginning with EZB or EZD.
z/OS Communications Server: IP Messages Volume 3 (EZY)	SC27-3656	This volume contains TCP/IP messages beginning with EZY.
z/OS Communications Server: IP Messages Volume 4 (EZZ, SNM)	SC27-3657	This volume contains TCP/IP messages beginning with EZZ and SNM.
z/OS Communications Server: IP and SNA Codes	SC27-3648	This document describes codes and other information that appear in z/OS Communications Server messages.
